Figure 8. A plot of the frequency dependence of the power transmission coefficient (A), as well as its first (B) and second derivative (C), with respect to frequency (arbitrary vertical scale). Note that the curve possesses two inflection points (points where the second derivative is equal to zero).

(VCO) to step through the resonance curve of a transmission resonator at around 1 GHz. The incident and transmitted power were monitored by detectors which were, in turn, monitored by the computer. The power transmission coefficient was obtained by a division of these signals and a polynomial fitted to a smoothed version of this data. By differentiation of this polynomial, the inflection points of the resonance curve were found (see Fig. 8). To find how the inflection points are related to the Q , we need to find when the second frequency derivative of Eq. 18 is equal to zero; that is,

$$\frac{\partial^2}{\partial \Delta f^2} \{|s_{21}(\Delta f_{inf})|^2\} = 0 \quad (49)$$

which has as its solution

$$\Delta f_{inf} = \pm \frac{f_0}{2\sqrt{3}Q_L} \quad (50)$$

The experimental results were limited by frequency instability in the VCO to around 5%.

Frequency Lock Technique. An interesting method for accurately measuring the phase as a function of frequency is presented in the paper by Linzer et al. (47). In this method, a Klystron is frequency locked to a resonator. Typically, any frequency locking system is set up to detect the imaginary part of the reflection or transmission coefficient and then use this to stabilize the oscillator. If a phase offset is introduced into the feedback mechanism so that the locking system is now partially sensitive to the real part of the reflection coefficient as well, then it will lock at some distance from the center of resonance. The particular dependence of the oscillator frequency on this phase shift is determined by the loaded Q of the resonator, and hence by a measurement of the frequency offset in the system as a function of the feedback phase shift, the loaded Q can be measured with an accuracy of around 1–2%.

Vector Static Frequency Domain Methods

Q Circles Method. If one measures both the phase and magnitude (or real and imaginary components) of s_{11} using either

the VSWR method, a reflection bridge (48), or a network analyzer, then it is possible to plot s_{11} directly on a Smith Chart. If plots of the loci of Eqs. 29 and 30 for all Δf_L and Δf_U are also placed on the chart, then the intersections of the s_{11} curve and these two solution sets give the loaded and unloaded half bandwidths. This graphical solution method is outlined in detail by Ginzton (17).

Straight-Line Methods. If one can measure the real and imaginary components of s_{11} or s_{21} of a resonator separately, then one can plot the following ratios as a function of Δf for each of the different resonator types:

$$\frac{\text{Im}[s_{11}(\Delta f)]}{\text{Re}[s_{11}(\Delta f)]} [\text{reaction Eq. (49)}],$$

$$\frac{\text{Im}[s_{21}(\Delta f)]}{\text{Re}[s_{21}(\Delta f)]} (\text{transmission}),$$

$$\frac{\text{Im}[s_{11}(\Delta f)]}{\text{Re}[s_{11}(\Delta f)] + 1} (\text{reflection})$$

All of these ratios yield a straight line with a slope of $2Q_L/f_0$. Clearly by a measurement of the slope of these straight line plots, we can measure Q_L .

Dynamic Frequency Domain Techniques

There are two main dynamic frequency domain techniques, the harmonic or inflection point technique and the intermodulation method. Both of these techniques rely on the fact that at two frequency points on either side of the resonant frequency, there are points where the second derivative of the resonance curve is equal to zero (see Fig. 8 and Numerical Methods above). It is important to note that the sweep rates (Hz s^{-1}) for both of these techniques need to be much slower than $(f_0/Q_L)^2$ for the measurement to be accurate. In this sense, the measurements are still quasi-static, although we have chosen to term them dynamic because the measurement is made at a frequency which differs from the sweep frequency.

Harmonic (Inflection Points) Technique. If a frequency modulated signal is incident on the resonance curve shown in Fig. 8, and we monitor the power of the transmitted signal, it is clear that part of the frequency modulation (FM) will be converted to amplitude modulation (AM) by the resonator. If the frequency deviation is small, the amplitude of the transmitted AM at the fundamental FM frequency will be proportional to the slope of the curve measured at the carrier frequency. If the resonance has nonzero curvature; that is, if the second derivative is not zero, then the transmitted signal will also contain an AM component at the second harmonic of the FM. Thus, a measurement of the amplitude of the second harmonic AM as a function of frequency will yield a curve which is proportional to that shown as the second derivative curve (C) on Fig. 8. Since extremely sensitive synchronous detection techniques exist (such as lock in amplifiers), this method can very accurately find the points for which there is no second harmonic AM (17,18). Using Eq. 50 this value can be easily converted to the loaded Q of the resonator.

Intermodulation Method. A potential problem arises in the previous method if the FM signal is not completely free from

higher harmonic content. If the incident signal already contains the second harmonic component, then the measurement of the inflection points will be in error. To avoid this, we can make use of an intermodulation method. If we simultaneously frequency modulate an incident signal at two different frequencies, then it is clear that we will generate AM components in the transmitted signal at the two fundamental FM frequencies. However, if there is any non-linearity of the curve, then we will also generate AM components at the difference and sum frequency of the two components. If we set our system to detect one of these intermodulation components, such as the difference frequency, then we can be sure that this could only have been generated via the nonlinearity of the resonance curve (17,18). Once again, when identification of the inflection points is completed, we can calculate Q_L using Eq. 50.

MODERN MEASUREMENT TECHNIQUES

Because of the advent of powerful personal computers for data analysis, combined with the wide availability of microwave equipment with computer interfaces, many new techniques have been devised recently which allow the lifting of the restrictions which were previously placed on Q measurement. For example, accurate measurements can now be made in the presence of a transmission line or coupling reactance. An additional advantage of computer aided measurement is that large numbers of measurements, which would be tedious to take manually, are easily made. The data averaging which occurs from using such large numbers of data samples gives improved immunity to random noise in the Q measurement. This section will describe some of these latest methods and is divided into sections which highlight the major advantage of the technique.

Scalar High Resolution Measurements

Luiten et al. (50) have developed a new data averaging technique which doesn't require the use of expensive network analyzers and relies on measurement of the square of the magnitude of the reflection or transmission coefficient as a function of frequency. The acquired data is then fitted using a nonlinear algorithm to the expected shape of a completely general resonance (Eqs. 17 or 18). The fitting mechanism is adaptive, which gives the program a robustness and an ability to follow resonances if the resonance parameters change smoothly with time. This feature was used to great advantage to measure the temperature dependence of thermal, electrical, and magnetic properties of TiO_2 and Al_2O_3 crystals (10). The extreme frequency stability of the source in this case (fractional frequency stability $\sim 10^{-15}$) meant that the Q measurements had a resolution of 0.03% despite the loaded bandwidth being only 10 Hz.

Kajfez (24) has developed a technique which uses a scalar network analyzer to measure the values of the reflection coefficient as a function of frequency. This technique takes into account moderate coupling losses and, therefore, allows the off-resonance reflection coefficient to differ from 1. When compared to vector curve-fitting methods, this technique, like all scalar techniques, suffers from the disadvantage that it is impossible to tell whether a resonator is over or under-coupled. Nonetheless, its accuracy appears to be comparable to the vector methods ($\sim 0.2\%$).

Vector High Resolution Measurements

A simple modification to the Q -circles method has been suggested by Hearn et al. (51) to take into account losses in the coupling network. It can be shown that Eq. 30 is equivalent to the condition that the magnitude of the real and imaginary parts of the impedance of the resonator are equal. In the case where there is loss in the coupling mechanism or the transmission lines, a correction needs to be made; otherwise, the estimated Q will be less than the true value. Hearn et al. (51) have suggested a simple correction which reduces the errors of the traditional measurement by around 80 times in the case of high coupling loss and small coupling. Unfortunately, this correction cannot be implemented with a simple Smith Chart overlay, although it is easily implemented in a automated measurement system.

Sanchez et al. (49) report an absorption resonator Q measurement system based on a computer driven network analyzer. This system empirically removes the effects of any loss in the coupling network, or transmission lines, by rescaling the data by a factor obtained from the transmission coefficient far from resonance. A fit is performed to the Q -circle from which the coupling and Q is found. The Q_U measurement error is around 1%.

Kajfez (52,53) has developed a method which uses a network analyzer combined with a computer analysis to generate and fit Q -circles [Figs. 3(d) and 6]. Instead of graphically finding the solutions, he uses a least square fitting routine to an expression which includes the effects of frequency independent line and coupling reactance as well as any losses in the coupling network. This technique avoids the ambiguity that exists between over and under-coupled resonators in scalar techniques. The technique's accuracy is estimated as around 0.1% when utilizing approximately 1000 data points.

In the presence of significant line inductance, we find that instead of the ideal circle which should be seen in a plot of the real and imaginary components of the resonator impedance, we find a curve which is nearly circular but with a smaller diameter and which crosses over itself (54). By finding the two frequencies corresponding to the crossing over point as well as those corresponding to the maximum and minimum of the imaginary impedance component (the critical points), we can determine Q_U very accurately. These measurements are relatively easy using a modern network analyzer and will generate Q -factors which have an accuracy of about 0.5%.

Measuring Resonance Parameters in Presence of Other Resonances

Kajfez et al. (55) have developed an overlay for a network analyzer which takes into account the effects of inductance and loss in the coupling and transmission network as well as the effects of any distant resonant modes. These effects are modeled as a frequency dependent reactance in a series with the mode of interest. The effect of this frequency dependent series inductance is to cause the Q circle to develop distortions which make its apparent diameter smaller than it would otherwise be. If an accurate determination of the reference plane of the measurement is made, this technique can also measure the inductance of the coupling network.

Sauer et al. (56) have modeled the effects of reflections which exist in the lines between the measuring apparatus and

the resonator under test. These reflections create subsidiary line resonances which distort the resonance shape and create errors in the measurement of the Q -factor. The model can accurately fit experimental data taken in the presence of interfering line resonances yielding a Q -factor with an accuracy of $\sim 1\%$.

An extensive analysis and experimental procedure has been developed which allows for the accurate measurement of Q factors and coupling coefficients of two or more modes which are in extremely close proximity (19,57). The process relies on developing an expression which fully represents the circuit shown in Fig. 1(b) with enough free parameters to represent all visible resonance curves in the data as well as an additional frequency dependent term to represent any coupling reactance. The free parameters are then adjusted by a least squares fitting procedure to the experimental data. Even in the situation where a double loop is visible on the Smith Chart because two resonances are within a few bandwidths of each other, the accuracy of the Q measurement is around 2%.

Measuring Extremely Low Resonators

Resonators measurements are generally made through transmission lines or coupling networks which have poorly understood characteristics. The interaction of these external networks causes distortions to the resonance and, therefore, to the apparent Q -factor. This is an especially difficult problem when the Q factor of the resonator is low as the frequency rate of change of the resonator impedance becomes comparable to that of the external circuit parameters. Kajfez et al. (58) have developed an expression for determining Q_U when it is measured through an arbitrary two port. Using a similar approach, Drozd et al. (15) have developed a general Q -factor measuring method based on the full s_{11} parameters as determined by a computer driven network analyzer. The loaded Q is shown to be given by

$$Q_L = \frac{\omega_0}{2R_k} \left| \frac{dX_k}{d\omega} \right| \quad (51)$$

where X_k is the total reactance of the k th resonance and R_k is the total resistance of the k th resonance. The frequency derivative of the reactance is estimated from a number of measurements of s_{11} in the immediate neighborhood of center frequency of the resonance. Measuring near to the center of resonance gives immunity from the influences of stray inductance in the transmission line and coupling mechanism. This method proves to be far more accurate than a measurement of the half-power points or of the critical points, both of which are relatively distant from the resonant frequency. In addition, this method does not make the common assumption of Eq. 16 which is really only valid when the Q is greater than a few thousand. As a result, this method yields accurate results even for Q -factors of the order of 2.

Oscillator Phase Noise Determination

Fuchs (59) has made use of Leeson's (60) relation that in a simple microwave oscillator, the loaded Q -factor of the resonator directly determines the phase noise of the oscillator. By artificially introducing high levels of component phase noise, the oscillator noise floor becomes dominant over the phase noise measurement system's internal noise. From a plot of the phase

noise of the oscillator, the loaded Q can be directly determined to an accuracy of around 10%.

Theoretical Q Estimates

Theoretical estimation of Q factors has always been extremely difficult for all but the simplest metallic cavities with known surface resistance. Recently, a number of attempts have been made to model more complex hybrid dielectric resonators and estimate the Q factors on purely theoretical grounds (61,62,38). These estimates have value in that they could allow an independent verification of the veracity of Q measurement techniques. Unfortunately, as the accuracy of these calculations is still only around 10%, their predictive power is not yet useful in determining the accuracy of various measurement techniques.

ACKNOWLEDGEMENT

The author would like to thank Tony Mann for a critical reading of the manuscript. He would also like to thank all the personnel of the Sapphire Clock and Low Phase Noise Oscillator projects at UWA for providing an innovative and challenging environment in which to work.

Q-METERS

The concept of resonance is one that is well known to all students of science. There is hardly a field of science that does not have a prominent example of the resonant phenomenon. Resonance is used in popular examples for solving differential equations in mathematics texts, linear systems, and electrical circuits. Resonance is found from the most microscopic atomic structure to the orbits of celestial bodies and orbiting satellites.

Resonance requires at least two energy storage elements that are coupled so that the energy stored in one element may be transferred to the other. An example of this is the pendulum. The pendulum swings from left to right at a constant frequency. When the pendulum has reached the highest point of its swing, the velocity of the pendulum bob reaches zero and the velocity reverses. Thus, the pendulum begins to swing in the reverse direction and will continue to swing until it reaches the opposite side and the process is repeated.

What causes this periodic activity to take place? A pendulum hanging straight down will not move (as Newton showed). A mass at rest will remain at rest unless acted upon by an external force. The pendulum bob hanging at its lowest position is in the lowest energy state, which is a stable condition for a mechanical system. If the pendulum were pulled to one side by a small amount, the pendulum would be raised slightly in the vertical direction. This slight raising of the pendulum mass would constitute an additional energy in the system. Certainly, pulling the pendulum mass to one side requires a force to be exerted through a distance, which is energy.

At the point when the pendulum is pulled to one side and before the bob is released, the pendulum system has a certain amount of potential energy. The actual amount of potential energy is not important at this time.

To keep the pendulum mass at the displaced position, it is necessary to retain a hold of the mass. Once the mass is released, the natural force of gravity will tend to pull the pendulum bob to its original position, hanging straight down. This is the lowest energy position, where the potential energy is zero. Mechanical systems attempt to assume the lowest energy level if there are no restraints, such as holding the pendulum mass.

The natural forces of nature—gravity in this example—tug at the pendulum bob; and when the bob has reached the lowest point of its swing, because forces have been acting on a mass, there has been acceleration of the bob and it now has a velocity. The pendulum will not stop at the lowest kinetic energy state because there is nothing to stop the swinging mass. The system is now an isolated system.

This situation can be further understood if the energy content of the system is investigated. One of the most powerful tools for analyzing physical systems is the concept of conservation of energy. All energy is conserved: mechanical, electrical, heat, and so on. Energy is a scalar so the complexity of vector calculations may be avoided. In the process of conservation of energy, the form of energy may be changed. Thus electric energy may become heat energy, and mechanical energy may be converted to electric energy. Even mass can be converted into energy and vice versa.

In the pendulum example, the energy conversion is simple; it is the conversion from potential energy to kinetic energy.

When the pendulum mass was pulled to its maximum deflection, the added energy was potential. Since the bob was not moving and thus had no velocity, the entire energy of the system was potential. When the mass was released and accelerated to the lowest point of its travel, the energy was all kinetic because this was the original point where the bob hung before energy was added to the system by pulling the bob to one side.

Therefore, as the pendulum swings, the energy is transferred from potential to kinetic but the total energy remains constant.

The pendulum would swing for all eternity if the energy did, in fact, remain constant. However, a swinging pendulum eventually comes to rest. The pendulum must give up some of its energy in moving the air to make way for the swinging bob. This energy expended in moving the air is not replaced and must come from the total energy of the pendulum. The bearings that the pendulum swings about will have some friction; and this, too, will subtract from the total energy content of the pendulum.

A pendulum can be made to have the least amount of friction so that it will swing for a long time. The pendulum clock is enclosed in a cabinet to reduce the effects of air friction due to moving air, and very low friction knife edge supports are used. The typical “grandfather” clock can run more than a week with just the energy from a weight.

In addition to reducing friction, a pendulum can be made to swing for a long time by increasing the mass of the bob. Foucault pendulums, found in a number of science museums, will swing for days with no external energy sources due to their bob mass of thousands of kilograms.

The pendulum swings with a constant frequency regardless of amplitude, provided that it is not swinging at a very great amplitude. Even though the amplitude of the pendulum’s oscillations is constantly decreasing, the period of oscillation remains the same until the very last oscillation.

Electric resonant circuits operate in a fashion similar to that of the pendulum. Two energy storage elements are required to create an electric resonant circuit. This would appear, at first, to be quite different from the example of the mechanical pendulum which had only one storage element, the bob at the end of the pendulum. Although there is, physically, only one bob, energy is stored two ways, kinetic and potential. Therefore, there are two energy storage “means,” to borrow a term from the patent attorneys. In the electrical circuit, two different physical devices are required to store energy two different ways.

A capacitor stores energy in an electric field that resides in the dielectric between the conducting plates of a capacitor. This energy storage means could be likened to potential energy

because the charges that create the electric field can be static, with no motion—that is, no current. The energy stored in a capacitor is

$$E(t) = \frac{1}{2}CV^2(t) \quad (1)$$

where $E(t)$ is the energy contained in the capacitor as a function of time in joules, $V(t)$ is the voltage across the capacitor, and C is a parameter called capacitance, with the units of farads which could actually be defined by this very equation. C defines how much energy is stored per volt of electric potential difference.

Opposite the capacitor, a magnetic field is the storage means for energy in an inductor. A magnetic field is created by current, or moving charges. Thus, the energy storage in an inductor could be viewed as kinetic energy. The energy stored in an inductor is

$$E(t) = \frac{1}{2}LI^2(t) \quad (2)$$

where $E(t)$ is energy, as before, $I(t)$ is the current within the inductor, and L is a parameter called inductance, with the units of henrys, which could, as in the case of the capacitor, be defined by this equation.

In the case of the pendulum, since the bob stored both the potential and kinetic energies there was no need to connect the two energy means. With two separate energy storage devices in the electric resonant circuit it is necessary to connect the two together. This can be done in two ways: a parallel connection and a series connection. The circuit shown in Fig. 1 is a resonant circuit that could be either parallel or series, because there is only one way to connect the inductor and the capacitor. Later in the discussion of electric circuit resonance the differences between series and parallel will become evident.

The circuit shown in the figure will oscillate if there is any energy in the circuit, and the oscillations will continue infinitely because the circuit shows no method of converting the internal energy of the circuit to any other form. The frequency of the oscillations will be

$$F_0 = \frac{1}{2\pi(LC)^{1/2}} \quad (3)$$

where F_0 is the resonant frequency in Hz or 1/s.

No resonant circuit can oscillate for eternity and the circuit in Fig. 1 must include a resistance, which is the circuit element that represents the conversion of energy to another form or represents a loss of energy from the circuit.

Now, it is clear that series and parallel resonant circuits are different. Figure 2 shows a series and a parallel resonant circuit with an energy loss element, a resistor.

Figure 1. A simple resonant circuit with no energy dissipation.

Figure 2. Series (a) and parallel (b) resonant circuits with energy dissipation.

As an aid to the understanding of resonance, a parameter is desired that would quantify how quickly or how slowly energy is lost from a resonant circuit. If the fraction of the energy that is lost for each cycle of oscillation were the parameter used, it would provide a good indicator of how quickly the energy was lost from the circuit. As an example, if one-tenth of the energy were lost each cycle, the energy would decay exponentially and could be easily predicted. Based on this premise, a factor called Q is defined as

$$Q = 2\pi \left(\frac{E_s}{E_d} \right) \quad (4)$$

where E_s is the total energy stored in a system and E_d is the energy dissipated per cycle of oscillation. Notice that Q has no units because it is a ratio of energies. Q factor can be used to describe resonance that involves electric circuits, mechanical devices, and combinations of electric and mechanical devices such as control systems.

In the discussion of the pendulum, the actual mechanisms responsible for energy loss were discussed and included air resistance and friction. It would be useful to investigate the loss mechanisms in the electric resonant circuit. First, consider a resonant circuit that receives no external energy and provides no energy to any external circuits. The resonant circuit has a finite initial energy and simply oscillates until the internal energy is totally exhausted. Of course an isolated resonant circuit has no use and must be eventually connected to other circuits to be of use, and this will be discussed further. A resonant circuit that has no external energy source or sink loses energy due to its inductor or capacitor.

The Q of a circuit that has no external energy paths, either source or sink, is called the unloaded Q . When other circuits are coupled to the resonant circuit, the Q for this situation is called the loaded Q . In the example of the clock pendulum, some energy is required to be removed from the swinging pendulum to drive the escapement of the clock, and energy must be replaced by the weights to keep the pendulum in motion. Both the extraction and addition of energy to the pendulum will reduce the Q .

In the case of the capacitor, there are several loss mechanisms. First is dielectric heating. Second are resistive losses due to the finite resistance of the conducting plates of the capacitor. Finally, there is radiation, which occurs when the electric field is not totally contained in the dielectric of the capacitor and can radiate. Generally, capacitors are not the major factor in resonant circuit losses. Even at the highest

frequencies, capacitors can be manufactured to have very low losses.

The inductor loses energy in three major ways. First is the resistive loss due to the wire used to make the inductor. At higher frequencies, this can become significant because of the increase of resistance due to the skin effect. Second are the losses due to energy dissipated in the core material of the inductor. When air or some other nonmagnetic material is used in the core, losses are virtually zero. However, when ferromagnetic material such as ferrite is used, the losses can be quite significant. The final major loss mechanism in an inductor is radiation. Unlike the capacitor, an inductor can have considerable radiation.

The solenoid inductor is the worst form factor when it comes to radiation. Solenoids are actually used as H -field antennas at low frequencies. By bending the solenoid around on itself to create a toroidal shape the radiation from the end of the solenoid can be significantly reduced. This type of inductor is expensive to make and difficult to work with and is avoided for many designs.

The Q of an inductor is a function of the frequency of measurement. The loss mechanisms for inductor loss are functions of frequency. Skin effect causes increased resistance with increasing frequency, and hence increased resistance losses. Radiation also increases with increasing frequency because the physical dimensions of the inductor become a more significant part of a wavelength. When ferromagnetic material is used in the core of an inductor, the frequency dependence of the inductor's Q can become quite complex. Shielded enclosures are often used to reduce the amount of radiation from an inductor, and this adds even more complexity to the Q factor calculation.

For most resonant circuits, the losses of the inductor are the major losses of the circuit, and the quality of the inductor will set the quality of the resonant circuit.

Because the inductor is the major loss element in a resonant circuit, it is common to attach a Q value to the inductor, alone. The very same definition of Q is applied except the resonant circuit is the inductor for which the Q value will be associated and a perfect capacitor. Therefore, the losses in the resonant circuit are those of only the inductor.

If the loss of a resonant circuit is considered to be that of the inductor alone, the resistance shown in the series resonant circuit of Fig. 2(a) or 2(b) is associated with the inductor. To find a relationship between Q , the equivalent resistance, and the inductance of an inductor, the current of the series circuit is given as

$$i(t) = I(t) \cos(2\pi F_0 t) \quad (5)$$

where $i(t)$ is the circuit current and $I(t)$ is the peak amplitude that is decreasing in some unspecified manner. A cosine function is assumed for the circuit current. A sine function could be employed as well as the inclusion of a phase angle. The solution to the circuit current of Fig. 1(a) is a sinusoid, which is either a sine or cosine function. The initial conditions will determine which of the two functions or a possible phase angle will solve the equation. For the purpose of understanding Q , the cosine function with a phase angle of zero will suffice.

Assume that a relatively high Q is involved such that $I(t)$ does not change much during the time of one cycle. The

root-mean-square (rms) value of $i(t)$ is $(0.707) I(t)$, where $I(t)$, is treated as a constant. The power during this cycle is $(I_{\text{rms}})^2 R$. The energy dissipated during the cycle is simply the time duration of one cycle times the power dissipated during the cycle, which is then

$$E_d = \frac{(I_{\text{rms}})^2 R}{F_0} = \frac{\frac{1}{2}(I^2(t)R)}{F_0} \quad (6)$$

Returning to the definition of Q and using the equations for E_d and E_s , the following relationship is obtained:

$$Q = \frac{2\pi E_s}{E_d} = \frac{2(\frac{1}{2}LI^2(t))}{\frac{1}{2}I^2(t)R/F_0} = \frac{2\pi F_0 L}{R} = \frac{X_L}{R} \quad (7)$$

where X_L is the inductive reactance.

The entire concept of Q is applied to circuits and systems where only a small fraction of the energy is dissipated per cycle or typically for Q values greater than about 10. Circuits with Q values significantly less than 10 do not oscillate but have a more exponential decay. Q values between 1 and 10 represent highly damped circuits where the normal assumptions concerning the calculation and measurement of Q may not produce accurate predictions of circuit behavior.

A similar analysis may be applied to the parallel resonant circuit as shown in Fig. 2(b). In this example, the voltage is the common parameter to the two circuit elements and may be represented by

$$v(t) = V(t) \cos(2\pi F_0 t) \quad (8)$$

where $v(t)$ is the circuit voltage and $V(t)$ is the peak amplitude. The same reasoning as was applied to the series circuit is used here to justify the form of the equation for $v(t)$. Likewise the same analysis will be applied to determine the relationship between Q and the circuit elements:

$$E_d = \frac{(V_{\text{rms}}(t))^2}{RF_0} = \frac{\frac{1}{2}V^2(t)}{RF_0} \quad (9)$$

For the stored energy to calculate Q , the energy stored in the capacitor will be used because this is a voltage equation and the energy stored in the capacitor is a function of voltage. Therefore,

$$E_s(t) = \frac{1}{2}CV(t)^2 \quad (10)$$

$$Q = \frac{2\pi E_s}{E_d} = \frac{2\pi(\frac{1}{2}CV^2(t))}{\frac{1}{2}V^2(t)/RF_0} = 2\pi F_0 CR = \frac{R}{X_C} = \frac{R}{X_L} \quad (11)$$

where X_C is the capacitive reactance.

MEASURING Q

The next consideration is measuring Q . From the discussion thus far, it would appear that if a resonant circuit were set into oscillation along with the number of cycles required to reach half-amplitude or other criterion, then Q could be determined in this fashion. This technique would work and produce the

value of Q . However, there are other methods of measuring Q that are more practical. In order to understand the measurement of Q , consider the impedance of a series resonant circuit at near resonance:

$$Z(f) = R + j(X_L - X_C) = R + j\left(2\pi fL - \frac{1}{2\pi fC}\right) \quad (12)$$

Using the substitutions

$$L = \frac{1}{4\pi^2 F_0^2 C} \quad \text{and} \quad C = \frac{1}{4\pi^2 F_0^2 L} \quad (13)$$

the impedance may be rewritten as

$$\begin{aligned} Z(f) &= R + j\left(\frac{2\pi f F_0 L}{F_0} - \frac{4\pi^2 F_0^2 L}{2\pi f}\right) \\ &= R + j(2\pi F_0 L)\left(\frac{f}{F_0} - \frac{F_0}{f}\right) \\ &= R\left[1 + j\left(\frac{2\pi F_0 L}{R}\right)\left(\frac{f}{F_0} - \frac{F_0}{f}\right)\right] \\ &= R\left[1 + jQ\left(\frac{f}{F_0} - \frac{F_0}{f}\right)\right] \end{aligned} \quad (14)$$

From this equation, the real part of the resonant circuit is a constant at R while the imaginary part is zero at the resonant frequency. Also, notice that if the frequency at which the impedance is measured is greater than the resonant frequency, then the sign of the imaginary part of the impedance is positive, indicating that the impedance becomes more inductive. Below the resonant frequency sign is negative, indicating that the impedance is more capacitive.

For the case of the parallel resonant circuit a similar equation is derived for the admittance of the circuit:

$$Y(f) = \frac{1}{R[1 + jQ(f/F_0 - F_0/f)]} \quad (15)$$

In this situation, when the frequency is greater than the resonant frequency the admittance becomes positive, indicating an inductive circuit. When the frequency is less than the resonant frequency, the admittance is capacitive.

Q was shown to be a parameter that described how the oscillations of a resonant circuit decayed in time. This was the time-domain picture of Q applied to a resonant circuit. When analyzed in the frequency domain, a circuit with a high Q has a narrow bandwidth. To determine the relationship between Q and the resonant circuit bandwidth the impedance of a series resonant circuit is considered:

$$Z(f) = R\left[1 + jQ\left(\frac{f}{F_0} - \frac{F_0}{f}\right)\right] \quad (16)$$

The series resonant circuit has a minimum impedance of, simply, R at the resonant frequency. The half-power level of a system is the usual way of specifying bandwidth of a circuit. In the case of a series circuit driven from a current source, half-power in the resonant circuit would occur when the magnitude of the impedance is $1.414R$.

Therefore,

$$|Z(F_{3dB})| = 1.414R \quad (17)$$

$$Z^2(F_{3dB}) = 2R^2 = R^2 \left[1 + Q^2 \left(\frac{F_{3dB}}{F_0} - \frac{F_0}{F_{3dB}}\right)^2\right] \quad (18)$$

Rearranging, we obtain

$$F_{3dB}^2 - \frac{F_0 F_{3dB}}{Q} - F_0^2 = 0 \quad (19)$$

Solving this equation for F_{3dB} , we obtain

$$F_{3dB} = \left(\frac{F_0}{2Q}\right)(1 \pm (1 + 4Q^2)^{1/2}) \quad (20)$$

For $Q \gg 1$ the equation above reduces to

$$F_{3dB} = \left(\frac{F_0}{2Q}\right)(1 \pm 2Q) \quad (21)$$

Again, by rearranging we obtain

$$F_{3dB} = F_{0-}^+ \left(\frac{F_0}{2Q}\right) \quad (22)$$

There are two 3 dB frequencies, one below the resonant frequency and a second above the resonant frequency. The difference between these two frequencies is the 3 dB bandwidth, BW, and is

$$BW = \frac{F_0}{Q} \quad (23)$$

Because a resonant circuit is highly frequency-selective, it is the major component of filters. The bandwidth of a resonant circuit is dependent on the Q of the circuit. When a resonant circuit is used in a filter the Q of the circuit is set by adding resistors to the basic resonant circuit to decrease the loaded Q and achieve the necessary bandwidth required for the filter design.

The unloaded Q will determine the bandwidth of the basic resonant circuit. To understand the relationship between Q and bandwidth, consider the driven resonant circuit in Fig. 3. In this example a 0 Ω generator is shown providing the input driving function to the circuit. Thus, the loaded Q and the unloaded Q are the same. If a real generator were used, some finite amount of impedance must be added to the voltage generator and the loaded Q will be less than the unloaded Q . In this circuit the maximum circuit current will be found at the resonant frequency and is V_{in}/R .

Figure 3. A driven resonant circuit.

Generally, the unloaded Q of a resonant circuit is significantly higher than the desired loaded Q . This is done so that the loaded Q can be controlled. Unloaded Q s are of a function of parameters that are not easily controlled.

The discussion thus far is of Q as associated with a resonant circuit. It was also shown that the Q of a resonant circuit is mainly set by the inductor because the inductor tends to have significantly more loss than capacitors. The Q of an inductor is the Q of a resonant circuit that is constructed with the inductor with a perfect capacitor. The Q of a capacitor is that of a resonant circuit with a perfect inductor. A resonator such as a quartz crystal or ceramic resonator is often described using a Q factor; this would be the Q of the resonator, alone.

For the case of Q -factor for inductors and capacitors, the Q of these components is a function of frequency. Generally, the higher the frequency the lower the Q because high frequencies exacerbate the loss mechanisms such as skin effect and radiation. Because of this frequency dependence, Q -factor must be measured and specified at a frequency near that which the inductor will operate.

Q -factor is also used for devices that are, in themselves, a resonant circuit. One example of this is the quartz crystal. This resonator has very high values of Q extending from tens of thousands to over 1 million. Ceramic resonators are similar to quartz crystals except the Q -factors are considerably lower and the ceramic devices do not have the superb frequency stability found in quartz crystals.

There are other devices such as ultrasonic transducers that are essentially resonators that are characterized by a Q -factor.

THE Q-METER

A method of measuring Q , primarily of inductors, is the appropriately named Q -meter. This device was invented in the mid-1930s by the Boonton Radio Company in Boonton, NJ. These instruments were manufactured for more than 40 years, mostly by Boonton Radio. There were a few other manufacturers such as The Marconi Corporation in England, and there was also a do-it-yourself kit by the venerable Heathkit Company that was a copy of the classic Boonton meter. When Boonton Radio was purchased by Hewlett-Packard in the 1960s a new, solid-state Q -meter was designed and was available for another two decades or so.

The Q -meter, as shown in Fig. 4, consists of an oscillator with a very low output impedance which was used to excite a resonant circuit which was made up of the unknown inductance and an internal calibrated capacitor. This instrument not only

Figure 4. The basic schematic of a Q -meter.

Figure 5. A driven resonant circuit with finite Q .

provides the ability to measure Q at a variety of frequencies, but could be used to measure inductance as well.

An oscillator feeds the resonant circuit which is in series resonance. A high-impedance alternating-current (ac) voltmeter is connected to the inductor and the actual inductor voltage is measured. The calibrated capacitor resonates the unknown inductor, and resonance is indicated by the maximum voltage indication of the voltmeter.

Historically, the output resistance of the generator was $0.02\ \Omega$ and the voltage was $0.02\ \text{V}$.

For a resonant circuit with an applied voltage from a $0\ \Omega$ generator, the voltage across the inductor or capacitor is Q times the applied voltage. The voltage-increasing phenomenon gives rise to the English name for a Q -meter, namely, "circuit magnification meter." To derive this relationship, consider the circuit shown in Fig. 5. In this example the generator has exactly $0\ \Omega$ internal resistance, which is, of course, only theoretically possible. The actual $0.02\ \Omega$ source resistance of the Q -meter causes only small errors for medium- or high- Q inductors.

At resonance the rms circuit current is

$$I = \frac{E_{\text{gen}}}{R} \quad (24)$$

where E_{gen} is the rms generator voltage.

The inductor rms voltage is

$$E_{\text{ind}} = IX_L = \frac{E_{\text{gen}}X_L}{R} = E_{\text{gen}}Q \quad (25)$$

The inductor voltage is Q times the generator, which shows how the input voltage is "magnified" by Q .

The voltage source in the Q -meter is not $0\ \Omega$ but $0.02\ \Omega$. The actual source voltage is determined by measuring the current in the $0.02\ \Omega$ resistor using a thermocouple ammeter. From the previous equation, the inductor voltage, which is the actual indication of Q , is directly proportional to the generator voltage. The accuracy of the meter depends on the precision of the generator voltage. The Q -meter provided a control to accurately set the generator voltage using a meter. Also, the generator voltage could be reduced to increase the scale factor of the meter. The meter was labeled "multiply Q by" with a prominent 1 on the scale along with other convenient values such as 2, 5, and 10.

The capacitor must not contribute significantly to the energy loss in the resonant circuit formed by the unknown inductor and the Q -meter's capacitor. Generally, it is easy to make a capacitor with significantly lower losses than the inductor under test, and the losses of the resonant circuit are those of the inductor. In the Q -meter, the resistance of the driving generator is very low and does not contribute to the total losses. Also, a high-impedance

voltmeter is used to measure the voltage across the inductor and is the indicator of Q .

The vacuum tube circuit used as a voltmeter in the early Q -meters was called the infinite impedance detector. Although the input impedance was not infinite, the actual impedance was quite high. This was due to the fact that vacuum tubes are inherently high-impedance devices and the infinite impedance detector used a high level of feedback in the circuit, which further increased the impedance. For a modern Q -meter, a field-effect transistor (FET) would be an acceptable replacement for the high-impedance vacuum tube. The input impedance of the vacuum tube voltmeter circuit is a high resistance in parallel with a small capacitor.

The capacitive part of the input impedance of the voltmeter can be compensated by including the fixed capacitance of the voltmeter in the calibration of the calibrated variable capacitor. The resistive part of the voltmeter would cause errors for extremely high Q . The typical Q -meter is capable of measuring Q values as high as 400 or so with accuracy. Very few conventional inductors would have Q values exceeding this range.

The resistive component of the variable capacitor is due to losses in the capacitor. In order to keep the losses low, the variable capacitor of the Q -meter is carefully constructed of the highest-quality materials. The capacitor is a conventional mechanically adjusted parallel-plate capacitor. The plates are either silver- or gold-plated, and the insulators supporting the fixed plates are a low-loss ceramic or glass. The shaft supporting the rotating plates has a large rotating contact to ensure a low-loss path to ground. The capacitor is mounted to the top of the Q -meter so that the "high" terminal of the inductor is directly connected to the stator plates of the calibrated capacitor. This reduces the amount of residual inductance in the tuned circuit.

In spite of all of the cautions taken to create a low-loss capacitor, the variable capacitor represents exposed plates that can radiate and lose energy. For measurements made at low frequencies, below about 1 MHz, the wavelengths involved are so long relative to the dimensions of the capacitor that no significant radiation occurs. This is not the case when the desired measuring frequency is in the very high frequency (VHF) range and higher. Because of this reason and other factors, Q -meters were made in several frequency ranges.

Special small geometry capacitors were made for the higher-frequency Q -meter to reduce the amount of radiation. Since the amount of capacitance required of a VHF range Q -meter was significantly less than the lower-frequency counterparts, the capacitor loss was mostly achieved by simply scaling down a conventional parallel-plate variable capacitor.

In addition to measuring inductance and Q of an inductor, the Q -meter can measure capacitors. The method of measuring capacitors is to resonate an inductor using the internal calibrated capacitor and adding the unknown capacitor in parallel with the calibrated capacitor. The additional capacitance of the external capacitor will detune the resonant circuit. The circuit can be returned to resonance by adjusting the calibrated capacitor. The amount of capacitance removed from the calibrated capacitor is equal to the amount of capacitance added by the external capacitor.

A set of inductors, called a "standard inductor set," sometimes called a "working inductor," was available from the Q -meter manufacturer to make these capacitor measurements. The actual value of the inductor was not important because it

was necessary to resonate the inductor at the frequency of interest. The inductance needs to be such that the Q -meter will resonate with the external capacitor and without it.

What is important, however, concerning the standard inductors, is that the Q of the working inductor is as high as practical. The inductors were typically large because it was made from large-gauge wire, often Litz wire. The inductor is shielded to prevent radiation.

When an inductor is resonated using the calibrated capacitor in a Q -meter, the inductance of the unknown may be calculated using the familiar resonance equation. This is making the assumption, however, that the unknown is a pure inductance. This is not exactly the case.

Although there are exceptions, inductors are made from wire wound into a solenoid or toroid shape. If a single layer of wire will not produce the necessary inductance, additional layers of wire can be added. In many cases, dozens of layers may be involved with hundreds of turns. When wires lie side by side with only the thin enamel insulation of the wire to separate the wires, capacitance is added to the inductor. This added capacitance is called distributed capacitance and can have an effect on the measurement of inductance.

When an unknown inductor is resonated in a Q -meter, the value of capacitance that is in parallel with the inductance is the external capacitance plus the distributed capacitance. Therefore, the capacitance indicated on the calibrated capacitor is that which is required to resonate the inductor at the desired frequency.

The typical inductor has an equivalent circuit as shown in Fig. 6. If this inductor was to be used in an oscillator in a parallel resonant circuit, the external capacitance required to resonate the inductor in the oscillator needs to be known. The actual inductance is not a factor.

The circuit shown in the figure also has a resonant frequency of its own, with no external components called the self-resonant frequency. When the series impedance of the inductor is an important factor such as the three-pole low-pass filter shown in Fig. 7, the self-resonant frequency of the inductor is important. In this example, the distributed capacitance causes two zeros to appear in the transfer function of the filter which will affect the performance of the filter in the stop band.

The Q -meter can measure the distributed capacitance of an inductor. The inductor is resonated at a frequency near the frequency where the inductor will be operated. The capacitance required for resonance is recorded. Notice that the inductance is not measured; only the capacitance required to resonate the inductor at the set frequency. The inductor is resonated at a second frequency and the capacitance is noted.

Historically, the two frequencies at which the inductor is resonated are a ratio of two to one. In other words, the inductor

Figure 6. The equivalent circuit for an inductor showing the distributed capacitance.

Figure 7. (a) The theoretical schematic of a three-pole low-pass filter. (b) The actual schematic showing indicators with finite Q and distributed capacitance.

is resonated at a frequency and then at twice that frequency. Using this convention the distributed capacitance, C_0 , can be calculated by the following reasoning:

For resonance at a frequency F_0 the resonance equation is

$$F_0 = \frac{1}{2\pi[L(C_0 + C_d)]^{1/2}} \quad (26)$$

where C_0 is the capacitance set on the Q -meter and C_d is the distributed capacitance. The frequency of the Q -meter oscillator is set to twice the previous frequency and the inductor is resonated again. In this case the resonance equation is

$$2F_0 = \frac{1}{2\pi[L(C_1 + C_d)]^{1/2}} \quad (27)$$

where C_1 is the capacitance set on the Q -meter for this higher frequency.

Taking the ratio of the two frequencies, the following result is obtained:

$$2 = (C_0 + C_d)^{1/2} / (C_1 + C_d)^{1/2} \quad (28)$$

Solving for C_d the result is

$$C_d = \frac{C_0 - 4C_1}{3} \quad (29)$$

In many cases it is not desirable to use a frequency ratio as high as two to one, particularly for a measuring frequency that is

near the upper frequency region of the meter. Almost any ratio can be used; but if the ratio is not sufficient, the difference in resonating capacitance for the two frequencies will be small, making it difficult to read an accurate difference. Therefore, the calculated distributed capacitance will be prone to error. Some models of Q -meters had a precise ΔC dial to increase the accuracy of these measurements. One ratio that produces good accuracy is 1.414, or the square root of two. Using this ratio the equation for the distributed capacitance is

$$C_d = (C_0 - 2C_1) \quad (30)$$

Although the Q -meter has been around for more than 60 years and is no longer available as a new instrument, there are thousands of the units in use. The older meters are doomed because their vacuum tubes are no longer available. There is lasting evidence of the Q -meter's long influence on inductors. The variable capacitor dial on the Q -meter was calibrated not only in microfarads and picofarads, but also in inductance. The inductance scale was only accurate if the frequency of the oscillator was set to one of several specific frequencies (250 kHz, 790 kHz, 2.5 MHz, etc.) which were etched on the front panel of the meter. These steps are in multiples of the square root of 10 so that the inductance scale on the variable capacitor may be used in multiples of 10. A new inductor of the latest modern design specifies a Q at a specific frequency which is, more often than not, one of the frequencies etched on the front panel of a 50-year-old Q -meter.

The Q -meter can measure reactances that are low Q , low values of inductance, or high values of capacitance. The difficulty in measuring low inductance is that large capacitance is required to resonate the inductance. For the case of a capacitor, the usual technique of measuring capacitance is to resonate a "working inductor," place the unknown capacitor across the calibrated capacitor, and note how much capacitance is to be removed from the calibrated capacitor to restore resonance. For capacitor values greater than the range of the calibrated capacitor, this could not be done because it would not be possible to remove an amount of capacitance equal to the unknown. To measure large capacitors and small inductors, the unknown circuit element is placed in series with a working inductor; the change in Q and capacitance is determined to find the capacitance, inductance, or Q of the unknown.

Assume that a working inductor is resonated with the Q -meter's calibrated capacitor, C_1 . This capacitance can be represented as

$$L = \frac{1}{4\pi^2 C_1 F_0^2} \quad (31)$$

The unknown is added in series as shown in Fig. 8. If the unknown is a capacitor, C_x , the calibrated capacitor will have to be increased in value because the unknown is in series with the calibrated capacitor and will reduce the total capacitance across the working inductor. The dial capacitance is changed to bring the inductor to resonance. The new capacitance is the combination of the dial and the unknown, and together they are equal to the original capacitance as resonance is reestablished. Therefore,

$$\frac{1}{C_1} = \frac{1}{C_x} + \frac{1}{C_2} \quad (32)$$

Figure 8. Simplified schematic of the method of measuring small inductors or large capacitors.

where C_x is the unknown capacitance and C_2 is the dial capacitance required to establish resonance with the unknown in place. Solving for C_x , we obtain

$$C_x = \frac{C_1 C_2}{C_2 - C_1} \quad (33)$$

If the unknown is an inductor, L_x , and there is no mutual inductance between the working inductor (this is the reason for shielding the working inductor), the circuit inductance will increase by an amount equal to the added inductance. Therefore, the calibrated capacitance must be reduced to account for the increase in inductance. The new inductance is

$$L_2 = L + L_x = \frac{1}{4\pi^2 C_1 F_0^2} + L_x = \frac{1}{4\pi^2 C_2 F_0^2} \quad (34)$$

Solving for L_x , we obtain

$$L_x = \frac{C_1 - C_2}{4\pi^2 C_1 C_2 F_0^2} \quad (35)$$

To derive the relationship of the measured Q and the Q of the unknown, consider the situation at resonance with just the working inductor. The indicated Q_1 is

$$Q_1 = 2\pi f L / R = \frac{1}{2\pi f C_1 R} \quad (36)$$

When an unknown is added to the circuit, the equivalent series resistances add but the additional reactance is removed by either increasing or decreasing the calibrated capacitance until resonance is restored. The Q is measured by the voltage across the calibrated capacitor and the measured Q is relative to that circuit element. With both the unknown and the working inductor present in the circuit the indicated Q will be Q_2 and the setting of the calibrated capacitor will be C_2 . Thus the total circuit resistance for this situation is

$$R + R_x = \frac{1}{2\pi f C_2 Q_2} \quad (37)$$

Solving for R_x we obtain

$$R_x = \left(\frac{1}{2\pi f} \right) \left(\frac{1}{C_2 Q_2} - \frac{1}{C_1 Q_1} \right) \quad (38)$$

The highest Q that can be measured by the Q -meter is under 1000. Conventional inductors are seldom manufactured with Q values as high as 1000. Ceramic resonators and other electromechanical resonators can have Q values as high as several thousand. Theoretically, the Q -meter could measure very high Q values if the “multiply Q by” control were reduced sufficiently to permit the Q to fall within the range of the meter. Even if this were possible, there is another problem with the use of the Q -meter for very high Q -circuits. The bandwidth of a circuit is inversely proportional to Q , and for very high Q -circuits the bandwidth can be so narrow that it becomes nearly impossible to adjust the frequency of the oscillator in the Q -meter to exact resonance.

An instrument (which is similar to the Q -meter) used for very-high- Q resonators is the crystal impedance meter or CI-meter. The first major difference between the CI-meter and the Q -meter is that the resonator is put in an oscillator circuit such that it is not necessary to adjust the signal generator with great accuracy.

The quality of a quartz or ceramic resonator is usually specified by the equivalent series resistance. Figure 9 shows the equivalent circuit of a quartz or ceramic resonator. The inductor L_0 is due to the motion of the quartz bar and is called the motional inductance. The capacitor C_0 is called the motional capacitance and is also due to the mechanical motion. The capacitance C_p is due to the electrodes plated on the quartz bar and the capacitance of the mechanical supports for the crystal and is called the parallel capacitance of the crystal. R is the equivalent series resistance and represents the losses in the crystal.

There are two resonant frequencies of the quartz resonator: the series and the parallel resonance. The series resonant frequency occurs when the circuit is at the minimum impedance, which is, essentially, the equivalent series resistance. There would also be a reactance due to the capacitance C_p ; but because this reactance is so much higher than the relatively low resistance of R , its effect can be discounted.

In the parallel mode of oscillation, the quartz crystal resonates with its motional capacitance in series with the capacitor C_p , with the two capacitors in parallel with the motional inductance.

In a quartz resonator, the equivalent inductance is in the tens and hundreds of millihenrys while the motional capacitance is very small, on the order of femtofarads. Although the capacitance C_p is small, it is large compared to C_0 . Therefore, the parallel resonant frequency of the quartz crystal is only slightly higher than the series resonant frequency, typically on the order of 0.1%.

The equivalent series resistance of a quartz crystal is measured in two ways. The first method is to place the quartz crystal in a resonant circuit and measure the input and output voltage

Figure 9. The equivalent circuit of quartz or ceramic resonator.

Figure 10. A simplified diagram of a crystal impedance meter.

of the crystal. Then the crystal is replaced with a variable resistor; and because of tuned circuits in the oscillator, the oscillator will continue to oscillate at nearly the resonant frequency of the crystal. The resistance value is adjusted until the input and output voltages and currents are the same as when the crystal was in the oscillator circuit. This method requires manual manipulation; and although it has been used for many years, it cannot be applied to an all-electronic method.

A method that can be adapted to an all-electronic method is similar to a Q -meter in reverse. The oscillator is adjusted to operate in the series mode of the crystal, and the crystal current passes through a low resistance (Fig. 10). Measuring the voltage across the low resistance provides an indication of

the crystal current while the voltage across the crystal provides the applied voltage. The resistance is simply the voltage divided by the current.

ELECTROMAGNETIC VARIABLES

ELECTRIC STRENGTH

When a dielectric material is subjected to electric voltage, two different types of currents are induced. Applied voltage exerts force on the bound charges that give rise to displacement current. On the other hand, free charge carriers move under the influence of this force, which constitutes the conduction current. There are no free charge carriers in an ideal dielectric material. If the applied voltage is constant with time (dc), then the displacement current shows up only as a transient phenomenon that results in the polarization charge at steady-state condition. Displacement current will be nonzero at the steady state if applied voltage is time-dependent, and it is also known as the capacitive current or the polarization current. Conduction current (or leakage current) produces heat as a result of I^2R loss while the displacement current represents the energy stored. The two currents increase with a rise in applied voltage. This is true as long as the applied voltage is not sufficiently significant to introduce sharp or irreversible changes in the material.

In the foregoing description, it is assumed that the applied voltage remains below a certain limit such that the properties of dielectric material are preserved. However, if the applied voltage is high enough to exert a large force on bound charge carriers, then the material may break down. This change in characteristics of material may be irreversible. In this case, the electric resistance of the dielectric material decreases sharply; this gives rise to a large conduction current flowing through certain channels formed between the electrodes, practically producing a short-circuit. Maximum voltage V_{bd} applied at the moment of breakdown is known as the breakdown voltage of that material. The point of breakdown generates a spark or an electric arc that can fuse, burn or crack the material and the electrodes. When the applied voltage is removed, the solid dielectric may exhibit a trace of breakdown in the form of a punctured, fused or burnt-through hole, generally speaking, of an irregular shape. If this sample is again subjected to electric voltage, then the breakdown occurs in most cases at the already punctured spot even at a rather low voltage. Thus, a breakdown of solid insulation is a failure that puts the device out of operation and requires serious repairs. The liquid as well as gaseous dielectrics generally recover after the breakdown voltage is removed because of the mobility of constituent particles. However, if the power and duration of the electric arc are large, then the entire volume may change and the material may not recover.

Experiments indicate that the breakdown voltage of a material depends on the thickness between the two electrodes. The thicker the material, the more it withstands higher voltages; V_{bd} grows nonlinearly when thickness increases. On the other hand, layers of the same thickness but made of different dielectric material exhibit different breakdown voltage. This indicates that every insulating material has the unique ability to resist breakdown. This parameter is an electric field intensity value known as the electric strength E_{bs} .

For the simplest case of a uniform electric field produced by voltage V_{bd} in a dielectric of thickness d , one can write

$$E_{bs} = \frac{V_{bd}}{d} \quad (1)$$

Dielectric (or electric) strength may be regarded as the electric field intensity at a given point in a dielectric material that causes the breakdown at that location. Generally, the electric strength of an electrical insulating material is understood to mean average breakdown intensity. In Eq. (1), V_{bd} is in volts, d is in meters, and E_{bs} is in V/m. Other commonly used units of electric strength are kilovolts/millimeter, kilovolts/centimeter, and volts/micrometer. Another unit—volt/mil—is frequently used in the United States. Since a mil is one thousandth of an inch, 1 V/mil is equal to 39.37 kV/m. Alternately, 1 MV/m is equal to 25.4 V/mil.

The electric strength depends on various factors including temperature, humidity, frequency, and duration of the applied voltage. Its value varies over a broad range and therefore it is important to include the conditions under which a given datum is measured. For example, the electric strength for mica ranges from 100 to 300 MV/m, from 15 to 25 MV/m for transformer oil, while it is only 2 to 5 MV/m for air under normal conditions of pressure and temperature. Table 1 shows typical electric strength and the dielectric constant of selected materials. The table also shows that high-quality solid dielectrics possess higher electric strength, in general, in comparison with those of liquid and gaseous dielectrics. Therefore, the electric strength of the medium surrounding a specimen needs to be taken into account. For example, consider a comparatively thick solid test sample that is placed in air, as shown in Fig. 1. In this case, an increase in the applied voltage may cause first not a breakdown through the specimen, but a surface discharge or flashover through the surrounding medium.

The aforementioned characteristics lead to the conclusion that solid dense dielectrics should have higher electric strengths in comparison with those porous dielectrics containing many gaseous inclusions. The electric strength of porous dielectrics can be increased appreciably by impregnating it with high-quality liquid or solidifying insulating materials. The operating voltage V_{op} of insulating material in an electrical device (machine, cable, etc.) should be less than the breakdown voltage of that material. The ratio of the breakdown voltage to the operating voltage (V_{bd}/V_{op}) is generally called the safety factor of electric strength of insulation.

Two main kinds of breakdown occur largely in solid dielectrics: the electric and electrothermal breakdown. Electric

Table 1. Dielectric Constant and Electric Strength of Certain Materials (5)

Material	Dielectric Constant	Electric Strength (kV/m)
Air	1	30
Barium titanate	1200	75
Oil	2.3	150
Paper	3	200
Porcelain	7	200
Glass	6	300

Quartz (fused)	4	400
Polystyrene	2.6	500
Mica	6	2000

Figure 1. An arrangement of the electrodes with flashover path.

breakdown represents the destruction of a dielectric material due to the force of an applied electric field. It occurs either because accelerating free charged particles (electrons, ions) interact with the material structure or because of inelastic displacement of bound charges in a dielectric under the action of an external electric field. The secondary processes (heating, chemical reactions, and so forth), which may occur in a dielectric under the action of an electric field, never take place in this intrinsic electric breakdown.

Theoretical analysis of electric breakdown is extremely complex. Experimental results frequently differ from those calculated on the basis of the structure and various parameters of materials. Estimated values of intrinsic electric strength are generally higher than the experimental results. This discrepancy is sometimes attributed to minute cracks and other defects present in the material.

Electrothermal breakdown occurs due to loss of electrical energy in a material. The energy loss raises the temperature of insulating material and that, in turn, increases the energy loss even further. This process continues up to the point when the dielectric is fused, burnt, ruptured, or develops cracks.

BREAKDOWN IN LIQUIDS

Petroleum oils are important liquid dielectrics because of their frequent use in transformers, capacitors and cables that operate at high voltage. These are mixtures of various hydrocarbons and serve as neutral or weakly polarized dielectrics. In order to be employed in electrical insulation they must be free of water, oxidation products, aging and other contaminants. Even a small amount of water can influence the electric strength of petroleum oils significantly. This may be attributed to the fact that the dielectric constant of water (around 80) is much higher than that of oil (in the range of 2.2 to 2.4). Water droplets present in oil as emulsion, become elongated by the applied electric force and are broken into still finer droplets. These fine droplets form chains and are drawn into the sites where field intensity is especially high (i.e., towards the edges of the electrodes). It is precisely these sites that form the foci for the development of oil breakdown. The fibrous impurities reduce the electric strength of oil even more sharply.

Electric strength of the liquid dielectric material is found to increase noticeably when its thickness d between the electrodes is reduced. The following empirical relation can be used to

estimate the electric strength of petroleum oil with d ranging from 0.01 to 1.0 mm (1):

$$E_{bd} = 31.3 d^{-0.2085} \quad (2)$$

In Eq. (2), E_{bd} is in MV/m (acting value) and d is in millimeters.

BREAKDOWN IN GASEOUS DIELECTRIC MATERIAL

Besides chemical composition, pressure, and temperature of the gas, the design of electrodes and their separation affect the breakdown voltage and its pattern. In case of a comparatively uniform field, a gradual increase in applied voltage produces a breakdown of the entire gap between the electrodes. Generally, a spark is produced instantaneously and becomes an electric arc if the source of current has sufficient power.

If the field distribution is inhomogeneous, then an increase in voltage may first result in a discharge in the gas that appears only at the points where electric field intensity is strongest (for example, at sharp spots) without expanding over the entire gap between the electrodes. This discharge is commonly known as corona discharge (or for the sake of brevity, simply as corona) and it has a bluish luminescence. It is associated with a characteristic sound, that is, buzzing or crackling. The corona appears mainly because of chemical transformation of gas in that volume and the rapid growth of energy expenditure as voltage is increased. Peek's law may be used to estimate the latter as follows:

$$P_c = Af(V - V_c)^2 \quad \text{for } V \geq V_c \quad (3)$$

where P_c is power expressed in watts that is liberated in corona, and A is a constant that depends on the electrode geometry, gas composition, pressure and temperature. For example, it will be smaller if the electrode surface is made smoother; A has unit of watts/square volt, f represents frequency in hertz; V in volts is the voltage between electrodes, and V_c is voltage at which the corona appears initially.

As voltage is increased further, the corona occupies more and more space, causing a spark or an arc discharge between the electrodes puncturing the gas gap. Ordinarily, it develops during a very short time—of the order of several microseconds or less. In view of this, the breakdown voltage is practically the same for a direct current as well as for alternating current with a frequency up to a few kilohertz. If the breakdown occurs due to voltage pulses of very short duration, then the magnitude of breakdown voltage becomes larger than that of a low-frequency alternating voltage. The ratio of breakdown voltage with a pulse of given duration and form to breakdown voltage under alternating current of low frequency is known as the pulse coefficient β . When an electric field has a fairly high frequency (of the order of 100 MHz or so) the value of β reaches 1.5 to 2.

The influence of pressure and temperature of a gas on its electric strength is of great importance. The electric strength of air rises with increase in pressure above the normal atmospheric value. When it drops below the normal atmospheric pressure, the electric strength of the gas passes through a minimum and then increases appreciably in the region of reduced pressure. This is why gases are employed as an insulating medium at a high or markedly reduced pressure. This

Table 2. Comparative Values of Electric Strength of Gaseous Dielectrics (1)

Gas	Chemical Composition	Molecular Mass	Electric Strength Relative to Air
Helium	He	4	0.06
Hydrogen	H ₂	2	0.6
Carbon dioxide	CO ₂	44	0.9
Nitrogen	N ₂	28	1.0
Freon-12	CCl ₂ F ₂	120	2.6
Perfluoromethylcyclohexane (vapor)	C ₇ F ₁₄	350	6.0
Perfluorodibutylether (vapor)	C ₈ F ₁₈ O	454	7.5
Perfluorodimethylcyclohexane (vapor)	C ₈ F ₁₆	400	8.5
Perfluorophenatrene (vapor)	C ₁₄ F ₂₄	624	10.0

phenomenon can be explained via the theory of collision ionization as a cause of gas puncture. A gas always contains some electrically charged particles (electrons, negative and positive ions) generated by cosmic rays, radiation of radioactive matter, ultraviolet rays and other factors. Similar to the molecules of a gas, these particles are in a state of chaotic thermal motion. These charged particles are accelerated by the applied electric field. Hence, they acquire a velocity that results in higher kinetic energy until they collide with a molecule. If λ denotes the mean distance traversed by a charged particle before colliding with a molecule and the charge on that particle is q , then its kinetic energy in a uniform field with an intensity E at the moment of collision will be given as follows:

$$W = Eq\lambda \quad (4)$$

If this energy is sufficient to ionize the molecule, that is, to separate it into a positive ion and an electron, then the gas may be punctured. This occurs because the new particles generated upon collision ionization will, in turn, be accelerated by the electric field and ionize the other molecules. This process will continue until a complete breakdown occurs in the gap. A rise in pressure (with temperature remaining the same) increases the density of gas, and, in turn, reduces the mean molecular distance and diminishes the value of λ . It is true that λ increases in the region of high vacuum, but there is much less probability of collision between the charged particles and the molecules of rarefied gas. The latter effect dominates the former (the effect of increase in λ). At high vacuum, the value of λ can even exceed the dimensions of the container.

In practical calculations, the effect on the electric strength of air to slight deviations in normal pressure p and temperature T ($p = 760$ mm Hg, $T = 293$ K) is estimated as follows. Assume that V_{bdo} represents the breakdown voltage at normal condition and V_{bd} is its new value. Then

$$v_{bd} = V_{bdo}d \quad (5)$$

where d is the relative density of air. It is the ratio of the density of air at a pressure of p and a temperature T to the density of air in normal condition, and given by

$$d = 0.385526 \frac{p}{T} \quad (6)$$

In this equation p is measured in mm Hg and T in Kelvin.

Detailed study of the breakdown in gases with various pressure p and the electrode separation t indicates that the magnitude of breakdown voltage in a comparatively homogeneous field depends not on the value of p and t taken separately, but a product of these two parameters; this is known as Paschen's law. A definite minimum breakdown voltage V_{bdm} describes each gas. When the voltage is less than this value, the gas-filled gap of any length and under any pressure can not be punctured. The value of V_{bdm} is 326 V for air for $p \cdot t = 5.67$ mm Hg · mm. In the case of inert gases, V_{bdm} also depends on the material of the electrode (cathode). If the cathode is made of an alkali or alkaline-earth metal that possesses a low work function of electrons (or is at least coated with such metal) then V_{bdm} is reduced. This fact is utilized to make gas-discharge devices.

It may be inferred that gases varying in their chemical composition have different electric strength under the same conditions. Thus, the electric strengths of hydrogen and inert gases, such as argon, neon, and helium, are lower compared with air. There are also gases that possess an electric strength appreciably larger than that of air. The gases with high electric strengths that can be employed as electrical insulation in high-voltage devices (especially at high pressure) have rather high molecular mass and density. These are primarily the gases containing strongly electronegative elements—fluorine, chlorine, and so forth. The electronegativity is an arithmetic sum of the energies of ionization and affinity to electron. The metalloid properties in a given element with higher electronegativity are more pronounced, while the metallic properties manifest themselves more at a lower electronegativity. The high electric strength of electronegative gases is due to the ability of the molecules of these gases to combine easily with free electrons

**Figure 2.** An assembly of spherical and cylindrical electrode geometry.

Figure 3. A two-spherical electrode assembly.

or to absorb part of the energy of the electrons colliding with them. Table 2 illustrates some of these properties.

ELECTRODE GEOMETRY USED FOR MEASUREMENTS

The value of electric strength is, in general, influenced by the shape of the electrode. If the measurement conditions are unknown, the specified value of electric strength will have very little practical importance. In that case, the designer must measure it before proceeding with the design. A commonly used electrode system is depicted in Fig. 2. Here, a cylindrical electrode is used as ground while the high voltage is applied through a spherical electrode that is placed over a recessed section of the sample-under-test. Conducting paint or an evaporated metallic film that extends over the normal thickness facilitates the contacts between the electrode and the specimen. Depending on the chemical compatibility, mineral or synthetic oils are used as the immersing medium to control the flashover and corona discharge along an external path. The spherical electrode can be rotated after each breakdown to avoid subsequent breakdown originating from the previously pitted electrode surface. If both electrodes are spherical, then their alignment may become a problem. This can be circumvented by the use of a translucent polymethyl methacrylate (PMMA) disk that has a cylindrical hole with a diameter equal to that of the spherical electrodes, as shown in Fig. 3. The sample-under-test is in the form of a disk without recessed surfaces. It is in contact with the spherical electrodes that together with the specimen are embedded in epoxy resin. This kind of system is preferred for precise measurement of electric strength. Various kinds of cylindrical disk

Figure 4. A direct voltage test arrangement for specimen.

Figure 5. An alternating voltage test arrangement.

electrodes have also been used for routine measurement (2,3). However, those are not described here for the sake of brevity.

TEST APPARATUS

The test circuit requires a means to generate a controlled high voltage. In case of a direct voltage testing, the polarity of applied voltage may be another parameter that needs to be taken into account. Figure 4 shows a test circuit that employs the voltage multiplication to generate high dc from an ac source. A voltmeter connected via a voltage divider circuit monitors the voltage applied to electrodes. The purpose of resistor R is to limit the current at breakdown. It should not have too large a value that can produce large voltage drop. Separate circuits generate the positive and negative voltages.

A low-frequency (up to a few kilohertz) alternating voltage test circuit is illustrated in Fig. 5. An oscillator that feeds the primary side of a transformer via the power amplifier generates the desired frequency signal. A feedback from the transformer is used to regulate the power amplifier. The transformer output is applied to electrodes via a resistor that limits the current and protects the circuit. The detector block senses the breakdown of specimen and signals the electronic switch to interrupt the input.

When the alternating voltage has a fairly high frequency (in microwave range), the power capacity is a more significant specification than the breakdown voltage (4). However, in case of dielectric materials it is perhaps useful to convert the results to a corresponding voltage to permit correlation with data available at the lower frequency. The specimen of a specific geometry is placed inside the microwave cavity and the breakdown power is monitored.

ELECTROMAGNETIC FIELD MEASUREMENT

To establish standards for conducting electromagnetic (EM) field measurements, measurements must be made (1) in anechoic chambers, (2) at open area test sites, and (3) within guided-wave structures; and a means to transfer these measurements from one situation to another must be developed. The underlying principles of these measurement and transfer standards are: (1) measurements and (2) theoretical modeling. That is, a parameter or a set of parameters is measured, or a parameter is calculated by established physical and mathematical principles.

Various electromagnetic field sensors for measuring radio-frequency (RF) electric and magnetic fields are discussed below. For electric field measurements, electrically short dipole antennas with a high input impedance load, such as a field effect transistor (FET) and a high-frequency diode detector, are discussed. Since the input impedance of an electrically short dipole antenna is predominantly a capacitive reactance, very broadband frequency responses can be achieved with a high impedance capacitive load. However, because conventional dipole antennas support a standing wave current distribution, the useful frequency range of these dipole antennas is usually limited by their natural resonant frequencies. In order to suppress these resonances, a resistively loaded dipole antenna has been developed. To obtain a standard antenna with increased sensitivity at a specific frequency, a half-wave tuned dipole antenna with a diode is used, to measure the induced open circuit voltage. Also used was a tuned receiver with a half-wave tuned dipole antenna, to further improve antenna sensitivity.

For magnetic field measurements, this article discusses an electrically small, resistively loaded loop antenna to achieve a broadband response. Resistive loading is achieved either with the loading resistance at the loop terminal, or by uniform resistive loading along the loop antenna. This short-circuit current loop configuration gives a very flat frequency response over a wide frequency range.

In the region near a transmitting antenna or a scatterer, the electric and magnetic field vectors are not necessarily (spatially) orthogonal or in phase. For time-harmonic fields, the end points of the field vectors trace out polarization ellipses, and the Poynting vectors lie on the surface of a cone with its end point on an ellipse. In these cases, the electric and magnetic fields may be measured separately or, using the single-loop antenna element described in this article, they may be measured simultaneously.

Photonic sensors are also discussed; they provide the wide bandwidth and low dispersion necessary to maintain the fidelity of time-domain signals. Since they consist of electro-optic modulators and optical fibers, they are free from

electromagnetic interference, and there is minimal perturbation of the field being measured.

Throughout the discussion, the interplay between measured quantities and predicted (modeled) quantities is emphasized. The ability of measurements and the restrictions imposed by rigorous theoretical analysis of given models are discussed for the frequencies from 10 kHz to 40 GHz and upward.

ELECTRIC FIELD SENSORS

An Electrically Short Dipole Antenna with a Capacitive Load

Most electric field sensors consist of dipole antennas. The induced open circuit voltage V_{oc} at the dipole antenna terminal is given by

$$V_{oc} = E_{inc} L_{eff} \quad (1)$$

where E_{inc} is the normal incident electric field strength and L_{eff} is the effective length of the dipole antenna. For an electrically short dipole antenna whose physical length is much shorter than the wavelength, the effective length L_{eff} and driving point capacitance C_a are approximately (1)

$$L_{eff} = \frac{L(\Omega - 1)}{4(\Omega - 2 - \ln 4)} \quad (2)$$

and

$$C_a = \frac{4\pi\epsilon_0 L}{2(\Omega - 2 - \ln 4)} \quad (3)$$

where L is the physical length of the dipole antenna, ϵ_0 is the free space permittivity, Ω is the antenna thickness factor $\Omega = 2 \ln (L/a)$, and a is the antenna radius.

For an electrically short dipole antenna with a capacitive load C , the transfer function is given by (1)

$$S(f) = \frac{V_o(f)}{E_{inc}(f)} = \frac{h\kappa/2}{1 + C/C_a} \quad (4)$$

where

$$C_a = \frac{4\pi h}{c\zeta_0(\Omega - 2 - \ln 4)} \quad (5)$$

$$\kappa = \frac{\Omega - 1}{\Omega - 2 + \ln 4} \quad (6)$$

where

- a = antenna radius
- C = capacitance of load
- C_a = capacitance of antenna
- E_{inc} = incident electric field
- h = half of the physical length of the dipole antenna
- V_o = output voltage of the antenna
- ζ_0 = free space impedance
- c = speed of light in free space
- Ω = antenna thickness factor, $\Omega = 2 \ln (2 h/a)$

Since the input impedance of an electrically short dipole antenna is almost purely capacitive, it is possible to achieve

Figure 1. Thevenin's equivalent circuit of an electrically short dipole antenna with a shunt diode detector.

a frequency independent transfer function with a capacitive load, as indicated in Eq. (4). In practice, the load impedance is seldom purely capacitive, but also may have a resistive component. This resistive component will cause a 6 dB per octave roll-off at the low end of the frequency range.

An Electrically Short Dipole Antenna with a Diode

A common standard sensor used for EM field measurements is an electrically short dipole antenna with a diode load connected to a dc metering unit by an RF filter transmission line. The main advantage of including a diode is to make the frequency response of the sensor very flat, even at higher frequencies where an FET amplifier is not readily available. When used with a high-input impedance detector, the sensor can serve as a portable and compact transfer standard.

Figure 1 represents a dipole antenna, which can be used to determine the signal from the transmission line for a given incident electric field (2). This circuit is valid for the frequency range to be considered (dc and $f > 1$ MHz). In Fig. 1, the small antenna resistance has been neglected. The stray gap capacitance of the filter line from the antenna terminal connections has been included in the effective shunt capacitance C_d . The antenna capacitance is given by C_a .

When a first-order, nonlinear differential equation associated with the Thevenin's equivalent nonlinear circuit (shown in Fig. 1) is solved for the detected dc voltage V_o , for a small induced RF voltage V_i (2)

$$V_o = -\frac{\alpha}{4} \left(\frac{V_i}{1 + C_d/C_a} \right)^2 \quad (7)$$

where α ($\simeq 38 \text{ V}^{-1}$) is derived from the diode characteristics, while for large V_i

$$V_o \simeq -\frac{V_i}{1 + C_d/C_a} \quad (8)$$

Equation (7) indicates that for a small induced RF voltage V_i , the output dc voltage V_o is a square law function of the induced voltage. On the other hand, Eq. (8) indicates that, for a large induced voltage V_i , the output dc voltage V_o is directly proportional to the induced voltage.

A Resistively Loaded Dipole Antenna with a Diode

A conventional dipole antenna essentially supports a standing wave current distribution and is, therefore, highly frequency sensitive. For the antenna to have a flat frequency response beyond any natural resonant frequency, a traveling wave dipole antenna was realized by use of continuously tapered resistive

loading (3,4). If the internal impedance per unit length $Z^i(z)$ as a function of the axial coordinate z is expressed as

$$Z^i(z) = \frac{60\Psi}{h - |z|} \quad (9)$$

then the current distribution $I_z(z)$ along the linear antenna is that of a traveling wave

$$I_z(z) = \frac{V_i}{60\Psi(1 - j/kh)} \left[1 - \frac{|z|}{h} \right] e^{-jk|z|} \quad (10)$$

where $2h$ is the dipole antenna's total physical length, k is the wavenumber, V_i is the driving voltage, and Ψ is given by

$$\Psi = 2 \left[\sinh^{-1} \frac{h}{a} - C(2ka, 2kh) - jS(2ka, 2kh) \right] + \frac{j}{kh} (1 - e^{-j2kh}) \quad (11)$$

where a is the radius of the dipole, and $C(x, y)$ and $S(x, y)$ are the generalized cosine and sine integrals. The main advantage of a resistively loaded dipole antenna with a diode is the very flat frequency response of the sensor system. A shortcoming of this sensor system is the relatively low sensitivity. To overcome this problem, a standard half-wave tuned dipole antenna should be used.

A Tuned Half-Wave Dipole Antenna

The magnitude of the electric field component at a given point in an electromagnetic field is determined from the open circuit voltage V_{oc} induced in a standard half-wave receiving dipole antenna as obtained from Eq. (1). The induced voltage is measured across the center gap of the dipole antenna, which is oriented parallel to the electric field vector of the incident field.

The RF voltage induced in the half-wave standard dipole antenna is rectified by a high impedance Schottky barrier diode connected in shunt across the center gap of the antenna. The diode output is filtered by a balanced RC network, and this dc voltage is measured with a high impedance dc voltmeter.

The effective length h_e of a thin dipole antenna near resonance and the required total length L for resonance are given by (1)

$$h_e = \frac{\lambda}{\pi} \tan \left(\frac{\pi h}{\lambda} \right) \quad (12)$$

and

$$L = (\lambda/2) \left[1 - \frac{0.2257}{\ln(\lambda/D) - 1} \right] \quad (13)$$

where D is the diameter of the standard dipole antenna.

To further increase the sensitivity of a standard antenna, a half-wave tuned dipole antenna with a narrow band receiver should be used. In this case, the transfer function $S(f)$ is given by

$$S(f) = \frac{V_L(f)}{E_{inc}(f)} = \frac{h_e Z_a}{Z_a + Z_r} \quad (14)$$

where V_L is the voltage across the receiver load, E_{inc} is the

incident electric field, h_e is the effective length of the tuned dipole, Z_a is the antenna impedance, and Z_r is the receiver input impedance ($\sim 50 \Omega$). The input impedance of the antenna Z_a is complicated and is given in (1). When the cable losses are significant, they should be included in Z_a .

MAGNETIC FIELD SENSORS

An Electrically Small Loop Antenna with a Loading Resistance

A magnetic field sensor consists of an electrically small, balanced loop antenna. The voltage V_i induced in an electrically small loop antenna by an electromagnetic wave incident on the loop antenna is determined from Maxwell's equations and Stokes's theorem, and is given by (1)

$$V_i = \int E_i dl = j\omega\mu H_i NS \quad (15)$$

where E_i is the tangential electric field induced around the loop antenna, l is the circumference of the loop antenna, ω is the angular frequency of E_i , μ is the permeability of the loop antenna core, H_i is the component of the magnetic field normal to the plane of the loop antenna, N is the number of loop antenna turns, and S is the area of the loop antenna. The induced voltage V_i of an electrically small loop antenna is proportional to frequency, the number of loop turns, and the area of the loop antenna.

To make the response of a loop antenna flat over the frequency range of interest, the Q of the antenna has to be reduced through a loading resistance. The resonance of a loop antenna is the result of the combined effect of the distributed capacitance of the loop antenna, the gap capacitance, and the capacitance of the amplifier along with the inductance of the loop antenna. The equivalent circuit for an electrically small loop antenna is shown in Fig. 2. Here V_i is the induced voltage, L is the loop inductance, C is the capacitance, R is the loading resistance, and V_o is the voltage across the loading resistance. Then the response of an electrically small loop antenna is given by (1)

$$\frac{V_o}{V_i} = \frac{-j\frac{1}{\delta}}{\frac{1}{Q} + j\left(\delta - \frac{1}{\delta}\right)} \quad (16)$$

where

$$Q = \frac{R}{X_0}, \quad X_0 = \omega_0 L = \frac{1}{\omega_0 C}, \quad \delta = \frac{\omega}{\omega_0}, \quad \omega_0 = \frac{1}{\sqrt{LC}} \quad (17)$$

Figure 2. Thevenin's equivalent circuit of an electrically small loop antenna with a loading resistance.

The inductance L and the capacitance C of a loop antenna can be given by

$$L = \mu b \ln\left(\frac{b}{a}\right) \quad (18)$$

and

$$C = \frac{2\epsilon b}{\ln\left(\frac{b}{a}\right)} \quad (19)$$

where μ is the permeability of the medium, b is the loop antenna radius, and a is the radius of the loop wire.

The transfer function of $S(f)$ of an electrically small loop antenna can be obtained by combining Eqs. (15) and (16).

$$S(f) = \frac{V_o}{H_i} = \omega_0 \mu NS \frac{1}{\frac{1}{Q} + j\left(\delta - \frac{1}{\delta}\right)} \quad (20)$$

The normalized transfer function $S_n(f)$ of a loop antenna with a loading resistor is given by

$$S_n(f) = \frac{1}{\frac{1}{Q} + j\left(\delta - \frac{1}{\delta}\right)} \quad (21)$$

as a function of the normalized frequency $\delta = \omega/\omega_0$ and is given in Fig. 3 for various $Q < 1$. Figure 3 shows that the upper frequency end ω_h of the 3 dB roll-off point is given by $\delta_h Q = 1$ and, similarly, the corresponding low frequency ω_l of the 3 dB roll-off point is given by $\delta_l/Q = 1$. Thus, from these conditions,

$$\delta_h \delta_l = \frac{\omega_h \omega_l}{\omega_0^2} = 1 \quad (22)$$

or

$$\omega_0 = \sqrt{\omega_h \omega_l} \quad (23)$$

The self-resonant frequency of a loop antenna is therefore the geometrical mean of the highest and lowest cutoff frequencies.

AN ELECTROMAGNETIC FIELD SENSOR FOR SIMULTANEOUS ELECTRIC AND MAGNETIC FIELD MEASUREMENTS

The electric and magnetic field sensors discussed above measure either the electric or magnetic field only and, therefore, cannot measure complicated EM fields such as those with reactive near field components and multipath reflections. For this reason, a single sensor capable of performing simultaneous electric and magnetic field measurements was developed (5,6). In this case, a loop antenna is loaded at diametrically opposite points with equal impedances. Across one load, the magnetic loop response adds to the electric dipole response, whereas across the other load, the magnetic loop response subtracts from the electric dipole response. Thus, by taking the sum and difference of currents across loads at diametrically opposite points, the magnetic loop response and electric dipole response can be separated. That is, the sum current gives a

Figure 3. The normalized transfer function of a loop antenna as a function of normalized frequency for different values of Q .

measure of the magnetic field, whereas the difference current gives a measure of the electric field.

To explain the basic characteristics of a doubly loaded loop antenna, the currents I_1 and I_2 at each load are given by (5)

$$I_1 = 2\pi b E_{\text{inc}} \left(\frac{f_0 Y_0}{1 + 2Y_0 Z_L} + \frac{f_1 Y_1}{1 + 2Y_1 Z_L} \right) \quad (24)$$

and

$$I_2 = 2\pi b E_{\text{inc}} \left(\frac{f_0 Y_0}{1 + 2Y_0 Z_L} - \frac{f_1 Y_1}{1 + 2Y_1 Z_L} \right) \quad (25)$$

where b is the radius of the loop, E_{inc} is the incident electric field, Z_L is the load impedance, Y_0 is the admittance for the magnetic loop response, and Y_1 is the admittance for the electric dipole antenna response of a loop. In general, Y_0 is much larger than

Y_1 . f_0 and f_1 are Fourier coefficients of the incident wave. For a loop antenna orientation of maximum electric and magnetic field response, $f_0 = j\beta b/2$ and $f_1 = 1/2$. Taking the sum and difference of these currents yields (5)

$$I_{\Sigma} = \frac{1}{2} (I_1 + I_2) = 2\pi b E_{\text{inc}} \frac{f_0 Y_0}{1 + 2Y_0 Z_L} \quad (26)$$

and

$$I_{\Delta} = \frac{1}{2} (I_1 - I_2) = 2\pi b E_{\text{inc}} \frac{f_1 Y_1}{1 + 2Y_1 Z_L} \quad (27)$$

This indicates that the sum current can be used to measure the magnetic field and the difference current can be used to measure the electric field. In general, $2Y_0 Z_L > 1$ for the magnetic field loop antenna current. Therefore, when the antenna

Figure 4. Measurement system of a photonic EM field sensor.

is oriented for maximum response, I_{Σ} can be approximated as

$$I_{\Sigma} \cong j \frac{E_{\text{inc}}}{2Z_L} \pi b^2 \beta \quad (28)$$

This indicates that the magnetic loop current is approximately proportional to the product of frequency and the area of the loop antenna, and is inversely proportional to the load impedance. Similarly, for the electric field dipole current, assuming that $2Y_1 Z_L \ll 1$,

$$I_{\Delta} \cong \pi b E_{\text{inc}} Y_1 \quad (29)$$

which is approximately proportional to the product of the circumference of the loop antenna and frequency, since Y_1 has a capacitive susceptance (positive) and increases with frequency. This device is intended not only to measure the polarization ellipses of the electric and magnetic field vectors in the near field region, but also to measure the time-dependent Poynting vector and thus describe the energy flow.

PHOTONIC ELECTROMAGNETIC FIELD SENSORS

Properly designed photonic EM field sensors provide the wide bandwidth and low dispersion necessary to maintain the fidelity of time-domain signals so that both amplitude and phase information can be retrieved (7). They are free from electro-

magnetic interference, and there is minimal perturbation of the field being measured.

A number of photonic passive sensors for EM field measurements have been reported in the literature (7). These are systems in which the sensor head contains no active electronics or power supplies. Optical measurement systems of the typical photonic EM field sensors is shown schematically in Fig. 4. Light from a laser is launched into an optical fiber link and serves as an optical signal carrier. At the sensor head, the EM field induces a voltage across the modulator crystal and changes its index of refraction. The crystal index changes occur at the frequency of the impressed EM field and result in a modulation in the amplitude of the optical carrier. At the receiver end of the fiber the light is converted to an electrical signal by a photodiode and is suitably amplified for analysis with a spectrum analyzer, oscilloscope, or other signal processor. The electro-optic interaction is weak, and, except for very high fields, the gain of a small antenna is usually required to obtain adequate modulation.

For the measurement of a pulsed electric field, an antenna with a flat broadband response is most desirable. A resistively loaded dipole antenna gives a nonresonant frequency response and is, therefore, ideal for use in the time-domain measurement of electromagnetic fields (3,4). Electro-optical modulators that are driven by antenna feeds are characterized as a function of the voltage applied to their electrodes. A convenient parameter for characterizing a modulator's performance is the voltage V_{π} that is needed across the electrode to drive a modulator

Table 1. Transfer Functions for Electro-Optic Modulators

Modulator	General	Small Signal
Pockels Cell	$\cos^2\left(\frac{\pi}{2}V_n + \frac{\phi_0}{2}\right)$	$\frac{\pi}{2V_\pi}$
Mach-Zehnder	$\cos^2\left(\frac{\pi}{2}V_n + \frac{\phi_0}{2}\right)$	$\frac{\pi}{2V_\pi}$
4-Port Coupler	$\frac{1}{1+3V_n^2}\sin^2\left(\frac{\pi}{2}\sqrt{1+3V_n^2}\right)$	$\approx \frac{1.6}{V_\pi}$
3-Port Coupler	$\frac{1}{2} - \frac{2V_n}{1+4V_n^2}\sin\left(\frac{\pi}{2\sqrt{2}}\sqrt{1+4V_n^2}\right)$	$\frac{2}{V_\pi}\sin\frac{\pi}{2\sqrt{2}} = \frac{1.79}{V_\pi}$

between maximum and minimum optical power levels. In general, a modulator transfer function is nonlinear. However, in most cases of interest, the field-induced RF voltages on the modulator's electrodes are small compared to V_π , and a small signal linear transfer function evaluated at the operating bias point is appropriate. The most desirable operating bias point is where the modulator's sensitivity and linear range are at maximum. The physical characteristics of four modulators used in photonic EM field sensors are given in Table 1.

Pockels Cell

Pockels cell modulators often are used in EM field sensors. The small signal transfer function takes the form given in Table 1, when the constant phase shift Φ_0 is set equal to $-\pi/2$ by introducing a quarter wave retardation plate into the cell. This biases the modulator at its point of maximum sensitivity and linearity. The characteristic voltage of a bulk crystal modulator is limited by (1) the magnitude of the electro-optic coefficients for available materials, (2) the minimum dimensions of crystals that can be handled as discrete optical elements, and (3) the maximum crystals lengths acceptable for the highest desired operating frequency. For operation to 5 GHz, the lowest obtainable values for V_π are on the order of 100 V for LiNbO_3 . It is relatively easy to increase V_π and reduce the modulator's sensitivity in order to measure high fields. In one application of this technology for measuring fields from electromagnetic pulses, a crystal of $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ (BGO), which has cubic symmetry and reduced temperature sensitivity, is used in a Pockels cell modulator and has a V_π of approximately 2100 V.

Mach-Zehnder Interferometer

Modulators based on Mach-Zehnder (MZ) interferometers and fabricated using optical guided wave (OGW) technologies have found widespread use in the fiber optics communications industry. Their use as EM field sensors also has been investigated (7). Photolithography is used to fabricate OGW modulators by defining the waveguide channels and then diffusing titanium into the surface of a LiNbO_3 crystal along these channels. The transfer function for an MZ interferometer is identical to that of the Pockels cell. The static phase shift Φ_0 is due to differences in the optical path length in the interferometer arms. Significantly, V_π for this device is typically two orders of magnitude smaller than that for a Pockels cell modulator of the same material and frequency response. The higher sensitivity is typical of most OGW modulators and arises from the higher fields created in the crystal with the closely spaced electrodes that are

achievable using photo lithography. The principal problems to date with the MZ interferometer have been the difficulty in obtaining the correct value for Φ_0 during fabrication, and its temperature and wavelength dependence.

Directional Coupler

Directional couplers are also OGW devices that have been investigated for use as EM field sensors (7). In the interaction region, the two waveguides lie close enough together that the evanescent field of the lightwave in one guide couples into the other guide. In such a coupled-mode system, the energy in one lightguide can be switched to the other guide by changing the relative propagation constants in the channels with the electro-optic effect. If the fabrication parameters are chosen correctly, the transfer function given in the literature (7) for the directional coupler can be written in the form given in Table 1.

ELECTROMAGNETIC FIELD STANDARDS

Transverse Electromagnetic Cell

Transverse electromagnetic (TEM) transmission line cells are devices used for establishing standard EM fields in a shielded environment (8). Their application is becoming increasingly widespread because of their versatility, measurement accuracy, and ease of operation.

A TEM cell is essentially a 50 Ω triplate transmission line with the sides closed in, to prevent radiation of RF energy into the environment and to provide electrical isolation. A properly designed cell, terminated in its characteristic impedance, is capable of producing a calculable electric and magnetic field for calibrating an electrically small antenna or RF sensor. The cell consists of a section of rectangular coaxial transmission line tapered at each end to adapt to standard coaxial connectors. The line and tapered transitions are designed to have a nominal characteristic impedance of 50 Ω along their length, to ensure minimum voltage standing wave ratio. A fairly uniform EM field is established between the plates inside the cell when RF energy is conducted in the line from a transmitter connected to the cell's input port. A 50 Ω termination is connected to the cell's output port. The expression for determining the electric field E in the cell is given by

$$E = \frac{V}{b} = \frac{\sqrt{PZ_0}}{b} \quad (30)$$

where V is the rms voltage on the septum (center conductor), b is the separation distance between the septum and lower or

Figure 5. Cross-sectional view of a TEM cell.

upper walls, P is the net power flow to the cell and Z_0 is the real part of the cell's characteristic impedance $\cong 50 \Omega$.

A wave traveling through a cell has essentially the free space impedance ($\cong 120\pi \Omega$), thus providing a close approximation to a far-field plane wave propagating in free space. The design of TEM cells can be based on an approximate equation for the characteristic impedance of a rectangular transmission line (8)

$$Z_0 \cong \frac{377}{4} \left\{ \left[\frac{p}{q} - \frac{2}{\pi} \ln \left(\sinh \frac{\pi g}{2q} \right) \right] - \frac{\Delta c}{\epsilon_0} \right\}^{-1} \quad (31)$$

where p , q , and g are shown in Fig. 5, and $\Delta c/\epsilon_0$ is related to the fringing capacitance between the edges of the septum and the side walls. For large gaps ($g/p > 0.2$) this fringing term approaches zero (8).

The upper useful frequency for a cell is limited by distortion in the test field caused by multimoding and resonances that occur within the cell at frequencies above the cell's multimode cut off. Resonant frequencies associated with these modes can be found from the expression (8)

$$F_{\text{res}} = \sqrt{f_{mn}^2 + \left(\frac{c\ell}{2L} \right)^2} \quad (32)$$

where f_{mn} are the frequencies of the higher-order mode(s) excited inside the cell, c is the wave propagation velocity ($\cong 3.0 \times 10^8$ m/s), L is the resonant length of the cell in meters, and ℓ , m , and n are integers corresponding to multiples of the resonant length and the particular waveguide mode. The influence of the first-order TE modes does not become significant until approaching their resonances. Since most cells are designed with the center plate (septum) centered symmetrically, the odd-order TE modes are not excited in an empty cell. The presence of a device placed in the cell will, however, excite these modes in varying degrees, depending on its size, shape, and placement.

Waveguide Chamber

For the frequency range of 300 MHz to 1000 MHz, one can use a waveguide section with a rectangular cross-section with a width-to-height (aspect) ratio of two to one. The length of a guide "cell" must exceed two wavelengths over the specified frequency band, in order to create a fairly uniform field within the guide. Electromagnetic power is transmitted through the

guide to a matched resistive load, and the maximum frequency is limited by the requirement that power propagates in the guide in the dominant TE_{10} mode. In this well-known case, the direction of the electric field vector is across the narrow face of the guide.

Assuming good conductivity of the waveguide walls, an air dielectric, and sinusoidal excitation, the lowest cutoff frequency f_{co} is

$$f_{\text{co}} = \frac{c}{2a} \quad (33)$$

where c is the wave propagation velocity ($\cong 3.0 \times 10^8$ m/s) and a is the guide width.

The longest or cutoff wavelength is given by $\lambda_{\text{co}} = 2a$. The wavelength λ_{wg} inside the guide for these operating conditions is

$$\frac{1}{\lambda_{\text{wg}}} = \sqrt{\left(\frac{1}{\lambda_0} \right)^2 - \left(\frac{1}{\lambda_{\text{co}}} \right)^2} \quad (34)$$

where λ_0 is the free space wavelength.

The transverse impedance Z_w of the wave traveling in the guide is

$$Z_w = \frac{-E_y}{H_z} = \zeta_0 \left(\frac{\lambda_{\text{wg}}}{\lambda_0} \right) = \frac{\zeta_0}{\sqrt{1 - (\lambda_0/2a)^2}} \quad (35)$$

where ζ_0 is the intrinsic impedance of free space ($\cong 120\pi$).

The direction of the electric field vector is across the narrow face of the guide, and its rms magnitude at the center of a rectangular waveguide is given by

$$E = \sqrt{\frac{2Z_w P_z}{ab}} \quad (36)$$

and, similarly, the rms magnitude of the magnetic field in the guide center is given by

$$H = \sqrt{\frac{2P_z}{Z_w ab}} \quad (37)$$

where P_z is the total power flow in the guide, and ab is the cross-sectional area of the waveguide ($= 0.5 a^2$).

Microwave Anechoic Chambers

Microwave anechoic chambers currently are used for a variety of indoor antenna measurements, electromagnetic field measurements, electromagnetic interference (EMI) measurements, and electromagnetic compatibility (EMC) measurements. The primary requirement is that a transmitting antenna at one location within a chamber or at a chamber wall generates a known field throughout a volume of the chamber, which has dimensions sufficient to perform EM field measurements. This volume is frequently called a *quiet zone*, and the level of reflected waves within it will determine the performance of the anechoic chamber.

Electromagnetic field measurements in an anechoic chamber usually are performed in the near-field region of a transmitting standard antenna. To establish the standard field, the

radiated field intensity in the near-field region of the transmitting antenna is calculated. The antennas typically used for the anechoic chamber measurements consist of a series of open-ended waveguides at frequencies below 450 MHz, and a series of rectangular pyramidal horn antennas at frequencies above 450 MHz.

The electric field strength at a specific distance from the radiating antenna is calculated from measurements of the power delivered to the transmitting antenna and a knowledge of the gain of the antenna as a function of frequency and distance to the field point. The equation used to calculate the electric field E on the boresight axis of the transmitting antenna is

$$E = \frac{1}{d} \sqrt{\frac{\zeta_0 P_{\text{net}} G}{4\pi}} \cong \frac{\sqrt{30 P_{\text{net}} G}}{d} \quad (38)$$

where P_{net} is the net power delivered to the transmitting antenna, ζ_0 is the free space impedance ($\cong 120\pi \Omega$), G is the near-field gain of the transmitting antenna at the given frequency and distance, and d is the distance from the center of the aperture of the transmitting antenna (horn or open-ended waveguide) to the on-axis field point.

The net power P_{net} delivered to the transmitting antenna is the difference between the incident P_{inc} and reflected P_{refl} powers as measured with a calibrated directional coupler (4 ports) with calibrated power meters. In order for measurements to be accurate, an anechoic chamber must provide a truly free space test environment. The performance of a rectangular RF anechoic chamber can be determined by measuring the relative insertion loss versus separation distance between a source antenna and a receiving antenna.

Antenna insertion loss is the ratio of power received by a receiving antenna or probe to the power accepted by the transmitting antenna. If the anechoic chamber is a perfect free-space simulator, the relative insertion loss between two polarization-matched antennas will vary with distance according to the Friis transmission formula (9)

$$P_r/P_t = G_r G_t (\lambda/4\pi d)^2 \quad (39)$$

where P_t is the net power delivered to the transmitting antenna, P_r is the power received by the receiving antenna, G_t is the near-field gain of the transmitting antenna, G_r is the near-field gain of the receiving antenna, d is the separation distance between the two antennas, and λ is the wavelength. Experimental data can be compared with the calculated free space transmission loss, using appropriate near-field transmitting antenna gains. The difference between the measured and calculated transmission loss is a measure of reflections from chamber surfaces.

Open Area Test Sites

An open area test site typically is used for the antenna calibration in the frequency range of 10 kHz to 1000 MHz. A calibration consists of determining the antenna factor that permits a receiver (RF voltmeter) to be used with the calibrated antenna to conduct measurements of field strength.

At frequencies below about 50 MHz, loop antennas are calibrated in a quasi-static, near-zone, magnetic field produced by a balanced single turn transmitting loop with a 10 cm radius. Above 25 MHz, dipole antennas are calibrated in a far-zone

electric field, which is evaluated in terms of the open circuit voltage induced in a self-resonant receiving dipole antenna. Between 30 kHz and 300 MHz, vertical monopole antennas and small probes are evaluated in an elliptically polarized electromagnetic field produced by a transmitting monopole antenna above a conducting ground screen.

Field strength can be evaluated using two independent techniques: (1) the standard field method, and (2) the standard antenna method. For the standard field method, a transmitted field is calculated in terms of the type and dimensions of a transmitting antenna, its current distribution or net delivered power, the frequency of the transmitted signal, the distance from the transmitting antenna to the field point, and the effect of ground reflections (if present). For the standard antenna method, an unknown field is measured with a calculable receiving antenna. The voltage or current induced in a standard antenna by the component of field being evaluated is measured. The field strength then is calculated in terms of this induced voltage, the dimensions and form of the receiving antenna, and its orientation with respect to the field vector.

All of the techniques described above for field strength standards are applicable only to steady state RF fields with sinusoidal time variation. They are not intended for use with pulsed fields or other broadband applications.

Magnetic Field Strength Standards for Loop Antennas at 10 kHz to 50 MHz (Standard Field Method)

The response of an electrically small receiving loop antenna is proportional to the average normal component of magnetic field strength incident on the antenna. A calculable quasistatic magnetic field can be produced to calibrate these antennas using a circular single-turn balanced transmitting loop. Up to 30 MHz, the current in a loop with a 10 cm radius is approximately constant in amplitude and phase around the loop. The receiving loop antenna being calibrated is positioned on the same axis as the transmitting loop at a distance of 1.5 m to 3 m. The normal component of the magnetic field, averaged over the area of the receiving loop, is given by (10)

$$H = \frac{\beta I r_1}{r_2} \sum_{m=0}^{\infty} \frac{1}{(2m+1)!} \cdot \frac{1 \cdot 3 \dots (2m+1)}{2 \cdot 4 \dots (2m+2)} \left[\frac{\beta r_1 r_2}{R_0} \right]^{m+1} h_{2m+1}^{(2)}(\beta R_0) \quad (40)$$

where

H = rms value of the magnetic field

I = rms current in the transmitting loop

r_1 = radius of the transmitting loop

r_2 = radius of the receiving loop

$R_0 = \sqrt{d^2 + r_1^2 + r_2^2}$

d = axial distance between the two loops

$\beta = 2\pi/\lambda_0$

λ_0 = free-space wavelength

$h_n^{(2)}$ = nth order spherical Hankel function of the second kind

The current in the transmitting loop antenna is measured with a vacuum thermocouple calibrated with direct current. The thermocouple is at the top of the loop winding.

While coaxial loop antennas normally are used for calibration purposes, the two loop antennas also can be positioned in the same plane. Coplanar loop antennas are advantageous under certain conditions (e.g., with some ferrite core antennas in which the core length is large). In the coplanar loop antenna set-up, the calibrating value of H would be half of that given by Eq. (41).

The calibration and subsequent measurement of magnetic field strength H often are expressed in terms of the electric field E that would exist if the measurement were made in free space, in which case $E/H \cong 120\pi \Omega$. When such a field strength meter is used to make measurements near the ground, the indicated value of the electric field is not necessarily valid. The same is true for measurements made in the near zone of a transmitting antenna. However, the value of the magnetic component H still can be measured correctly.

For calibrating loop antennas or magnetic field sensors at a higher field, it is possible to use the calculable magnetic field generated in a TEM cell, or a waveguide chamber, or at the center of a flat multiturn coil, or at the midpoint of a Helmholtz coil pair.

Electric Field Strength Standards for Dipole Antennas from 25 MHz to 1000 MHz (Standard Antenna Method)

The magnitude of the electric field component at a given point in a locally generated field is determined from the open circuit voltage V_{oc} induced in a standard (calculable) half-wave receiving dipole antenna. The induced voltage is measured across the center gap of the dipole antenna, which is oriented parallel to the electric field vector of the incident field. In using the standard antenna method, a plane wave field can be generated by a suitable transmitting antenna, such as a log periodic or half-wave dipole antenna. The magnitude of this incident field is measured with the standard dipole antenna by the relation

$$E_{inc} = \frac{V_{oc}}{L_{eff}} \quad (41)$$

where E_{inc} is the field strength of the locally generated field, V_{oc} is the open circuit voltage induced in the standard dipole antenna, and L_{eff} is the effective length of the standard dipole antenna.

The RF voltage V_{oc} picked up by the $\lambda/2$ standard dipole is detected by a high-impedance Schottky barrier diode connected in shunt across the center gap of the antenna. The diode output is filtered by a balanced RC network, and this dc voltage is measured with a high-impedance dc voltmeter. The RF-to-dc characteristic of the dipole antenna and its filter circuit is obtained experimentally. Assuming a cosinusoidal current distribution on an infinitesimally thin dipole, the effective length of a half-wave dipole antenna in free space is given by Eq. (12).

Electric Field Strength Standards for Vertical Monopole Antennas 30 kHz to 300 MHz (Standard Field Method)

Several approaches were considered for generating a standard (calculable) field to calibrate vertically polarized antennas. The system chosen for this measurement consists of a thin cylindrical transmitting monopole antenna over a metallic ground plane. The field strength is calculated in terms of the magnitude and distribution of the monopole antenna current, and other factors such as: (1) monopole height, (2) horizontal distance

from the transmitting antenna to the field point, (3) vertical height of this point above the ground plane, and (4) electrical conductivity of the ground plane.

The height of the transmitting monopole antenna is adjustable, with a maximum height of about 3 m. The electrical height of this antenna is $\lambda/4$ (resonant) at 25 MHz, but only 0.0003λ at 30 kHz. At frequencies above 25 MHz, the antenna height is reduced to a $\lambda/4$ value. The base diameter of the monopole antenna is about 1 cm. The monopole antenna is excited through a coaxial cable from a transmitting room located beneath a concrete ground slab which is covered by a conducting metal screen to form the electrical ground plane.

Equations (42), (43), and (44) give the magnitudes of the three field components E_z , E_ρ , and H_ϕ , respectively, of a transmitting $\lambda/4$ monopole antenna above a perfect ground plane of infinite extent:

$$E_z = 30I_0 \left(\frac{e^{-j\beta r_1}}{r_1} + \frac{e^{-j\beta r_2}}{r_2} \right) \quad (42)$$

$$E_\rho = \frac{30I_0}{r_0} \left[\left(\frac{e^{-j\beta r_1}}{r_1} \right) \left(z - \frac{\lambda}{4} \right) + \left(\frac{e^{-j\beta r_2}}{r_2} \right) \left(z + \frac{\lambda}{4} \right) \right] \quad (43)$$

$$H_\phi = \frac{I_0}{4\pi r_0} (e^{-j\beta r_1} + e^{-j\beta r_2}) \quad (44)$$

where

E_z = vertical electric field component

E_ρ = horizontal electric field component

H_ϕ = magnetic field, encircling the monopole antenna

I_0 = rms base current of the monopole antenna

$\beta = 2\pi/\lambda$ = the wavelength constant

$r_1 = [d^2 + (z - l)^2]^{1/2}$

$r_2 = [d^2 + (z + l)^2]^{1/2}$

$r_0 = [d^2 + z^2]^{1/2}$

l = monopole antenna length

d = horizontal distance between the monopole antenna and the field point

z = vertical distance from the ground plane to the field point

For frequencies near self-resonance, the monopole antenna base current is measured with an RF ammeter consisting of a thermo-converter that has been calibrated with known values of dc current. At lower frequencies, where the monopole antenna input impedance Z_{in} is a high-capacitive reactance, the base current is calculated from Ohm's law in terms of the base voltage measured with a high-input impedance voltmeter and the theoretical input impedance. At very low frequencies, Z_{in} may be calculated from the antenna capacitive reactance (11).

$$Z_{in} = 1/(j\omega C_a) \quad (45)$$

where

$$C_a = \frac{5.56 \times 10^{-11} h}{\ln(h/a) - 1} \quad (46)$$

where C_a is the monopole antenna input capacitance (F), h is the monopole antenna height (m), and a is the monopole antenna radius (m).

The standard field equations are relatively simple for a ground plane with infinite extent and infinite conductivity. In addition, the current on a vertical monopole antenna with finite diameter departs from the sinusoidal current distribution of a filamentary monopole antenna. This does not seriously affect the calculated values of current-related field components, such as the magnetic field or the far-zone electric field. However, the low-frequency near-zone quasi-static electric field components are more nearly charge-related and are given by the spatial derivative of the current distribution. Hence, there is greater uncertainty in calculating the electric field components at frequencies well below that of a $\lambda/4$ -resonant monopole antenna.

If a transmitting monopole antenna is electrically short; that is, if the height is less than $\lambda/4$ and the frequency is below resonance, the current distribution is triangular. The field equations are a little more complicated; only the vertical electric field is given below (11)

$$E_z = \frac{-j30I_0}{\sin(\beta\ell)} \left[\frac{e^{-j\beta r_1}}{r_1} + \frac{e^{-j\beta r_2}}{r_2} - 2\cos(\beta\ell)e^{-j\beta r_0} \right] \quad (47)$$

The EM field values in the half space above a perfect ground are the same as those in each half volume of a center fed $\lambda/2$ dipole antenna in free space. The input impedance of a monopole antenna above perfect ground is half that of a dipole antenna in free space. The power required to generate a given field strength is half that required for a dipole antenna, but the radiated power goes into half the volume, so the field is the same. Measurements of Z_{in} with a commercial impedance meter are performed to check the theoretical values from 0.5 MHz to 50 MHz. Measurements of the monopole antenna capacitance can be made at lower frequencies with a commercial Q meter.

FUTURE DIRECTIONS

Established techniques for EM field measurements will be probably extended to higher frequencies; however, such work would not involve fundamental changes in the instrumentation or measurement strategy. The measurement methods described earlier are suitable only for (1) measuring plane-wave sinusoidal fields of a given frequency and (2) calibrating the devices that measure such fields.

The challenge of the future resides in the development of standards for measurement of fields that are nonsinusoidal and/or nonplanar. The fundamental requirement for EM field sensors is that their outputs provide amplitude and phase information simultaneously over a broad spectrum for nonsinusoidal fields. For fields containing more than one frequency component, it is clear that such simultaneous measurement is necessary. Similarly, if phase information is preserved, then measurements of single-frequency nonplanar fields can be made in terms of true energy density or in terms of the Poynting vector.

The standard techniques of today rely upon very high-resistance transmission lines to convey dc voltage and current to regions external to the field under measurement. Future standards of measurement employ optically sensed EM field sensors whose optical-sensing signal paths will not perturb the EM field under measurement, but will also convey field

amplitude and phase information to a region external to the field for measurement. Optically sensed sensors are being built today. However, additional work is needed to transform these experimental devices into stable elements for standards applications. Also, standard fields need to be developed, in order to calibrate these probes of the future.

MAGNETIC FIELD MEASUREMENT

RELEVANCE OF ELECTROMAGNETIC FIELD MEASUREMENTS

The measurement of electromagnetic (em) fields is relevant for various purposes: for scientific and technical applications, for radio propagation, for Electromagnetic Compatibility (EMC) tests (i.e. testing of the immunity of electronic equipment to electromagnetic fields and the measurement of radiated electromagnetic emissions aiming at the protection of radio reception from radio interference), and for safety reasons (i.e. the protection of persons from excessive field strengths). For radio propagation and EMC measurements, below about 30 MHz a distinction is made between electric and magnetic components of the em field to be measured. In the area of human safety, this distinction is continued to even higher frequencies.

QUANTITIES AND UNITS OF MAGNETIC FIELDS

Especially in the measurement of radio propagation and of radio interference, magnetic field measurements with loop antennas have traditionally been used to determine the received field intensity which was quantified in units of the electric field strength, i.e. in $\mu\text{V/m}$, respectively, in $\text{dB}(\mu\text{V/m})$. For radio propagation this can be justified for far field conditions where electric field strength E and magnetic field strength H are related via the impedance Z_0 of the free space; $E = HZ_0$ (see also antenna factor definition). Commercial EMC standards (1) and (2) specify radiated disturbance measurements below 30 MHz with a loop antenna; however, until 1990 measurement results and limits were expressed in $\text{dB}(\mu\text{V/m})$. Since this measurement is done at less than the far field distance from the equipment under test (EUT) over a wide frequency range, the use of units of the electric field strength was difficult to justify. Therefore, the CISPR (the International Special Committee on Radio Interference) decided in 1990 to use units of the magnetic field strength $\mu\text{A/m}$, respectively, $\text{dB}(\mu\text{A/m})$.

Guidelines and standards for human exposure to em fields specify the limits of electric and magnetic fields. In the low frequency range [i.e., below 1 MHz (3)], limits of the electric field strength are not proportional to limits of the magnetic field strength. Magnetic field limits in frequency ranges below 10 kHz are frequently expressed in units (T and G, for Tesla and Gauss) of the magnetic flux density B despite the absence of magnetic material in human tissue. Some standards specify magnetic field limits in A/m instead of T (see (4) in contrast to (5)). For easier comparison with other applications we therefore convert limits of the magnetic flux density to limits of the magnetic field strength using $H = B/\mu_0$ or $1 \text{ T} = 10^7/4\pi \text{ A/m} \approx 0.796 \cdot 10^6 \text{ A/m}$ and $1 \text{ G} = 79.6 \text{ A/m}$. At higher frequency ranges all standards specify limits of the magnetic field strength in A/m. Above 1 MHz the limits of the magnetic field strength are related to limits of the electric field strength via the impedance of the free space. Nevertheless both quantities, electric and magnetic fields, have to be measured, since in the near field the exposition to either magnetic or electric field may be dangerous.

RANGE OF MAGNETIC FIELD LEVELS TO BE CONSIDERED FOR MEASUREMENT

In order to show the extremely wide range of magnetic field levels to be measured, we give limits of some national or regional standards. In different frequency ranges and applications magnetic field strength limits vary from as much as 10 MA/m down to less than 1 nA/m (i.e. over 16 decades). This wide range of field-strength levels will normally not be covered by one magnetic field meter. Different applications require either broadband or narrowband equipment.

On the high level end there are safety levels and limits of the magnetic field strength for the protection of persons which vary from as much as 4 MA/m (i.e. $4 \times 10^6 \text{ A/m}$ corresponding to the specified magnetic flux density of 5 T in nonferrous material) at frequencies below 0.1 Hz, to less than 0.1 A/m at frequencies above 10 MHz (see Fig. 1) (3–6). These limits of the magnetic field strength are derived from basic limits of the induced body current density (up to 10 MHz), respectively, basic limits of the specific absorption rate (SAR, above 10 MHz). There are also

Figure 1. Safety limits of the magnetic field strength derived from the European Prestandard ENV 50166 Parts 1 and 2: 120 dB(A/m) are equivalent to 1 MA/m corresponding to 1.25 T, 0 dB(A/m) are equivalent to 1 A/m.

derived limits of the electric field strength which are however not of concern here.

By using an approach different from the one of the safety standards, the Swedish standard MPR II, which has become an international de-facto standard for video display units (VDU) without scientific proof, specifies limits of the magnetic flux density in two frequency ranges, which are bounded by filters: a limit of 40 nT ($\approx 0.032 \text{ A/m}$) in the range 5 Hz to 2 kHz and a limit of 5 nT ($\approx 0.004 \text{ A/m}$) in the range 2 kHz to 400 kHz.

On the low level end there are limits for the protection of radio reception and electromagnetic compatibility in some military standards (see Figs. 2 and 3).

International and national monitoring of radio signals and the measurement of propagation characteristics require the measurement of low-level magnetic fields down to the order of $-30 \text{ dB}(\mu\text{A/m})$; see also subsequent discussions and refs. 7–9. For the protection of radio reception, international, regional (e.g. European) and national radiated emission limits and

Figure 2. Magnetic field strength limits derived from US MIL-STD-461D RE101 (Navy only) (7). These limits are originally given in dB(pT) (decibels above 1 pT). The measurement procedure requires a 36 turn shielded loop antenna with a diameter of 13.3 cm. Measurement distance is 7 cm for the upper limit and 50 cm for the lower limit.

Figure 3. Narrowband emission limits of the magnetic field strength derived from the German military standard VG 95343 Part 22 (8). This standard gives the limits of $H \cdot Z_0$ in $\text{dB}(\mu\text{V}/\text{m})$ of four equipment classes, the emissions have to be measured with a loop antenna calibrated in $\text{dB}(\mu\text{V}/\text{m})$ in the near field of the equipment under test (EUT). Therefore, the limits have been converted into $\text{dB}(\mu\text{A}/\text{m})$. The lower limit is Class 1, the upper is Class 4.

measurement procedures have been standardized for industrial, scientific, medical (ISM) and other equipment (1,2,10–12). An example is given in Fig. 4.

Radiated emission limits of fluorescent lamps and luminaires are specified in a $\text{dB}(\mu\text{A})$ using a large-loop-antenna system (LAS) (10). For further information, see the text below.

EQUIPMENT FOR MAGNETIC FIELD MEASUREMENTS

Magnetic Field Sensors Other Than Loop Antennas

An excellent overview of magnetic field sensors other than loop antennas is given in Ref. 13. Table 1 lists the different types of

Figure 4. Radiated emission limits for navigational receivers according to draft revision IEC 945 (IEC 80/124/FDIS), originally given in $\text{dB}(\mu\text{V}/\text{m})$, for the purpose of this article converted into $\text{dB}(\mu\text{A}/\text{m})$.

field sensors which are exploiting different physical principles of operation.

Magnetic Field-Strength Meters With Loop Antennas

Especially for the measurement of radio wave propagation and radiated electromagnetic disturbance pick-up devices, the antennas become larger and therefore they are used separate from the indicating instrument (see Fig. 5). The instrument is a selective voltmeter, a measuring receiver or a spectrum analyzer. The sensitivity pattern of a loop antenna can be represented by the surface of two spheres (see Figs. 6 and 7). In order to determine the maximum field strength, the loop antenna has to be turned into the direction of maximum sensitivity.

To obtain an isotropic field sensor, three loops have to be combined in such a way that the three orthogonal components

Table 1. Overview over Different Magnetic Field Sensors, their Underlying Physical Effects, their Applicable Level, and Frequency Ranges from Ref. 73. For Easier Comparison with the Rest of the Text, the Values of Ref. 73 Have Been Converted from G into A/m

Type	Principle of Operation	Level of Operation	Frequency Range
Search-coil magnetometer	Faraday's law of induction	10^{-6} to 10^9 A/m	1 Hz to 1 MHz
Flux-gate magnetometer	Induction law with hysteresis of magnetic material	10^{-4} to 10^4 A/m	dc to 10 kHz
Optically pumped magnetometer	Zeeman effect: splitting of spectral lines of atoms	10^{-6} to 10^2 A/m	dc
Nuclear-precession magnetometer	Response of nuclei of atoms to a magnetic field	10^{-5} to 10^2 A/m	dc (upper frequency limited by gating frequency of hydrocarbon fluid)
SQUID magnetometer	Superconducting quantum interference device	10^{-8} to 10^{-2} A/m; speciality: differential field measurements	dc
Hall-effect sensor	Hall effect	10^{-1} to 10^5 A/m	dc to 1 MHz
Magnetoresistive magnetometer	Magnetoresistive effect	10^{-4} to 10^4 A/m	dc to 1 GHz
Magnetodiode	Semiconductor diode with undoped silicon	10^{-2} to 10^3 A/m	dc to 1 MHz
Magnetotransistor	Hall and Suhl effects	10^{-3} to 10^3 A/m	dc to 1 MHz
Fiberoptic magnetometer	Mach-Zehnder interferometer	10^{-7} to 10^3 A/m	dc to 60 kHz
Magneto-optical sensor	Faraday polarization effect	10^2 to 10^9 A/m	dc to 1 GHz

Figure 5. Magnetic field strength measuring loop. The network may consist of a passive or active circuit.

of the magnetic field H_x , H_y and H_z are combined to fulfill the equation

$$H = \sqrt{H_x^2 + H_y^2 + H_z^2}$$

Isotropic performance is however only a reality in broadband magnetic field sensors, where each component is detected with a square-law detector and combined subsequently. For the measurement and detection of radio signals isotropic antennas are not available. Hybrids may be used for limited frequency ranges to achieve an omnidirectional azimuthal (not isotropic) pickup.

Antenna-Factor Definition. The output voltage V of a loop antenna is proportional to the average magnetic field strength H perpendicular to the loop area. If the antenna output is connected to a measuring receiver or a spectrum analyzer, the set consisting of antenna and receiver forms a selective magnetometer.

Figure 6. Cross section of a loop antenna sensitivity pattern. The arrow length H_α shows the indicated field strength at an angle α which is a fraction of the original field strength H , with $H_\alpha = H \cos \alpha$.

Figure 7. Direction of the field vectors (H , E , and P) under far-field conditions.

The proportionality constant is the antenna factor K_H for the average magnetic field strength H :

$$K_H = \frac{H}{V} \quad \text{in} \quad \frac{\text{A}}{\text{m}} \frac{1}{\text{V}} = \frac{1}{\Omega \text{m}} \quad (1a)$$

For the average magnetic flux density B the corresponding proportionality constant is

$$K_B = \frac{B}{V} = \frac{\mu_0 H}{V} = \mu_0 K_H \quad \text{in} \quad \frac{\text{Vs}}{\text{Am}} \frac{1}{\text{m}} \frac{1}{\text{V}} = \frac{\text{T}}{\text{m}^2 \text{V}} = \frac{\text{T}}{\text{V}} \quad (1b)$$

In the far field, where electric field and magnetic fields are related via the free-space wave impedance Z_0 , the loop antenna can be used to determine the electric field strength E . For this case the proportionality constant is:

$$K_E = \frac{E}{V} = \frac{Z_0 H}{V} = Z_0 K_H \quad \text{in} \quad \frac{\text{V}}{\text{Am}} \frac{1}{\text{m}} \frac{1}{\text{V}} = \frac{1}{\text{m}} \quad (1c)$$

In the area of radio wave propagation and radio disturbance measurement, quantities are expressed in logarithmic units. Therefore, the proportionality constants are converted into logarithmic values too:

$$k_H = 20 \log(K_H) \quad \text{in} \quad \text{dB} \left(\frac{1}{\Omega \text{m}} \right) \quad (2a)$$

$$k_B = 20 \log(K_B) \quad \text{in} \quad \text{dB} \left(\frac{\text{T}}{\text{V}} \right) \quad (2b)$$

$$k_E = 20 \log(K_E) \quad \text{in} \quad \text{dB} \left(\frac{1}{\text{m}} \right) \quad (2c)$$

By using logarithmic antenna factors, a field-strength level $20 \log(H)$ is obtained in $\text{dB}(\mu\text{A}/\text{m})$ from the measured output voltage level $20 \log(V)$ in $\text{dB}(\mu\text{V})$ by applying the equation: $20 \log(H) = 20 \log(V) + k_H$. The final section of this article describes a method to calibrate the antenna factors of circular loop antennas.

Concepts of Magnetic Field-Strength Meters. The loop antenna of a magnetic field-strength meter may be mounted on the measuring receiver or used as a separate unit, connected to the measuring receiver with a coaxial cable. CISPR 16-1, the basic standard for emission measurement instrumentation to commercial (i.e., nonmilitary) standards, requires a loop antenna in the frequency range of 9 kHz to 30 MHz which is completely enclosed by a square having sides 0.6 m in length. For

Figure 8. Detector response of a test receiver for impulsive interference as specified in Ref. 1.

protection against stray pick-up of electric fields, loop antennas employ a coaxial shielding structure. For optimum performance, the shielding structure may be arranged symmetrically in two half-circles around a circular loop with a slit between the two halves in order to avoid electric contact between the two shields.

For narrowband magnetic field measurements of radio disturbance, measuring receivers employ standardized bandwidths and weighting detectors in order to produce standardized measurement results for all types of perturbations including impulsive signals. For comparison with the emission limit, usually the quasi-peak (QP) detector is to be used.

To understand the function of a weighting curve in measuring receivers, the following interpretation is given. The test receiver has certain elements that determine a weighting curve (e.g. for the QP detector): the measurement bandwidth, the charge and discharge times of the detector circuit, and the time constant of the meter. When measured with a QP detector, for the frequency range given in Fig. 8, an impulsive signal with a constant impulse strength and a pulse repetition frequency of 100 Hz will cause a meter indication 10 dB above that of the indication when the pulse repetition frequency is 10 Hz. Or, to produce the same indication on the meter as a signal with 100-Hz repetition frequency, the level of the 10-Hz impulsive signal will have to be increased by an amount of 10 dB.

Earlier manually operated field-strength meters achieved high sensitivity by operating the loop at resonance (14). The sensitivity was raised by the amount of the Q -factor of the resonating circuit. One of the latest models which was used up to the 1980s, reached a sensitivity of -60 dB(μ A/m) with a measurement bandwidth of 200 Hz in the frequency range 100 kHz to 30 MHz (15).

For automated field-strength measurement systems, tuning of the loop circuit could no longer be afforded. A broadband active loop employs an output voltage proportional to the short-circuited loop current thus achieving a flat response of the antenna factor versus frequency (16).

A flat response of the system is also achieved using a current probe which measures the short-circuit current in the large-loop antenna system (LAS) described by Bergervoet and van Veen (9). It is essentially a magnetic-field-induced current measurement (see subsequent explanations). The highest sensitivity described in the literature for a wideband system

Figure 9. Sensitivity per hertz bandwidth of the active loop (16).

was achieved with a specially designed active loop. With additional frequency-dependant switching of elements (17) sensitivity is even better than that of manually operated field-strength meters with tuning of the loop circuit. Figure 9 shows the amplitude density of the minimum detectable magnetic field strength H_{Neq} in dB(μ A/m/ $\sqrt{\text{Hz}}$) equivalent to the internal electronic noise of the system consisting of antenna and measuring receiver.

MAGNETIC-FIELD-STRENGTH MEASUREMENT METHODS

Measurement of Magnetic Fields With Regard to Human Exposure to High em Fields

Usually, to measure magnetic fields with regard to human exposure to high fields, magnetic field-strength meters are using broadband detectors and apply an isotropic response. Modern concepts of low-frequency electric and magnetic field strength meters apply fast Fourier transform (FFT) for proper weighting of the total field with regard to frequency-dependent limits (18,19).

Use of Loop Antennas for Radio Wave Field-Strength Measurements Up to 30 MHz

ITU-R Recommendation PI.845-1 Annex 1 gives guidance to accurate measurement of radio wave field strengths. Rod antennas are the preferred receiving antennas since they provide omnidirectional azimuthal pickup. The positioning of vertical rod antennas is however important, since the result is very sensitive to field distortions by obstacles and sensitive to the effects of ground conductivity. It is a well-known fact that measurements with loop antennas are less sensitive to these effects and their calibration is not affected by ground conductivity apart from the fact that the polarization may deviate from horizontal if ground conductivity is poor. Therefore, many organizations use vertical monopoles for signal measurements but standardize results by means of calibration data involving comparisons for selected signals indicated by field-strength meters incorporating loop-receiving antennas. Accuracy requirements are given in Ref. 20, general information on equipment and methods of radio monitoring are given in Ref. 21.

Solutions to Problems With Ambients in Commercial EMI Standards. CISPR Class B radiated emission limits in the

Figure 10. Conversion factors ΔH for the limit of the magnetic field strength from 30-m measurement distance to 10-m and 3-m measurement distances above a conducting ground plane according to Ref. 26. The upper curve is for 30 to 3 m, and the lower curve is for 30 to 10 m distances.

frequency range 9 kHz to 30 MHz have been at 34 dB(μ V/m) at a distance of 30 m from the EUT for a long time. Moreover, the test setup with EUT and vertical loop antenna required turning of both EUT and loop antenna in order to find the maximum emission. On most of the open area test sites the ambient noise level makes compliance testing almost impossible. This is due to the fact that ambient noise itself is near or above the emission limit. Two different approaches were proposed as a solution to that problem:

(1) To reduce the measurement distance from 30 m to 10 m or even 3 m. A German group proposed frequency-dependent conversion factors, justified by calculations and an extensive amount of measurements. The conversion factors are given in Fig. 10. In Fig. 10 the slopes between 1.8 MHz and 16 MHz show the transition region from near field, where H is inversely proportional with r^3 or $r^{2.6}$, to far field, where H is inversely proportional with r .

(2) To reduce the measurement distance to zero. A Dutch group proposed the large-loop antenna system mentioned previously (9). With this method the EUT is placed in the center of a loop antenna system, which consists of three mutually perpendicular large loop antennas (Fig. 11). The magnetic field emitted by the EUT induces currents in the large loop antennas. Since there are three orthogonal loops, there is no need to rotate either the EUT or the loop antenna system. The current induced in each loop is measured by means of a current probe, which is connected to a CISPR measuring receiver. Since the current is measured, emission limits are given in dB(μ A) instead of dB(μ A/m). Each loop antenna is constructed of a coaxial cable which contains two slits, positioned symmetrically with respect to the position of the current probe. Each slit is loaded by resistors in order to achieve a frequency response flat to within ± 2 dB in the frequency range from 9 kHz to 30 MHz (9,10). In order to verify and validate the function of each large loop, a specially designed folded dipole has been developed (9,10). It produces both a magnetic dipole moment m_H and an electric dipole moment m_E , when a signal is connected to the folded dipole. The folded dipole serves to test the large loop antenna for its sensitivity in 8 positions.

Figure 11. Simplified drawing of a large loop antenna system with position of the EUT.

Problems in the Near Field to Far Field Transition Zone. Problems with magnetic field strength measurements in the transition region between near field and far field are discussed in detail in Ref. 22. When a small magnetic dipole is located in the free space, the electromagnetic field in a point $P(r, \theta, \phi)$ is described by the following three relations (see Fig. 12):

$$H_r = \frac{jk}{2\pi} \frac{m_H \cos \theta}{r^2} \left(1 + \frac{1}{jkr}\right) e^{-jkr} \quad (3a)$$

$$H_\theta = \frac{-k^2}{4\pi} \frac{m_H \sin \theta}{r} \left(1 + \frac{1}{jkr} - \frac{1}{(kr)^2}\right) e^{-jkr} \quad (3b)$$

$$E_\phi = \frac{Z_0 k^2}{4\pi} \frac{m_H \sin \theta}{r} \left(1 + \frac{1}{jkr}\right) e^{-jkr} \quad (3c)$$

where $k = 2\pi/\lambda$, and $m_H = \pi R^2 I_0$ is the magnetic dipole moment, a vector perpendicular to the plane of the dipole. Equations (3a–3c) completely describe the electromagnetic field of the magnetic dipole.

Figure 12. Field components H_r , H_θ , and E_ϕ in P at a distance r from the center of the magnetic dipole in the xy -plane.

Two situations are further discussed: (1) the near field, where r is much smaller than λ but larger than the maximum dimension of the source (i.e. $kr \ll 1$), and (2) the far field, where r is much larger than λ and much larger than the maximum dimension of the source (i.e. $kr \gg 1$).

For the near field case, where $kr \ll 1$ and using $e^{-jkr} = \cos(kr) - j\sin(kr)$, Eqs. (3a–3c) are simplified to

$$H_r = \frac{2m_H \cos \theta}{4\pi r^3} \quad (4a)$$

$$H_\theta = \frac{m_H \sin \theta}{4\pi r^3} \quad (4b)$$

$$E_\phi = \frac{kZ_0 m_H \sin \theta}{4\pi r^2} \quad (4c)$$

From Eqs. (4a–4c) we can see that H_r and H_θ are inversely proportional to r^3 , whereas E_ϕ is inversely proportional to r^2 .

For the far-field case where $kr \gg 1$, Eqs. (3a–3c) are reduced to

$$H_r = \frac{jk m_H \cos \theta}{2\pi r^2} e^{-jkr} \Rightarrow 0 \quad (5a)$$

$$H_\theta = \frac{-k^2 m_H \sin \theta}{4\pi r} e^{-jkr} \quad (5b)$$

$$E_\phi = \frac{k^2 Z_0 m_H \sin \theta}{4\pi r} e^{-ikr} \quad (5c)$$

From Eqs. (5a–5c) one can see that in the far field H_r vanishes in comparison to H_θ and that H_θ and E_ϕ are inversely proportional to r .

In the frequency range of 9 kHz to 30 MHz, where emission limits have been set, the corresponding wavelength is 33 km to 10 m. Since for compliance testing, ambient emissions on an open area test site require a reduction of the measurement distance to 10 m or even 3m, measurements are carried out in the near field zone over a wide frequency range. At the higher frequency range the transition zone and the beginning far field zone are reached. Goedbloed (22) investigated the transition zone and identified the critical condition where H_r and H_θ are equal in magnitude. It occurs where

$$\frac{2m_H}{4\pi r^3} \sqrt{1 + k^2 r^2} = \frac{m_H}{4\pi r^3} \sqrt{1 - k^2 r^2 + k^4 r^4} \quad (6)$$

or where

$$fr = 112.3 \text{ in MHz} \cdot \text{m} \quad (7)$$

For $r = 10$ m, $H_{\theta \max} > H_{r \max}$ at frequencies greater than 11 MHz.

The CISPR magnetic field measurement method is illustrated by Fig. 13, with the test setup on a metallic ground plane and the receiving antenna in the vertical plane. In Figs. 14 and 15, two different cases of radiating electrically small magnetic dipoles are illustrated: the first one with the dipole moment parallel to the ground plane and the second one with the dipole moment perpendicular to the ground plane. Because of the reflecting ground plane two sources are responsible for the field at the location of the receiving antenna: the original source and the mirror source. The points and crosses drawn in both

Figure 13. Basic CISPR setup for magnetic field measurements. Both EUT and loop antennas have to be turned round until the maximum indication on the receiver has been found.

sources show the direction of the current. In Fig. 14, the currents are equally oriented. In this case the loop antenna detects the radial component $H_{d,r}$ and the direct tangential component $H_{d,\theta} = 0$ since $\theta_d = 0$. Therefore, direct radiation will only contribute if $fd \ll 112 \text{ MHz} \cdot \text{m}$, see Eq. (7). In the case of $fd \gg 112 \text{ MHz} \cdot \text{m}$, the loop antenna will receive direct radiation if it is rotated by 90° . This may be observed frequently in practical measurements: at low frequencies the maximum radiation is found with the loop antenna in parallel to the EUT and at high frequencies with the loop antenna oriented perpendicular to the EUT. In addition to these direct components, the indirect radial and tangential components $H_{i,r}$ and $H_{i,\theta}$ are superpositioned in the loop antenna. Assuming near-field conditions it follows from Eqs. (4), that the magnitude of the magnetic field H_m is given by

$$H_m = H_{d,r} + H_{i,r} \cos \theta_i - H_{i,\theta} \sin \theta_i \quad (8)$$

$$= \frac{m_H}{4\pi d^3} \left(2 + \frac{d^3}{d_i^3} (2 \cos^2 \theta_i - \sin^2 \theta_i) \right)$$

where $d_i = \sqrt{(2h)^2 + d^2}$ is the distance between the mirror dipole and the loop antenna.

Goedbloed gives a numerical example with $m_H = 4\pi 10^3 \mu\text{Am}^2$ (e.g. 100 mA through a circular loop with a diameter of 0.40 m). Using Eq. (8) with $d = 3$ m and $h = 1.3$ m will give $H_m = 38.6 \text{ dB}(\mu\text{A/m})$ with the mirror source and $37.4 \text{ dB}(\mu\text{A/m})$

Figure 14. (a) Receiving conditions for a magnetic dipole with a horizontal dipole moment; (b) Vectors of the direct and indirect radiated H -field components.

Figure 15. (a) Receiving conditions for a magnetic dipole with a vertical dipole moment, and the receiving loop-antenna in the vertical position as specified by the standard; (b) Vectors of the indirect radiated H -field components (no reception of direct radiation).

without the mirror source, which shows that in this case the reflecting ground plane has little influence. The influence of the ground plane is quite different in the case of a vertical dipole moment, i.e. a dipole moment perpendicular to the ground plane as illustrated in Fig. 15. In the case of Fig. 15 the loop antenna does not receive direct radiation at all, as $H_{d,r}(\theta_d = \pi/2) = 0$ and $H_{d,\theta}$ is parallel to the loop antenna. Hence, the received signal is completely determined by the radiation coming from the mirror source, which also means that the result is determined by the quality of the reflecting ground plane. With the reflecting ground plane $H_m = H_{i,r} \sin \theta_i + H_{i,\theta} \cos \theta_i = 27.2 \text{ dB}(\mu\text{A/m})$, whereas without the reflecting ground plane no field strength will be measured. If the loop antenna were positioned horizontally above the ground plane at $h = 1.3 \text{ m}$, $H_m = H_{d,\theta} + H_{i,r} \cos \theta_i - H_{i,\theta} \sin \theta_i = 32.4 \text{ dB}(\mu\text{A/m})$ and $H_m = 31.4 \text{ dB}(\mu\text{A/m})$ without the reflecting ground plane. Measurements in a shielded room would even be less predictable, since the result would be determined by mirror sources on each side including the ceiling of the shielded room. Absorbers are not very helpful in the low frequency ranges. From these results, Goedbloed concludes that in order to judge the interference capability of an EUT, the method proposed by Bergervoet and Van Veen (9), is an efficient method of magnetic field measurements.

CALIBRATION OF A CIRCULAR LOOP ANTENNA

A time-varying magnetic field at a defined area S can be determined with a calibrated circular loop. For narrow-band magnetic field measurements, a measuring loop consists of an output interface (point X on Fig. 5), which links the induced current to a measuring receiver. It may have a passive or an active network between loop terminals and output. The measuring loop can also include a shielding over the loop circumference against any perturbation of strong and unwanted electric fields. The shielding should be interrupted at a point on the loop circumference.

Generally in the far-field the streamlines of magnetic flux are uniform, but in the near-field, i.e. in the vicinity of the generator of a magnetic field, they depend on the source and its periphery. Figure 19 shows the streamlines of the electromagnetic vectors generated by the transmitting loop L1. In the near-field, the spatial distribution of the magnetic flux, $B = \mu_0 H$, over the

measuring loop area is not known. Only the normal components of the magnetic flux, averaged over the closed-loop area, can induce a current through the loop conductor.

The measuring loop must have a calibration (conversion) factor or set of factors, that, at each frequency, expresses the relationship between the field strength impinging on the loop and the indication of the measuring receiver. The calibration of a measuring loop requires the generation of a well-defined standard magnetic field on its effective receiving surface. Such a magnetic field is generated by a circular transmitting loop when a defined root mean square (rms) current is passed through its conductor. The unit of the generated or measured magnetic field H_{av} is A/m and therefore is also an rms value. The subscript, av, strictly indicates the average value of the spatial distribution, not the average over a period of T of a periodic function. This statement is important for near-field calibration and measuring purposes. For far-field measurements the result indicates the rms value of the magnitude of the uniform field. In the following we discuss the requirements for the near-zone calibration of a measuring loop.

CALCULATION OF STANDARD NEAR-ZONE MAGNETIC FIELDS

To generate a standard magnetic field, a transmitting loop L1 is positioned coaxial and plane-parallel at a separation distance d from the loop L2, like in Fig. 16. The analytical formula for the calculation of the average magnetic field strength H_{av} in A/m generated by a circular filamentary loop at an axial distance d including the retardation due to the finite propagation time was obtained earlier by Greene (23). The average value of field strength H_{av} was derived from the retarded vector potential A_φ as tangential component on the point P of the periphery of loop L2:

$$H_{av} = \frac{I r_1}{\pi r_2} \int_0^\pi \frac{e^{-j\beta R(\varphi)}}{R(\varphi)} \cos(\varphi) d\varphi \quad (9a)$$

$$R(\varphi) = \sqrt{d^2 + r_1^2 + r_2^2 - 2r_1 r_2 \cos(\varphi)} \quad (9b)$$

Figure 16. Configuration of two circular loops.

In these equations for the thin circular loop, I is transmitting loop rms current in A, d is distance between the planes of the two coaxial loop antennas in m, r_1 and r_2 are filamentary loop radii of transmitting and receiving loops in m, respectively, β is wavelength constant, $\beta = 2\pi/\lambda$, and λ is wavelength in m.

Equations (9a) and (9b) can be determined by numerical integration. To this end we separate the real and imaginary parts of the integrand using Euler's formula $e^{-j\phi} = \cos(\phi) - j \sin(\phi)$ and rewrite Eq. (9a) as

$$H_{av} = \frac{I r_1}{\pi r_2} (F - jG) \quad (10a)$$

where

$$F = \int_0^\pi \frac{\cos[\beta R(\varphi)]}{R(\varphi)} \cos(\varphi) d\varphi \quad (10b)$$

$$G = \int_0^\pi \frac{\sin[\beta R(\varphi)]}{R(\varphi)} \cos(\varphi) d\varphi \quad (10c)$$

and the magnitude of H_{av} is then obtained as

$$|H_{av}| = \frac{I r_1}{\pi r_2} \sqrt{F^2 + G^2} \quad (10d)$$

It is possible to evaluate the integrals in Eqs. (10) by numerical integration with an appropriate mathematics software on a personal computer. Some mathematics software can directly calculate the complex integral of Eqs. (9).

ELECTRICAL PROPERTIES OF CIRCULAR LOOPS

Current Distribution Around a Loop

The current distribution around the transmitting loop is not constant in amplitude and in phase. A standing wave of current exists on the circumference of the loop. This current distribution along the loop circumference is discussed by Greene on pp. 323–324 (23). He has assumed the loop circumference $2\pi r_1$ being electrically smaller than the wave length λ and the loop current being constant in phase around the loop and the loop being sufficiently loss-free. The single-turn thin loop was considered as a circular balanced transmission line fed at points A and D and short-circuited at the points E and F (Fig. 17).

In an actual calibration setup the loop current I_1 is specified at the terminals A and D. The average current was given as a function of input current I_1 of the loop (24):

$$I_{av} = I_1 \frac{\tan(\beta \pi r_1)}{\beta \pi r_1} \quad (11)$$

The fraction of I_{av}/I_1 from Eq. (11) expressed in dB gives the conditions for determining of the highest frequency f and the radius of the loop r_1 . The deviation of this fraction is plotted in Fig. 18.

The current I in Eqs. (9) must be substituted with I_{av} from Eq. (11). Since Eq. (11) is an approximate expression, it is recommended to keep the radius of the transmitting loop small enough for the highest frequency of calibration to minimize the errors. For the dimensioning of the radius of the receiving loop these conditions are not very important, until the receiving loop is calibrated with an accurately defined standard magnetic

Figure 17. Current distribution on a circular loop.

field, but the resonance of the loop at higher frequencies must be taken into account.

Circular Loops With Finite Conductor Radii

A measuring loop can be constructed with one or more winding. The form of the loop is chosen as a circle, because of the simplicity of the theoretical calculation and calibration. The loop conductor has a finite radius. At high frequencies the loop current flows on the conductor surface and it shows the same proximity effect as two parallel, infinitely long cylindrical conductors. Figure 19 shows the cross-section of two loops intentionally in exaggerated dimensions. The streamlines of the electric field are orthogonal to the conductor surface of the transmitting loop L1 and they intersect at points A and A'. The total conductor current is assumed to flow through an equivalent thin filamentary loop with the radius $a_1 = \sqrt{r_1^2 - c_1^2}$, where $a_1 = \overline{OA} = \overline{OP} = \sqrt{\overline{OQ}^2 - \overline{QP}^2}$. The streamlines of the magnetic field are orthogonal to the streamlines of electric field. The receiving loop L2 with the finite conductor radius c_2 can encircle a part of magnetic field with its effective circular radius $b_2 = r_2 - c_2$.

The sum of the normal component of vectors H acting on the effective receiving area $S_2 = \pi b_2^2$ induces a current in the conductor of the receiving loop L2. This current flows through

Figure 18. Deviation of I_{av}/I_1 for a loop radius, 0.1 m as $20 \log(I_{av}/I_1)$ in dB versus frequency.

Figure 19. Filamentary loops of two loops with finite conductor radii and orthogonal streamlines of the electromagnetic vectors, produced from transmitting loop L1.

the filamentary loop with the radius a_2 . The average magnetic field vector H_{av} is defined as the integral of vectors H_n over effective receiving area S_2 , divided by S_2 . The magnetic streamlines, which flow through the conductor and outside of loop L2, cannot induce a current through the conductor along the filamentary loop Ar, Ar', of L2. The equivalent filamentary loop radii a_1 , a_2 and effective circular surface radii b_1 , b_2 can directly be seen from Fig. 19.

The equivalent thin current filament radius a_1 of the transmitting loop L1:

$$a_1 = \sqrt{r_1^2 - c_1^2} \quad (12a)$$

The equivalent thin current filament radius a_2 of the receiving loop L2:

$$a_2 = \sqrt{r_2^2 - c_2^2} \quad (12b)$$

The radius b_1 of the effective receiving circular area of the loop transmitting L1:

$$b_1 = r_1 - c_1 \quad (12c)$$

The radius b_2 of the effective receiving circular area of the receiving loop L2:

$$b_2 = r_2 - c_2 \quad (12d)$$

Impedance of a Circular Loop

The impedance of a loop can be defined at chosen terminals Q, D, as $Z = V/I_1$ (Fig. 17). Using Maxwell's equation with the Faraday's law $\text{curl} \mathbf{E} = -j\omega\Phi_m$ we can write the line integrals of the electric intensity E along the loop conductor through its cross section, along the path joining points D, Q, and the load

impedance Z_L between the terminals Q, A:

$$\int_{(AEFD)} E_s ds + \int_{(DQ)} E_s ds + \int_{(QA)} E_s ds = -j\omega\Phi_m \quad (13a)$$

Here, Φ_m is the magnetic flux. The impressed emf V acting along the path joining points D and Q is equal and opposite to the second term of Eq. (13a):

$$V = - \int_{(DQ)} E_s ds \quad (13b)$$

The impedance of the loop at the terminals D, Q can be written from Eqs. (13) dividing with I_1 as

$$Z = \frac{V}{I_1} = \frac{\int_{(AEFD)} E_s ds}{I_1} + \frac{\int_{(QA)} E_s ds}{I_1} + \frac{j\omega\Phi_m}{I_1} = Z_i + Z_L + Z_e \quad (14)$$

Z_i indicates the internal impedance of the loop conductor. Because of the skin effect, the internal impedance at high frequencies is not resistive. For the calculation of the Z_i we refer to Schelkunoff, p. 262 (25). Z_L is a known load or a source impedance on Fig. 17. Z_e is the external impedance of the loop:

$$Z_e = j\omega \frac{\Phi_m}{I_1} = j\omega \frac{\mu_0 H_{av} S}{I_1} \quad (15a)$$

We can consider that the loop consists of two coaxial and coplanar filamentary loops (i.e. separation distance $d = 0$). The radii a_1 and b_1 are defined in Eqs. (12). The average current I_{av} flows through the filamentary loop with the radius a_1 and generates an average magnetic field strength H_{av} on the effective circular surface $S_1 = \pi b_1^2$ of the filamentary loop with the radius b_1 . From the Eqs. (9) and (11) we can rewrite Eq. (15a), for the loop L1:

$$Z_e = j \frac{\tan(\beta\pi a_1)}{\beta\pi a_1} \mu_0 \omega a_1 b_1 \int_0^\pi \frac{e^{-j\beta R_0(\varphi)}}{R_0(\varphi)} \cos(\varphi) d\varphi \quad (15b)$$

$$R_0(\varphi) = \sqrt{a_1^2 + b_1^2 - 2a_1 b_1 \cos(\varphi)} \quad (15c)$$

The real and imaginary parts of Z_e are the radiation resistance and the external inductance of loops, respectively:

$$\text{Re}(Z_e) = \frac{\tan(\beta\pi a_1)}{\beta\pi a_1} \mu_0 \omega a_1 b_1 \int_0^\pi \frac{\sin(\beta R_0(\varphi))}{R_0(\varphi)} \cos(\varphi) d\varphi \quad (15d)$$

$$\text{Im}(Z_e) = \frac{\tan(\beta\pi a_1)}{\beta\pi a_1} \mu_0 \omega a_1 b_1 \int_0^\pi \frac{\cos(\beta R_0(\varphi))}{R_0(\varphi)} \cos(\varphi) d\varphi \quad (15e)$$

From Eq. (15e) we obtain the external self inductance:

$$L_e = \frac{\tan(\beta\pi a_1)}{\beta\pi a_1} \mu_0 a_1 b_1 \int_0^\pi \frac{\cos(\beta R_0(\varphi))}{R_0(\varphi)} \cos(\varphi) d\varphi \quad (15f)$$

Equations 15 include the effect of current distribution on the loop with finite conductor radii.

Mutual Impedance Between Two Circular Loops

The mutual impedance Z_{12} between two loops is defined as

$$Z_{12} = \frac{V_2}{I_1} = \frac{Z_2 I_2}{I_1} \quad (16)$$

The impedance of Z_2 in Eq. (16) can be defined like Eq. (14):

$$Z_2 = \frac{V_2}{I_2} = Z_{2i} + Z_L + Z_{2e} \quad (17)$$

here Z_{2i} is the internal impedance, Z_L is the load impedance, and Z_{2e} is the external impedance of the second loop L2.

The current ratio I_2 to I_1 in Eq. (16) can be calculated from Eqs. (9), (11), and (12). The current I_1 of the transmit loop with separation distance d :

$$I_1 = \frac{H_{av} \pi b_2}{\frac{\tan(\beta \pi a_1)}{\beta \pi a_1} a_1 \int_0^\pi \frac{e^{-j\beta R_d(\varphi)}}{R_d(\varphi)} \cos(\varphi) d\varphi} \quad (18a)$$

$$R_d(\varphi) = \sqrt{d^2 + a_1^2 + b_2^2 - 2a_1 b_2 \cos(\varphi)} \quad (18b)$$

and the current I_2 of the receive loop for the same H_{av} (here $d = 0$) is

$$I_2 = \frac{H_{av} \pi b_2}{\frac{\tan(\beta \pi a_2)}{\beta \pi a_2} a_2 \int_0^\pi \frac{e^{-j\beta R_0(\varphi)}}{R_0(\varphi)} \cos(\varphi) d\varphi} \quad (18c)$$

$$R_0(\varphi) = \sqrt{a_2^2 + b_2^2 - 2a_2 b_2 \cos(\varphi)} \quad (18d)$$

The general mutual impedance between two loops from Eqs. (16) and (17) is

$$Z_{12} = (Z_{2i} + Z_L + Z_{2e}) \frac{I_2}{I_1} = Z_{12i} + Z_{12L} + Z_{12e} \quad (19a)$$

where Z_{12i} is the mutual internal impedance, Z_{12L} denotes the mutual load impedance, and Z_{12e} is the external mutual impedance.

Arranging Eq. (15b) for Z_{2e} and the current ratio I_2/I_1 from Eqs. (18) the external mutual impedance yield

$$Z_{12e} = j \frac{\tan(\beta \pi a_1)}{\beta \pi a_1} \mu_0 \omega a_1 b_2 \int_0^\pi \frac{e^{-j\beta R_d(\varphi)}}{R_d(\varphi)} \cos(\varphi) d\varphi \quad (19b)$$

The real part of Z_{12e} may be described as mutual radiation resistance between two loops.

The imaginary part of Z_{12e} divided by ω gives the mutual inductance

$$M_{12e} = \frac{\tan(\beta \pi a_1)}{\beta \pi a_1} \mu_0 a_1 b_2 \int_0^\pi \frac{\cos(\beta R_d(\varphi))}{R_d(\varphi)} \cos(\varphi) d\varphi \quad (19c)$$

Equations (19b) and (19c) include the effect of current distribution on the loop with finite conductor radii.

DETERMINATION OF THE ANTENNA FACTOR

The antenna factor K is defined as a proportionality constant with necessary conversion of units. K is the ratio of the average magnetic field strength bounded by the loop to the measured output voltage V_L on the input impedance R_L of the measuring receiver. For the evaluation of the antenna factor there are two methods. The first is by calculation of the loop impedances, and the second is with the well-defined standard magnetic field calibration, which will also be needed for the verification of calculated antenna factors (24).

Determination of the Antenna Factor by Computing from the Loop Impedances

If a measurement loop (e.g. L2) has a simple geometric shape and a simple connection to a voltage measuring device with a known load R_L , we can determine the antenna factor by calculation. In the case of unloaded loop from Fig. 17 the open circuit voltage is

$$V_0 = j\omega\mu_0 H_{av} S_2 \quad (20a)$$

For the case of loaded loop the current is

$$I = \frac{V_0}{Z} = \frac{V_0}{R_L + Z_i + Z_e} \quad (20b)$$

The antenna factor from Eq. (9a) can be written with $V_L = Z_L I$ and Eqs. (20) as

$$K_H = \left| \frac{1}{j\omega\mu_0 S_2} \left(1 + \frac{Z_e}{R_L} + \frac{Z_i}{R_L} \right) \right| \quad \text{in} \quad \frac{\text{A}}{\text{m}} \frac{1}{\text{V}} \quad (21)$$

The effective loop area is $S_2 = \pi b_2^2$. The external loop impedance Z_e can be calculated with Eqs. (15). The internal impedance Z_i can be evaluated from Ref. 25.

Standard Magnetic Field Method

In the calibration setup in Fig. 20 we measure the voltages with standard laboratory measuring instrumentation with the 50 Ω impedance. The device to be calibrated consists at least of a loop and a cable with an output connector. Such a measuring loop can also include a passive or active network between the terminals C, D, and a coaxial shield on the circular loop conductor against unwanted electric fields, depending on its development and construction. The impedance Z_L at the terminals C, D is not accurately measurable. Such a complex loop must be calibrated with the standard magnetic field method. The antenna factor in Eqs. (1) can be defined through measuring of the voltage V_L and the uncertainties between loop terminals C, D and measuring receiver are fully calibrated. The attenuation ratio α of the voltages V_2 and V_L can be measured for each frequency:

$$\alpha = \frac{V_2}{V_L} \quad (22)$$

By using the Eqs. (22), (1), (11), and (12), with $V_2 = -I_1 R_2$, and $V_0 = \text{constant}$, Eq. (9a) can be rewritten:

$$K_H = \left| \alpha \frac{1}{R_2} \frac{\tan(\beta \pi a_1)}{\beta \pi a_1} \frac{a_1}{\pi b_2} \int_0^\pi \frac{e^{-j\beta R_d(\varphi)}}{R_d(\varphi)} \cos(\varphi) d\varphi \right| \quad (23)$$

Figure 20. Calibration setup for circular loop antennas.

R_d is defined by Eq. (18b). Equation (23) can also be expressed logarithmically

$$k_H = 20 \log(K_H) \quad \text{in dB} \left(\frac{\text{A}}{\text{m}} \frac{1}{\text{V}} \right)$$

Equation (23) reduces the calibration of the loop to an accurate measurement of attenuation α for each frequency. The other terms of Eq. (23) can be calculated depending on the geometrical configuration of the calibration setup at the working frequency band of the measuring loop. The calibration uncertainties are also calculable with the given expressions. The uncertainty of the separation distance d between two loops must be taken into consideration as well. At a separation distance $d < r_1$ the change of the magnetic field is high.

For a calibration setup the separation distance d can be defined as small as possible. However, the effect of the mutual impedance must be taken into account in the calibration process and a condition to define the separation distance d must be given (Fig. 20). If the second loop is open circuited, that is the current $I_2 = 0$, the current I_1 is defined only from the impedances of the transmitting loop. In the case of a short-circuited second loop, I_2 is maximum and the value of I_1 will change depending on the supply circuit and loading of the transmitting loop. A current ratio q between these two cases can be defined as the condition of the separation distance d between the two loops.

It is assumed that the generator voltage V_0 is constant. The measuring loop L2 is terminated by Z_L . For $Z_L = 0$ and $V_{CD} = 0$, one obtains the current I_1 in the transmitting loop as

$$I_{1(Z_L=0)} = \frac{V_0}{R_1 + R_2 + Z_{AB} - \frac{Z_{12}^2}{Z_{CD}}} \quad (24a)$$

and for $Z_L = \infty$, i.e. $I_2 = 0$

$$I_{1(Z_L=\infty)} = \frac{V_0}{R_1 + R_2 + Z_{AB}} \quad (24b)$$

The ratio of Eq. (24a) to Eq. (24b) is

$$q \equiv \frac{I_{1(Z_L=0)}}{I_{1(Z_L=\infty)}} = \left| \frac{R_1 + R_2 + Z_{AB}}{R_1 + R_2 + Z_{AB} \left(1 - \frac{Z_{12}^2}{Z_{AB} Z_{CD}} \right)} \right| \quad (25a)$$

and here with the coupling factor $k = Z_{12} / \sqrt{Z_{AB} Z_{CD}}$ between two loops:

$$q = \left| \frac{R_1 + R_2 + Z_{AB}}{R_1 + R_2 + Z_{AB}(1 - k^2)} \right| \quad (25b)$$

where $R_1 = R_2 = 50 \Omega$, Z_{AB} , Z_{CD} , and Z_{12} can be calculated from Eqs. (15) and (19). For greater accuracy one must try to keep the ratio q close to unity (e.g., $q = 1.001$).

The influence of the loading of the second loop on the transmitting loop can also be found experimentally. The change of the voltage V_2 at R_2 in Fig. 20 must be considerably small, e.g. < 0.05 dB, while putting a short-circuited measuring loop at the chosen separation distance.

With the determining of K_H or k_H the loop can completely be calibrated up to its 50Ω output. A network analyzer is usually used for the attenuation measurement instead of a discrete measurement at each frequency with signal generator and measuring receiver. A network analyzer can normalize the frequency characteristic of the transmit loop and gives a quick overview on measured attenuation for the frequency band.

ATTENUATION MEASUREMENT

When a signal is sent along any transmission path, many different mechanisms degrade it. Because of finite conductivity, every cable shows a resistive loss. Furthermore, the dielectric loss and the skin effect may be significant at higher frequencies, and imperfect screening of cables leads to radiation losses which might be quite important at higher frequencies. Single-mode optical fibers have two main intrinsic loss mechanisms, scattering loss and absorption loss. Scattering loss is dominated by Rayleigh scattering, and below 1600 nm absorption losses are caused mainly by OH absorption. Fibers that are bent too tightly or cabled too poorly may have, in addition, bend losses because of nonguided modes. Connectors show losses because of nonideal contacts and imperfect impedance matching, which reflect part of the signal to the transmitter. Filters built in the ‘transmission path have losses in the passband caused by finite conductivity and probably dielectric losses. Wireless transmission paths, such as microwave links, satellite links, broadcast or mobile communication, are affected by scattering caused by rain, clouds, and multiple reflections.

The two examples following clearly show how additional attenuation or losses influence a system:

In a radar system a total loss of 2 dB in the feeder system and the duplexer wastes 37% of the transmitter power. During the development of the different parts, the losses have to be measured very carefully to minimize the total loss.

Satellite systems quite often operate with cooled front ends at the receiver because the signals to be picked up are extremely weak. Therefore the front ends often operate with noise temperatures of 5 K. An additional loss of 0.1 dB from an uncooled waveguide would raise the noise temperature to 7 K.

Figure 1. Attenuation measurement in a matched system.

These examples show how important it is to measure the losses of the different parts of a transmission system as accurately as possible to optimize system parameters.

Many different methods and a variety of systems for measuring attenuation have been developed. The most important techniques are described in the following sections.

ATTENUATION

Definition

In the field of loss measurement, the most important terms are attenuation, insertion loss, mismatch loss and voltage loss (1,2). These terms are discussed in the following sections.

Attenuation. According to R. W. Beatty (3), attenuation is defined as the decrease in power level at the load caused by inserting a device between a Z_0 source and load, where Z_0 is the characteristic impedance of the line. Figure 1 shows the basic idea of such an attenuation measurement.

Attenuation is mostly expressed by a logarithmic scale in decibels (dB) or in nepers. The attenuation of a two-port device is defined as follows (4):

in decibels,

$$A = 10 \log \left[\frac{\text{power delivered to a matched load by a matched source}}{\text{power delivered to the same load when the two-port device is inserted}} \right] \quad (1)$$

in nepers,

$$A = \frac{1}{2} \ln \left[\frac{\text{power delivered to a matched load by a matched source}}{\text{power delivered to the same load when the two-port device is inserted}} \right] \quad (2)$$

Because $\log(x) = \ln(x)/\ln(10)$, the following relationship between decibels and nepers is valid:

$$\text{Attenuation in decibels} = 8.6858 \times \text{attenuation in nepers}$$

Attenuation is a property only of a two-port device.

Insertion Loss. In practical applications neither the source nor the load has an impedance exactly equal to Z_0 the char-

acteristic impedance of a line. Therefore source and load have a reflection coefficient of r_s and r_L , respectively. Let P_1 be the power delivered from the source to the load and P_2 be the power absorbed by the same load when the two-port device is inserted (Fig. 2).

Then the loss is defined by

$$L_1 = 10 \log \frac{P_1}{P_2} \quad (3)$$

The insertion loss depends on the property of the device and the reflection coefficients of the source and the load.

Scattering Parameters. Two-port networks, especially at radio frequencies, are very well characterized by scattering parameters.

A two-port device inserted between a source and a load is shown in Fig. 3.

The complex wave amplitudes a_1 , a_2 , b_1 , and b_2 shown in Fig. 3 are related as follows:

$$b_1 = s_{11}a_1 + s_{12}a_2 \quad (4)$$

and

$$b_2 = s_{21}a_1 + s_{22}a_2 \quad (5)$$

Setting up the signal flow graph for the configuration in Fig. 3 and using the nontouching loop rules of Mason (5,6), the insertion loss is given by the following expression:

$$L_1 = 20 \log \frac{|(1 - r_s s_{11})(1 - r_L s_{22}) - r_s r_L s_{12} s_{21}|}{|s_{21}| \cdot |1 - r_s r_L|} \quad (6)$$

For a matched system where $r_s = r_L = 0$, Eq. (6) delivers the attenuation

$$A = 20 \log \frac{1}{|s_{21}|} \quad (7)$$

Equations (6) and (7) clearly show that the insertion loss L_1 depends on the property of the two-port device and the reflection coefficients of the source r_s and the load r_L . Otherwise the attenuation is the pure property of the two-port device.

Voltage Loss. Voltage loss is used only for applications in the dc to UHF part of the spectrum where voltage is well defined.

Figure 2. Insertion loss measurement in a non-matched system.

Figure 3. Scattering parameters for a two-port device inserted between source and load.

According to Warner (4), it is defined as follows:

$$L_V = 20 \log \left[\frac{\text{voltage at the input of the two-port device}}{\text{voltage at the output of the two-port device}} \right] \quad (8)$$

and using the scattering parameters

$$L_V = 20 \log \frac{|(1 + s_{11})(1 - r_L s_{22}) + r_L s_{12} s_{21}|}{|s_{21}(1 - r_L)|} \quad (9)$$

Note that L_V is independent of the source reflection coefficient r_s .

When $s_{11} = 0$ and $r_L = 0$, the voltage loss is equal to the attenuation.

Mismatch Loss. At higher frequencies every real two-port device has an input and output reflection coefficient that differs from zero. Therefore, there is always a mismatch between the source and the two-port device and between the two-port device and the load (Fig. 4). This reflects part of the incoming and outgoing wave toward the source and toward the two-port device, respectively, resulting in additional losses.

The mismatch loss between the source and the two-port device is expressed as:

$$L_{m1} = 10 \log \frac{\text{power absorbed at the input of the two-port device}}{\text{maximal available power from the source}} \quad (10)$$

According to Fig. 3 the mismatch loss is given by

$$L_{m1} = \frac{(1 - |r_s|^2)(1 - |r_1|^2)}{|1 - r_s r_1|^2} \quad (11)$$

Similarly, the mismatch loss between the two-port device and the load is given by

$$L_{m2} = 10 \log \frac{\text{power absorbed by the load}}{\text{maximal available power at the output of the two-port device}} \quad (12)$$

Figure 4. Mismatch loss of a two-port device between a source and a load.

and with the parameters of Fig. 4

$$L_{m2} = 10 \log \frac{(1 - |r_2|^2)(1 - |r_L|^2)}{|1 - r_2 r_L|^2} \quad (13)$$

If several two-port devices are cascaded, the mismatch loss between them has to be calculated similarly and taken into account.

ATTENUATOR

Apart from the natural losses in devices and transmission paths, manufactured devices have well-defined losses. These devices called attenuators are used for measurement and for adjusting power levels to a defined value in transmission systems. Attenuators are probably the most important devices in measurement systems and therefore exist in a large number of different forms (7–9), such as symmetrical, coaxial, waveguide, optical, fixed-value, and variable-loss. The important properties of attenuators are: frequency range, attenuation accuracy, attenuation variation versus frequency, input and output impedance match (reflection coefficient), power handling capacity, and phase linearity.

Balanced-Line Attenuator

Balanced lines are used especially in telecommunications and lately in local area networks and in-house communications systems. Therefore, there is a demand for balanced-line attenuators. Chains of symmetrical double-T or double-Π circuits, as shown in Fig. 5, are mostly used (10).

The reference handbooks (10) give formulas and tables to determine the circuit elements for a given line impedance and different element attenuations. The circuit has to be symmetrical to the ground plane and well matched to the line impedance. Special techniques are given to optimize the circuit for small frequency dependency.

Variable-value attenuators are commercially available for different impedances (150 Ω, 120 Ω) in the frequency range from dc to several megahertz and have attenuation ranges from 0 dB to 132 dB.

Coaxial-Line Attenuator

Fixed-Value Coaxial Attenuator. Coaxial attenuators generally have multi-octave bandwidth or frequently operate from dc to several gigahertz (GHz). Coaxial transmission lines are generally operated in the transverse electromagnetic (TEM) mode and therefore an obvious solution for attenuators is to use lumped elements that are small compared to the wavelength. There are four major constructions: T-circuit, Π-circuit, distributed lossy line and distributed thin-film technology.

T-Circuit Attenuator. The T-attenuator circuit is shown in Fig. 6. The values of R_1 and R_2 are calculated from the following formulas, where K is the transmission coefficient (7,10).

$$R_1 = Z_0 \frac{K - 1}{K + 1} \quad (14)$$

$$R_2 = \frac{2Z_0 K}{K^2 - 1} \quad (15)$$

Figure 5. Basic symmetrical double-T and double-Π attenuation circuits.

The attenuation in decibels is given by

$$A(\text{dB}) = 20 \log K \quad (16)$$

Resistive rods for R_1 are often used, and disk resistors are used for R_2 , or film resistors are used for both R_1 and R_2 .

Π-Circuit Attenuator. Techniques similar to the T-circuit are used for the Π-circuit shown in Fig. 7, and the corresponding formulas are as follows (7,10):

$$R_1 = Z_0 \frac{K + 1}{K - 1} \quad (17)$$

$$R_2 = Z_0 \frac{K^2 - 1}{2K} \quad (18)$$

At higher microwave frequencies the elements of the T- and Π-attenuators have dimensions comparable to the wavelength, and therefore the reactance of the elements gets more important and therefore degrades the performance of the attenuator.

Lossy-Line Attenuator. Distributed lossy-line attenuators, explained by Weber (11), have very favorable performance. As long as the attenuation is not very high, they have a flat attenuation response and an excellent impedance match. The center conductor of the transmission line is mostly made of lossy material using thin film deposited on a substrate with a circular cross section. The disadvantage of lossy-line attenuators is that they have a lower frequency limit depending on their physical length.

Thin-Film Attenuator. Distributed thin-film attenuators (12) use a resistive material deposited on a dielectric substrate for the series and shunt losses (Fig. 8).

Strip transmission lines and narrow ground electrodes on the longitudinal sides are added to the input and output terminals. The characteristic impedance and the attenuation are constant and given as follows (7):

$$Z_0 = \rho \sqrt{\frac{D - a}{4a}} \quad (\Omega) \quad (19)$$

$$\alpha = \sqrt{\frac{4}{a(D - a)}} \quad (\text{in nepers per unit length}) \quad (20)$$

Figure 6. T-attenuator circuit.

Equation 20 shows that the attenuation is independent of the resistivity of the film as long as the film is homogenous. The attenuation depends only on the geometry and therefore is insensitive to temperature changes.

Variable-Value Coaxial Attenuator. There are two types of variable attenuators: continuous variable attenuators and step attenuators. Continuous variable attenuators have the advantage of being noninterruptive when changing attenuation. This feature is important for some measurements, for example, receiver sensitivity measurements. On the other hand, these attenuators may sometimes lack accuracy, settability, impedance match, high insertion loss and have limited bandwidth.

Step attenuators are very accurate and have the following qualities: good reproducibility, low insertion loss, excellent impedance match, and wide operating bandwidth. But most step attenuators are interruptive when changing the attenuation value.

Continuously Variable Attenuator

Piston Attenuator (Waveguide Beyond Cutoff Attenuator). The piston attenuator is one of the oldest continuously variable microwave attenuators (13). It is used especially as a precision attenuator or for handling high power levels. This type of attenuator uses a waveguide below its cutoff frequency. According to transmission line theory, the amplitude of a wave launched into such a waveguide decays exponentially. So the attenuation is calculable. Most constructions use a circular cross section and a magnetic coupling that generates the lowest cutoff higher order transverse electric mode (TE_{11}). Figure 9 shows the simplified construction of a piston attenuator. By sliding the two concentric cylinders into each other, the physical displacement of the coupling coil is changed and therefore also the attenuation. Special care must be taken to avoid unwanted higher order modes.

Attenuation as a function of wavelength is given per unit length as (10)

$$A = \frac{2\pi \cdot 20}{\lambda_c \cdot \ln 10} \sqrt{1 - \left(\frac{\lambda_c}{\lambda}\right)^2} \quad \text{in decibels per unit length} \quad (21)$$

where λ_c is the cutoff wavelength of the waveguide and λ is the free-space wavelength.

Figure 7. Π-attenuator circuit.

Figure 8. Distributed thin-film attenuator element.

If the operating frequency is chosen to be much lower than the cutoff frequency, the term λ_c/λ is negligibly small for the operating frequency band, and a flat attenuation frequency response is achieved. The advantages of cutoff attenuators are that they are calculable and that high accuracy is achieved (0.001 dB/10 dB for 60 dB attenuation). For this reason, cutoff attenuators are often used as standard attenuators. Their main disadvantage is the high insertion loss (15 to 20 dB) because tight coupling has to be avoided so as not to stimulate higher modes.

Resistant Card, T-, or Π -Type Attenuator. Several constructions of variable attenuators using resistive cards or resistive films are on the market (9). The variable card attenuator operates like a potentiometer. A resistive film is fixed on a substrate so that the resistance between the input and the output is varied with a movable coaxial wiper, and thus the amount of attenuation changes. This type of attenuator does not have good input and output impedance matches. More sophisticated constructions use T- or Π -type structures where the series and the shunt resistors are changed simultaneously. Therefore the input and output ports of these attenuators are quite well matched. The minimum insertion loss is on the order of 4 dB, and they operate up to several gigahertz.

Lossy-Line Attenuator. Lossy-line attenuators use a lossy center conductor partly covered with a thin sliding shield (7). This effectively changes the length of the resistive conductor and thus the attenuation. Some constructions use microstrip lines with variable lossy walls (9). This type of attenuator is limited in its maximal attenuation because of the length of the device.

Pin Attenuator. Pin attenuators change the loss in either a step or continuous mode. The series and shunt resistors are replaced by *pin* diodes, electronic devices that change their conductivity. The diodes are controlled by a bias current. Various types of circuits are available, such as series, shunt, bridged T, and Π (9). *Pin* attenuators are electronic circuits and therefore

Figure 9. Principle of a piston attenuator.

Figure 10. Principle of a waveguide flap attenuator.

may produce harmonics. Below about 10 MHz, the *pin* diode exhibits some rectifying behavior. At much higher frequencies, the *pin* diode behaves more like a variable resistor. Because of the matching circuits for input and output and the bias network, most devices operate in a limited frequency band. Attenuation from 2 dB to 80 dB is achieved.

Step Attenuator. Step attenuators always use a set of fixed attenuators that are switched into a line by different mechanisms. The steps are mostly 0.1 dB, 1 dB, and 10 dB. The 0.1 dB steps generally cover a range of 1.1 dB, the 1 dB steps a range of 11 dB, and the 10 dB steps cover a range up to 110 dB. The step attenuator has excellent repeatability, covers a wide frequency range (e.g., dc to 26.5 GHz), has a good impedance match, and mostly has a flat frequency response of the attenuation value.

In the turret-type coaxial attenuator a set of coaxial fixed attenuators is placed in a cylindrical arrangement. With a rotary motion the different elements (e.g., 0 dB, 10 dB, 20 dB, ...) are switched between the junctions of the transmission line.

Another type of step attenuator uses a variety of fixed attenuation elements. The different attenuation elements are cascaded by switches or bypassed. The switches may be activated manually or electrically.

Waveguide Attenuator

Waveguide attenuators work mostly in the entire usable waveguide bandwidth, which is not quite half an octave. To attenuate a wave propagated in a waveguide, either the electric or the magnetic field or even both are influenced. As an example, a resistive card inserted into the waveguide parallel to the *E*-field attenuates it. Another technique uses lossy walls that influence the current in the waveguide wall. Most of these attenuators are not phase-invariant.

Fixed-Value Waveguide Attenuator. The waveguide flap attenuator (Fig. 10) and the side-vane attenuator (Fig. 11) (7) are very popular.

The flap attenuator is based on a resistive card inserted in the center of the waveguide parallel to the *E*-field. The more the card dives into the waveguide, the more the *E*-field is weakened, and therefore attenuation increases. A smooth

Figure 11. Principle of a side-vane attenuator.

Figure 12. Lossy-wall attenuator.

card shape is chosen to minimize the reflection caused by the discontinuity.

The side-vane attenuator (Fig. 11) influences the E -field similarly. The vane is always completely inside the waveguide, but it uses the fact that the E -field varies along the broad side. For the most popular TE_{10} mode, the E -field is zero at the side wall and has its maximum in the center of the waveguide. Therefore the position of the resistive card defines the attenuation value. A smooth shape minimizes the reflection of the discontinuity.

Several constructions of lossy-wall attenuators exist. One version is shown in Fig. 12 (14).

Section 2 with equally spaced slots filled with a lossy material defines the attenuation. Sections 1 and 3 are configured to minimize the reflection due to the discontinuity in the wall. The lossy-wall attenuator withstands high power because the dissipated heat is transferred to any cooling system.

Variable-Value Waveguide Attenuator

Flap and Side-Vane Attenuator. By adding a mechanism that changes the position of the resistive card, the fixed-value-flap and side-vane attenuator are easily transformed into a variable-value attenuator. It is often used as a settable attenuator.

Rotary-Vane Attenuator. The rotary-vane attenuator was invented in the early 1950s by E. A. N. Whitebread (Elliot H. Brothers, London) and A. E. Bowen (Bell Telephone Laboratories). It was proposed and developed as a precision waveguide attenuator (15–19). The rotary-vane attenuator consists of three sections of waveguide that have a resistive film spanned across the waveguide, as shown in Fig. 13. The middle section has a circular cross section and can be rotated with respect to the two fixed-end sections. Figure 13 illustrates the principle

of a rotary-vane attenuator. For clarity, the transitions from a round to a rectangular waveguide at both ends are omitted.

The electric field is perpendicular to all resistive films whenever the films are aligned. In this case no current flows in the resistive film, and therefore no attenuation occurs. If the center part is rotated by an angle θ , the component $E_{\sin\theta}$ in θ produce a current flowing in the resistive film and are absorbed. Thus the resulting attenuation is given by

$$A(\text{dB}) = -40 \log(\cos \theta) + A_0 \quad (22)$$

The rotary vane attenuator has the following advantages:

The attenuation is almost independent of the frequency.

The phase shift is very small. The phase variations are smaller than 1° up to 40 dB attenuation.

The input and output VSWRs are very low under all conditions.

The attenuation is not sensitive to the resistive film as long as its attenuation is high enough.

The attenuation is not sensitive to temperature changes.

Rotary vane attenuators are commercially available for most of the known waveguide bands. They typically have an accuracy of 2% of the reading in decibels or 0.1 dB, whichever is greater.

Attenuator for Optical Fibers

Attenuators have to be adapted to an optical fiber system. Therefore different attenuators for single-mode or multimode applications are available and mostly operate within one or two wavelength windows. Various attenuation techniques are used to reduce the transmitting light, such as lateral or axial displacement of the fibers or optical prisms, and inserting absorbing filters.

Fixed- or Adjustable-Value Attenuator. A pair of lenses is used in most fiber optical attenuators to collimate the light of the input fiber and to refocus it to the output fiber. Any attenuation mechanism, such as absorbing filters or absorbing glass with variable thickness can be inserted into the optical beam path. Attention has to be given to the attenuation mechanism so that there is very little polarization-dependent loss. Fixed-value attenuators are commercially available for a range of 3 dB to 40 dB with an accuracy of 0.5 dB to 1 dB.

Figure 13. Principle of a rotary-vane attenuator.

Figure 14. Basic configuration of an optical section.

Variable-Value Attenuator. The reflection type variable attenuator often combines a series of 10 dB steps for the high values and a continuous variable attenuation of up to 10 dB or 15 dB. Figure 14 shows the basic configuration of an optical section (20).

A rod lens collimates the light of the fiber into a spatial beam that passes two neutral density filters (ND-filter). The second rod lens focuses the spatial beam into the output fiber. The ND-filter must have high uniformity, little attenuation change with time, and flat spectral transmittance. This is achieved by vacuum-depositing Ni and Cr alloys onto a glass substrate. The ND-filters are the reflecting type. To avoid multiple reflections and to ensure that the light is not reflected into the input lead, the two filters are inclined at a small angle with respect to the optical axis.

Commercially available attenuators of this type have an insertion loss of about 3.5 dB, a range of up to 65 dB, and an accuracy of about ± 0.5 dB per 10 dB. They are available for wavelengths of 850 nm, 1300 nm, and 1550 nm.

Calculable Attenuation Standards

Many attenuators have been described in the previous sections, but only a few are suitable as attenuation standards. An attenuation standard is a device that can be traced to the SI

units by an unbroken chain. The application of the described standards depend on the frequency band and the technique used in the measurement system.

Kelvin–Varley Divider. The Kelvin–Varley divider (KVD) was described for the first time by Varley in 1866 (21). It is a resistive voltage divider and operates from dc up to several hundred kilohertz. Figure 15 is an example of a four-decade Kelvin–Varley divider.

Each decade consists of eleven equal resistors except for the last decade which has only ten. The decades are connected by switches that always span two resistors. The value of the resistors of each following decade is reduced by a factor of 5. The four-decade Kelvin–Varley divider allows varying the output-to-input voltage ratio from zero to one in steps of one part in 10^4 . The unloaded KVD has a constant input impedance that is independent of the switch setting whereas the output resistance varies with the setting. The original type of KVD (Fig. 15) requires either very large or very small resistance values because each decade needs five times larger values. Due to stray capacitance, the divider reacts similarly to an RC -filter. For example, a 100 k Ω input impedance limits the 3 dB bandwidth to about 100 kHz. To avoid large resistance values, modified constructions with a resistor shunting the decades have been developed.

Figure 15. Principle of a four-decade Kelvin–Varley divider.

Figure 16. Principle of a seven-decade IVD.

Two major errors determine the accuracy: deviations of the resistors from nominal values and the resistances of the switch contacts and leads. The first three or four decades are the most sensitive, and therefore these resistors often are adjustable. Several calibration techniques have been developed and are described in the literature (22,23).

Today commercially available Kelvin–Varley dividers have up to seven decades, have an absolute linearity of ± 1 part in 10^7 , and long term stability of ± 1 part in 10^6 per year.

Inductive-Voltage Divider. The inductive-voltage divider (IVD), also called a ratio transformer, is an exceptionally accurate variable attenuation standard. It consists of a number of very accurately tapped autotransformers. The autotransformers are connected together by high quality switches. The IVD operates from 10 Hz to about 100 kHz, and the greatest accuracy is achieved at about 1 kHz. In 1962 Hill and Miller (24) described a multidecade IVD with seven decades and a resolution of 1 part in 10^7 . Figure 16 shows the principle of a seven-decade IVD with a setting of 0.4324785. The output-to-input voltage ratio can be set from zero to one.

The tapped autotransformers are constructed by winding exactly equal lengths of copper wire on a high permeability toroidal core. A superalloy having an extremely high permeability ($>100,000$) and low hysteresis loss is preferred as a core material. For an exact division of the tapped autotransformer, it is not necessary to have a 100% coupling between the ten inductors (4). But the 10 self-inductances and the 45 mutual inductances have to be exactly equal.

The following error sources limit the accuracy of IVDs:

- inequality in the series resistances and the leakage inductances of the sections in each autotransformer
- inhomogeneities in the magnetic cores
- distributed admittances between the windings
- internal loading caused by the later stages
- impedances of the connecting leads and switch contacts
- variations in the input voltage, frequency, and ambient temperature

With careful design the mentioned errors can be minimized. Recently, programmable binary IVDs with 30 bits, a resolution

of 1 part in 10^9 , and a linearity of 0.1 ppm have been developed (25).

IVDs with eight decades and an accuracy of four parts in 10^8 are commercially available.

Intermediate-Frequency Piston Attenuator. The IF piston attenuator is based on the same principle as the attenuator previously described for RF, but it is designed to operate at a specific, fixed frequency, mostly 30 MHz or 60 MHz. As Eq. 21 shows, attenuation depends on the cutoff wavelength λ_c , the free-space wavelength λ , and the displacement of the two coils. The waveguide dimensions, which can be determined, define the cutoff wavelength, and the displacement can be measured very precisely. Therefore the IF piston attenuator is used as a calculable standard. Figure 17 shows a simplified diagram of an IF piston attenuator.

The standard IF piston attenuator consists of a high-precision circular cylinder that has excellent conductivity, a fixed coil, and a movable coil mounted on a piston. The piston attenuator operates in the H_{11} (TE_{11}) mode that has the lowest attenuation. A well-designed metal strip filter in front of the fixed coil attenuates the higher modes. To allow smooth movement and to avoid any scratches, the plunger carrying the moving coil is insulated. Equation 23 expresses the attenuation per unit length more precisely:

$$A = \frac{s_{11}}{r} \sqrt{1 - \left(\frac{\lambda_c}{\lambda}\right)^2} \cdot \epsilon - \frac{\delta}{r} \quad (23)$$

Figure 17. Simplified IF piston attenuator.

in nepers per unit length, where $\lambda_c = 2\pi r/s_{11}$, λ_c is the cutoff wavelength, λ is the free-space wavelength, s_{11} the first zero of the Bessel function $J_1 = 1.8411838$, r the radius of the cylinder, and δ is the skin depth.

Highly accurate standard attenuators use a laser interferometer to accurately determine the displacement of the coil. Yell (26,27) and Bayer (28) developed extremely accurate IF piston attenuators with a dynamic range of 120 dB, a resolution of 0.0001 dB, and an accuracy of 0.0002 dB/10 dB over the linear range of 90 dB.

Rotary-Vane Attenuator. The principle of the rotary-vane attenuator is described in the section Variable Waveguide Attenuator. Because the attenuation is given by the equation

$$A(\text{dB}) = -40 \log(\cos \theta) + A_0 \quad (24)$$

where A_0 is the insertion loss at a setting of $\theta = 0$, the device can be used as a calculable primary standard.

The rotating angle θ of the center vane has to be determined very precisely, especially for higher attenuation values. As an example, a rotational angle accuracy of $\pm 0.001^\circ$ results in an attenuation accuracy of ± 0.01 dB at a setting of 60 dB. Especially precise optical readouts have been developed by national standards laboratories (29–31) to allow an angular resolution of $\pm 0.001^\circ$. Following are the main error sources for precision rotary-vane attenuators:

- misalignment of the end vanes
- insufficient attenuation of the central vane
- incorrect readout of the rotational angle
- eccentricity of the rotor
- leakage of the rotating joints
- internal reflections at the ends of the three vanes

Careful design of the attenuator results in an accuracy of ± 0.0015 dB up to 16 dB at 10 GHz.

Comparison of Attenuation Standards. The attenuation standards mentioned previously are used in various precision measurement systems, such as RF-, IF- or LF-substitution. The standards have very different accuracy depending on the attenuation setting. Figure 18 shows a comparison of different precision attenuation standards used in national metrology laboratories (32).

Optical Attenuation Standards. Imamura (33) shows one solution of a calculable optical attenuation standard that is used to calibrate precision attenuators. The key element is a rotating disk with a well-defined opening. The device operates as an optical chopping system (Fig. 19).

As long as the response of the detector is slow compared to the rotational speed ω , the ratio P_1 to P_0 defines the attenuation. In this case the attenuation depends only on the opening angle θ (in radians) and is given by the following equation:

$$A = -10 \cdot \log \frac{P_1}{P_0} = -10 \cdot \log \frac{\theta}{2\pi} \quad (25)$$

An opening angle of 36° defines an attenuation of 10 dB. Special care has to be paid to the diffraction of light at the edges

Figure 18. Comparison of attenuation standards.

of the disk openings and the stability of the light source and the sensor. The overall accuracy is estimated to be ± 0.008 dB for 10 dB attenuation.

MEASUREMENT OF ATTENUATION

Various kinds of measurement systems are used depending on the frequency range, the type of attenuator, the required accuracy and the available standards. Most of the modern attenuation measurement systems are computer- or microprocessor-controlled. They use the same principle as the manual systems but operate much faster. If maximum accuracy is required, manually controlled measurement systems are often preferred.

Low-Frequency Measurement Systems

Low frequency attenuation measurements are used mainly in communication systems where voice, video and data have to

Figure 19. Principle of an optical chopping system.

Figure 20. Principle of a direct measurement system.

be transmitted with as little distortion as possible. Dedicated test systems have been developed for testing and adjusting the communication systems working either with coaxial lines (50 Ω or 75 Ω) or balanced lines (124 Ω , 150 Ω , or 600 Ω).

Direct Measurement. Operation of communication systems requires a great number of test systems for which low-cost test systems that are easily handled were developed. The systems are based on current, voltage, or power measurement and operate in a frequency band from 200 Hz up to 30 MHz. The test system (Fig. 20) consists of a tuneable generator with a known constant output level and a wide-band voltmeter or a high-sensitivity, selective superheterodyne receiver.

Many test systems can be switched to operate in either coaxial-line (50 Ω or 75 Ω) or balanced line (124 Ω , 150 Ω , or 600 Ω) configuration. In the balanced-line mode the test systems have a limited frequency range of 200 Hz to several MHz depending on the impedance selected. In the selective-level meter mode, bandwidths of 25 Hz to 3.1 kHz are used, and the dynamic range achieved is on the order of 80 dB. The attenuation measurement accuracy in the frequency range indicated is about 1 dB.

Low-Frequency Substitution Method. The LF-substitution method is based on a precisely calibrated low-frequency reference attenuator used in a parallel or a serial configuration (Fig. 21).

Because the attenuation of the device under test (DUT) is compared with that of the reference attenuator, neither the output level of the generator nor the absolute level indication of the receiver have to be known. The only requirements are that generator and receiver remain stable during measurements. The accuracy is determined mainly by the calibration of the reference attenuator.

Radio Frequency and Microwave

In radio frequency and microwave many different measurement principles are known. They all have their own characteristics: one is meant to measure low values of attenuation, another to measure high values, a third to achieve highest accu-

Figure 21. Principle of a LF-substitution method.

Figure 22. Principle of the power ratio method.

racy. The most popular measurement principles are discussed in the following sections.

Power Ratio Method. The power ratio method (4,40) (Fig. 22) is very simple for measuring attenuation. It is commonly used as long as maximum accuracy is not required.

The method is based on the linearity of the power meter or the receiver used. First the power P_1 of the generator is measured without the device under test (DUT) and then P_2 is measured with the DUT inserted. The attenuation of the DUT is calculated by the ratio of P_2 to P_1 :

$$A(\text{dB}) = 10 \log \frac{P_2}{P_1} \quad (26)$$

To measure attenuation, the insertion points have to be matched either by tuners or matching pads. The square law characteristic of the power sensors and the noise limit the dynamic range to about 40 dB. If a tuned receiver is used instead of a power meter, the measurement range is extended to about 100 dB.

Several error sources influence the accuracy:

- the stability of the generator and the detector system
- the frequency stability of the generator
- the matching at the insertion points
- the square law region of the detector system
- the crosstalk for high attenuation measurement

Commercially available systems using a tuned receiver achieve a measurement uncertainty of 0.1 dB at 50 dB attenuation. These systems are easily automated by controlling the instruments with a computer.

In national standards laboratories very sophisticated systems have been developed resulting in an accuracy of 0.06 dB at 50 dB attenuation (34,35).

Voltage Ratio Method. The voltage ratio method makes use of high resolution ac-digital voltmeters (ac-DVM) available now. Because the ac-DVMs work only up to several MHz, the RF signals have to be down-converted to low frequency. Figure 23 shows the principle of a voltage ratio system working at an audio frequency of 50 kHz.

If a synthesizer locked to the same reference frequency is used as a signal generator and local oscillator, a very stable audio frequency f_a (e.g., 50 kHz) is generated. The audio frequency signal is amplified and measured with an ac-DVM. If U_1 is the voltage measured with the two insertion points clamped together and U_2 is the voltage with the DUT inserted, the

Figure 23. Principle of the voltage ratio method.

attenuation is given by

$$A(\text{dB}) = 20 \log \left(\frac{U_2}{U_1} \right) + C \quad (27)$$

where C is the correction factor in decibels for the nonlinearity of the amplifier and the DVM.

The dynamic range of the direct system is about 20 to 30 dB. More sophisticated systems achieve an uncertainty less than 0.001 dB for 20 dB attenuation. By adding a gauge block technique, for example, a calibrated step attenuator (10, 20, 30, 40, 50, 60, 70 dB) in series with the DUT in the RF path, the range is extended to 90 dB with excellent accuracy of 0.001 dB (32).

The error sources which limit the measurement uncertainty are

- the matching of the insertion points
- the generator output level stability
- the AF-amplifier stability
- the AF-amplifier and ac-DVM linearity
- the mixer linearity
- the gauge-block attenuator stability and reproducibility
- the crosstalk for high attenuation measurement

IF-Substitution Method. The IF-substitution method (4,40) (Fig. 24) gives good accuracy, operates over a large dynamic range, and is used up to very high frequencies. Most systems operate in a parallel substitution mode.

The signal passing through the DUT is mixed to an IF of 30 or 60 MHz. This signal is compared with the signal of the 30 MHz reference oscillator and the standard attenuator by a narrowband 30 MHz receiver (mostly with synchronous detection). In a first phase the insertion points are clamped together, and the standard attenuator is adjusted until there is no

Figure 24. Principle of the IF-substitution method.

switching signal (i.e., 1 kHz) detectable any longer. The reading A_1 of the standard attenuator is taken. In a second phase the DUT is inserted, the standard attenuator is adjusted so that the signal of the standard attenuator equals the signal of the mixer, and the reading A_2 is taken. The attenuation of the DUT is given by the difference A_2 minus A_1 between readings.

A piston attenuator, an inductive-voltage divider, or a high-precision resistive attenuator can be used as a standard attenuator.

In national standards laboratories very high-precision piston attenuators with a resolution of 0.0001 dB over a 100 dB range have been used in a parallel substitution system. The accuracy achieved is better than 0.001 dB per 10 dB step (27,32,36).

Accuracy of about 0.002 dB and a dynamic range of 100 dB have been achieved by using a seven-decade 50 kHz inductive voltage divider in a parallel substitution system (37).

Weinert (38) proposed a parallel IF complex vector substitution system using a high precision IF attenuator. The system has a single-step dynamic range of 140 dB and a display resolution of 0.001 dB.

The following error sources limit the accuracy and the dynamic range:

- the matching at the insertion points
- the level stability of the signal source
- the mixer linearity
- the noise balance
- the level stability of the IF reference oscillator
- the standard attenuator resolution and stability
- the crosstalk for high attenuation measurement

RF-Substitution Method. In the RF-substitution method (4,40) (Fig. 25), the reference standard attenuator and the DUT operate at the same frequency. Because the attenuation of the reference standard is compared either in a series or in a parallel substitution system with the DUT, the results are independent of the receiver characteristics. A rotary-vane attenuator, a piston attenuator, or a chain of well-matched and precisely calibrated attenuators (e.g., step attenuator) is used as a reference standard.

In the first step the insertion points are clamped together, and the reference standard is adjusted to a value A_1 according to the estimated attenuation of the DUT. The receiver shows the reading U_1 . In the second step the DUT is inserted, and the reference standard is adjusted to get the same reading U_1 at the receiver A_2 . The attenuation of the DUT is calculated as the difference between the two decibel readings of the reference attenuator, A_1 minus A_2 .

Figure 25. Principle of the series RF-substitution method.

Scalar Measurement. All of the attenuation measurement systems described in the previous sections provide scalar measurements. There are many commercial scalar network analyzers available (Fig. 26) (8,39). These analyzers measure the input reflection and the attenuation of the device under test. Because mostly wideband detectors are used, only the magnitude of two quantities can be determined.

The signal of the sweep generator is divided by a power splitter or a directional coupler into reference and measurement paths. The directional bridge or coupler measures the reflected wave of the DUT. The analyzer forms the ratio A/R which is proportional to the input reflection coefficient of the DUT. Using a third detector, the attenuation is measured by calculating the ratio B/R . Most scalar network analyzers are microprocessor- or computer-controlled and offer simple correction methods. The calibration for reflection measurements is frequently done by using open and short circuits, and a connect through normalization is used for the transmission path. Because these analyzers are broadband systems, they operate very fast and are easily expandable to highest frequencies. Commonly used scalar network analyzers operate from 10 MHz to 18 GHz or 26 GHz, and often their frequency range can be extended to 50 GHz in coaxial lines and to 110 GHz in wave guides. The dynamic range is limited to about 75 dB by the square law characteristic of the detectors and noise. The measurement accuracy achieved is quite reasonable for example, 0.6 dB measuring a 30 dB attenuator. The insertion points have to be well matched.

The following errors influence the measurement uncertainty:

- the harmonics of the sweep generator;
- the matching of the insertion points;
- the square law characteristic of the detectors; and
- the sweep generator level stability.

Vector Measurement. Vector measurements enable characterising a two-port circuit completely. In addition to the magni-

tude, the phase of the scattering parameters is also determined. There are two major concepts for measuring the complex parameters of a two port device: the vector network analyzer and the six-port technique.

Modern vector network analyzers (8,39,40) measure all four scattering parameters: s_{11} , s_{21} , s_{12} , and s_{22} without the necessity of turning the DUT around. Therefore they are symmetrical (Fig. 27) and measure in both directions.

The basic concept looks similar to that of the scalar network analyzer. The signal of the generator is divided into reference and measurement paths. In forward measurements, the directional bridge A determines the reflected signal, bridge B determines the transmitted signal, and vice versa for the reverse case. Instead of using diode detectors, the signals are down-converted to an intermediate frequency and analyzed in magnitude and phase. Synthesized sweep generators and synchronous detection are being used to obtain high accuracy for magnitude and phase measurements. Because the complex signals are measured, the main errors due to component imperfections may be corrected. Frequently a 12-term error model is applied to correct the source and load match, the bridge characteristics, the transmission leakage cross talk and down-converter characteristics. In the first phase well-known standards (e.g., open, short, line) are measured, and the 12 error parameters are determined. In the second phase the DUT is measured and the data corrected according to the calculated error terms. Several different techniques for measuring the error parameters are used, such as open-short-load, transmission-reflect-line, line-reflect-line, etc. Each technique uses different kinds of reference standards, such as short and open circuits, well defined lines, known loads.

Excellent performance is achieved by using the 12-term error correction technique. For example, at 20 GHz, load and source match better than -38 dB return loss, transmission tracking is better than 0.06 dB and cross talk is less than -104 dB. As a result a 30 dB attenuator can be measured at 20 GHz with an uncertainty of 0.07 dB.

Vector network analyzers are commercially available in coaxial configurations in frequency bands from about 100 kHz to 50 GHz and in waveguides up to 110 GHz. Some specially dedicated systems operate in waveguides up to 1000 GHz.

The measuring uncertainty is defined mainly by the following parameters:

- accuracy of the reference standards
- stability of the generator and of the detection system

Figure 26. Principle of a scalar network analyzer.

Figure 27. Principle of a vector network analyzer.

stability of the connection cables
 repeatability of the connectors
 accuracy of the built-in software to calculate the error parameters and DUT scattering parameters

The six-port technique is another method for measuring the complex scattering parameters of a device. The magnitude and the phase of the signal are calculated from four scalar power measurements made with detectors arranged as shown in Fig. 28 (8,40).

The four power sensors gather enough information to calculate the magnitude and phase of the reflection of the DUT and the power launched into it. The calibration of the six-port device is rather complicated because a set of quadratic equations has to be solved. The quadratic equations can be linearized and solved for both calibration and measurement (8,40).

The simplicity of the detection system is an advantage of the six-port device especially for wideband applications and very high operating frequencies. Compared to the vector network analyzer, the six-port device requires more calibration and more complicated mathematics.

Two six-port devices connected in the configuration shown in Fig. 29 are required to provide attenuation measurements.

Figure 28. Principle of six-port technique for reflection measurement.

The dividing circuit includes phase adjustments to obtain different ratios b_1/b_2 at the terminals of the DUT. Using state-of-the-art power sensors the dynamic range of a dual six-port device is as large as 60 dB.

To achieve maximum accuracy, through connection, reflection line TRL-calibration is frequently used. Because the six-port device determines the complex parameters during the calibration process, the test ports appear well matched. The measurement uncertainties are primarily limited by the calibration standards, mainly the reflection standard (short or open). Real-time operation is limited by the computing time and the response time of the power sensors.

Fiber Optics

Three main methods (41,42) are used for attenuation measurements: the insertion loss technique, the cut-back technique, and the backscattering method. The first two methods perform two-point (end to end) measurements and the last performs a one-ended characterization. Some of the methods are standardized (43,44).

Insertion Loss Method. The insertion loss technique consists of a stable laser source and a stable, accurate, optical power meter. The power P_2 of the laser source is sent into the DUT (e.g., an optical fiber), and the power P_3 is measured at the far end. The attenuation is given by the ratio of the two power

Figure 29. Principle of a dual six-port for s-parameter measurement.

Figure 30. Principle of the insertion-loss method.

levels as

$$A(\text{dB}) = 10 \log \left(\frac{P_3}{P_2} \right) \quad (28)$$

To achieve more accurate measurements in the first phase, the power of the source is directly measured and is remeasured in the second phase with the DUT inserted. More sophisticated measuring systems use a configuration shown in Fig. 30.

A second power sensor measures the power level of the source instantaneously by a power divider. In this configuration the power stability of the source is less important because P_1 is always used as a reference. By using cooled detectors, a dynamic range up to 90 dB is achieved.

The accuracy of the measurements is determined by the following factors:

- the power level and wavelength stability of the source
- the calibration and stability of the power sensors
- the reproducibility of the connectors
- the linearity of the detectors

The measurement uncertainties for the insertion-loss technique are on the order of 0.9 dB including the connector reproducibility. Sophisticated systems reach over a limited dynamic range of 50 dB and uncertainty of 0.2 dB.

Cut-Back Method. The cut-back method (41,45) (Fig. 31) is the most accurate technique, but it is destructive. This method was developed to measure the attenuation of fibers as a function of the wavelength. Using a light source combined with a monochromator, a fiber can be tested at any wavelength from 800 nm to 1600 nm with a spectral width of 3 nm. The light from the source is projected into the fiber by a lens.

The power $P_2(\lambda)$ is measured at the far end of the fiber (test length l_t) by using a cooled detector. Then the fiber is cut back

to a short length of 2 m to 3 m without changing the projecting conditions, and the power $P_1(\lambda)$ is recorded. If the power loss in the short length of fiber is assumed to be negligible, the attenuation is given by the following equation:

$$A(\lambda) = 10 \log[P_2(\lambda)/P_1(\lambda)] \quad (29)$$

Assuming a uniform fiber, the attenuation coefficient per unit length of the fiber is given by

$$\alpha(\lambda) = \frac{A(\lambda)}{(l_t - l_r)} \quad (30)$$

where l_t and l_r are given in kilometers. The achieved uncertainty for cable length of several kilometers is about 0.02 dB/km for multimode fibers and 0.004 dB/km for single mode.

Backscattering Method. The backscattering method is a one-ended measurement based on Rayleigh scattering in an optical fiber (41,46). Figure 32 shows the principle of an optical time-domain reflectometer (OTDR).

A laser pulse is projected into the fiber by a coupler, and the backscattered power is measured. The backscattered power is related to the attenuation loss of the fiber and the measured time delay is related to the distance in the fiber. The attenuation is calculated by using two values of the backscattered power at different time delays (different locations along the fiber). The OTDR has the advantage of providing attenuation and reflection information along the fiber. A typical recording is shown in Fig. 33.

The length of the pulse is responsible for the dead zone where no measurement is possible. A lead-in fiber allows masking the dead zone. From the measured data details in the fiber path, such as connector loss or splice loss, irregularities of attenuation and defects are analyzed.

Commercially available OTDRs have a dynamic range of about 35 dB and cover distances up to 65 km depending on the

Figure 31. Principle of the cut-back method.

Figure 32. Principle of an optical time-domain reflectometer.

fiber loss. A well-calibrated OTDR can produce a measurement uncertainty of about 0.02 dB/km.

ERRORS AND UNCERTAINTIES IN ATTENUATION MEASUREMENTS

Whenever measurements are made, the results differ from the true or theoretically correct values. The differences are the result of errors in the measurement system, and it should be the aim to minimize these errors. In practice there are limits because no measurement instruments operate perfectly. A statement of measurement uncertainty reflects the quality of the measured results, and it has to be accompanied by a statement of confidence.

The International Committee for Weights and Measures (CIPM) (47) has published a guide for expressing uncertainty in measurements which has been adopted by the European Cooperation for Accreditation of Laboratories (EA) (48). According to the guide, uncertainty is grouped in two categories: Type A and Type B.

Type A evaluation is the result of statistical analysis of a series of repeated observations and therefore includes random effects.

Type B evaluation is by definition other than Type A, for example, judgment based on data of calibration certificates, experiences with instruments, and manufacturers' specifications.

Type A Evaluation of Uncertainty Components

Random effects result in errors that vary unpredictably. For an estimate of the standard deviation $s(q_k)$ of a series of n readings, q_k is obtained from

$$s(q_k) = \sqrt{\frac{1}{(n-1)} \sum_{k=1}^n (q_k - \bar{q})^2} \quad (31)$$

where $\bar{q}$ is the mean of n measurements.

Figure 33. Typical backscattering signature of a fiber.

Figure 34. Example of an attenuation measurement system.

The random component of uncertainty is reduced by repeating the measurements. This yields the standard deviation of the mean $s(\bar{q})$

$$s(\bar{q}) = \frac{s(q_k)}{\sqrt{n}} \quad (32)$$

The standard uncertainty of the input estimate $\bar{q}$ is the experimental standard deviation of the mean (for $n \geq 10$)

$$u(\bar{q}) = s(\bar{q}) \quad (33)$$

Type B Evaluation of Uncertainty Components

Systematic effects that remain constant during measurements but change if the measurement conditions are altered cannot be corrected and therefore contribute to uncertainty. Other contributions arise from errors that are not possible or impractical to correct for, such as from calibration certificates or manufacturers' specifications. Most of these contributions are adequately represented by a symmetrical distribution. In RF metrology three main distributions are of interest: normal, rectangular, and U-shaped.

Normal Distribution. Uncertainties derived from multiple contributions are assumed to be normally distributed. Accredited calibration laboratories issue calibration certificates calculated for a normal distribution and a minimum level of confidence of 95% (approximate coverage factor $k = 2$). The standard uncertainty associated with the estimate x_i is given by

$$u(x_i) = \frac{\text{uncertainty}}{k} \quad (34)$$

Rectangular Distribution. This means that there is equal probability that the true value lies between limits. This is the case for most manufacturers' specifications that give a semi-range limit a_i :

$$u(x_i) = \frac{a_i}{\sqrt{3}} \quad (35)$$

U-Shaped Distribution. This distribution is applicable to mismatch uncertainty (49). Because the phases of the reflection coefficients (of source, DUT, load) in scalar measurement are not known, the mismatch loss has to be taken into account as an uncertainty. The mismatch uncertainty is asymmetrical to the measured result, and normally the larger of the two limits $M = 20 \log(1 - |\Gamma_G| |\Gamma_L|)$ is used. The standard uncertainty is

calculated as

$$u(x_i) = \frac{M}{\sqrt{2}} \quad (36)$$

Combined Standard Uncertainty

The combined standard uncertainty for uncorrelated input quantities is calculated as the square root of the sum of the squares of the individual standard uncertainties:

$$u_c(y) = \sqrt{\sum_{i=1}^m u_i^2(y)} \quad (37)$$

Expanded Uncertainty

The expanded uncertainty U defines an interval in which there is the true value with a specified confidence level. Normally accredited calibration laboratories are asked to use the coverage factor $k = 2$ (approximately 95% confidence level) giving:

$$U = k \cdot u_c(y)$$

Uncertainty in Attenuation Measurement

Let us assume a simple attenuation measuring setup, shown in Fig. 34, consisting of a generator, two matching circuits and a receiver. In the first phase when the two insertion points are clamped together, the receiver measures $P_1(f)$ (often called a normalization). In the second phase the DUT is inserted, and the receiver reads the values $P_2(f)$.

Attenuation as a function of the frequency is calculated from the ratio of the two sets of readings:

$$A(f) = 10 \log \left[\frac{P_2(f)}{P_1(f)} \right] \quad (38)$$

The following errors contribute to the uncertainty of the measurement:

The statistical errors of n repeated measurements (Type A) are given by the arithmetic experimental standard deviation:

$$s(A) = \sqrt{\frac{1}{(n-1)} \sum_{k=1}^n (A_k - \bar{A})^2} \quad (39)$$

($\bar{A}$ is the arithmetic mean of the measurements)

The standard uncertainty is calculated from

$$u_s(A) = s(\bar{A}) = \frac{s(A)}{\sqrt{n}} \quad (40)$$

The generator level stability a_G is taken from the manufacturer's specification and is assumed to be rectangularly distributed. The uncertainty is calculated as follows:

$$u_G = \frac{a_G}{\sqrt{3}} \quad (41)$$

The receiver level linearity and stability a_R is taken from the manufacturer's specification. The uncertainty is calculated as

$$u_R = \frac{a_R}{\sqrt{3}} \quad (42)$$

The noise level of the receiver influences the measurement of high attenuation values. It is given in the manufacturer's specification and contributes to the uncertainty as

$$u_N = \frac{a_N}{\sqrt{3}} \quad (43)$$

The cross talk of the measurement system a_I is determined by measurements and regarded as limits, and therefore contributes to the uncertainty as

$$u_I = \frac{a_I}{\sqrt{3}} \quad (44)$$

Two mismatch losses have to be taken into account, one during the normalization (often also called calibration) phase and the second while measuring the DUT.

Normalization Phase. The maximum mismatch loss (49) is calculated from the reflection coefficients of the source and the receiver as

$$M_C = 20 \log(1 - |r_G||r_L|) \quad (45)$$

As in scalar measurements, the phases of the reflection coefficients are unknown. The mismatch loss contributes to the measurement uncertainty and is normally assumed to be U-shaped distributed:

$$u_C = \frac{M_C}{\sqrt{2}} \quad (46)$$

Measurement Phase. There are two mismatch losses (49) that have to be considered: one between the generator and the input of the DUT and the other between the output of the DUT and the receiver. In addition, for small attenuation values the interaction between the input and the output connection has to be considered. The maximum limits of the mismatch loss which have to be used for the uncertainty are given by

$$M_m = 20 \log \frac{|1 - |r_G s_{11}| - |r_L s_{22}| - |r_G r_L s_{11} s_{22}| - |r_G r_L s_{21} s_{12}|}{1 - |r_G r_L|} \quad (47)$$

The uncertainty is given by

$$u_m = \frac{M_m}{\sqrt{2}} \quad (48)$$

The total uncertainty is calculated either from linear values or from decibel values as long as they are small:

$$u_c(A) = \sqrt{u_s^2 + u_G^2 + u_R^2 + u_N^2 + u_I^2 + u_C^2 + u_m^2} \quad (49)$$

The expanded uncertainty is calculated using a coverage factor $k = 2$ (approximately 95% confidence level) as

$$U(A) = k \cdot u_c(A) = 2 \cdot u_c(A) \quad (50)$$

The uncertainty has to be calculated for all of the measurement frequencies to find the maximum value of the uncertainty.

LOSS-ANGLE MEASUREMENT

Dielectrics, in the most general sense, may be considered as the broad class of *nonmetals* from the standpoint of their interaction with electric and magnetic fields. Hence gases, liquids, and solids can all be included, both with respect to their ability to store electric and magnetic field energy, as well as the accompanying dissipative processes occurring in the material when placed in an electric or magnetic field. How these phenomena can be described macroscopically and interpreted from the standpoint of molecular theory, how they can be accurately measured, and what the properties of various materials are provides the groundwork for their use in the rapidly growing microelectronic applications that shape much of our world today.

In a more narrow sense, dielectric materials may be classified from basic principles of the *energy-band model* as electrical insulators. The energy-band model forms the basis for development of all components in solid-state electronics. This model shows that the possible energies of electrons in a crystal are grouped in a certain number of allowed energy bands separated from one another by forbidden energy bands. The position of the Fermi energy, or energy of the topmost filled electron level in the sequence of allowed and forbidden bands, permits a unified treatment of metals, semiconductors, and insulators. According to the energy-band model, matter becomes dielectric (a poor conductor of electricity) when the conduction band and the valence band are separated by an energy gap higher than 5 eV. At normal temperatures only a small number of electrons have sufficient thermal energy necessary to make a transition to the conduction band. When temperature increases, the transition probability increases and the electrical conductivity σ can be written as

$$\sigma = \sigma_0 e^{-W/k_B T} \quad (1)$$

where W is the activation energy of the conduction process, k_B is Boltzmann's constant (1.38062×10^{-23} J/K), and T is the absolute temperature. In general, Eq. (1) is valid for crystalline and amorphous dielectrics, as well as partially crystalline dielectrics such as polymers.

Materials, whether in the solid, liquid, or gaseous states, may be electrically nonlinear, anisotropic, inhomogeneous, and dispersive both with respect to frequency and temperature.

Dissipation results from loss mechanisms that can differ in different types of materials. Because of all these complicating factors, both measurement technique and accuracy for evaluation of dielectric properties are requisite for physical understanding. Dielectric-loss-angle measurements reflect the different loss mechanisms occurring in a material placed in an electric field. This article addresses various measurement techniques for dielectric loss angle and permittivity evaluation of materials and is organized as follows:

- Electromagnetic characteristics of materials (constitutive equations, anisotropy, polar versus nonpolar materials, free charge versus bound charge, complex refractive index, polarization mechanisms, dispersion and relaxation processes)
- Permittivity and dielectric-loss-angle measurements (low-frequency complex impedance, free-space measurements for solids, liquids and gases, waveguide transmission and reflection techniques, resonance methods, and anisotropic material measurements)

ELECTROMAGNETIC CHARACTERISTICS OF MATERIALS

Physical Concepts Governing Electromagnetic Behavior

Any material is electromagnetically characterized by its permittivity ϵ (F/m), magnetic permeability μ (H/m), and electrical conductivity σ (S/m). Maxwell's equations, together with the constitutive equations relating field quantities in terms of material properties, completely govern electromagnetic wave propagation and behavior in that medium.

The constitutive equations for a linear, homogeneous, and isotropic medium may be expressed in the frequency domain as

$$\begin{aligned} \mathbf{B} &= \mu \mathbf{H} \\ \mathbf{J} &= \sigma \mathbf{E} \\ \mathbf{D} &= \epsilon \mathbf{E} \end{aligned} \quad (2)$$

where the magnetic induction $\mathbf{B}$ (Wb/m²) is related to the magnetic field $\mathbf{H}$ (A/m) by the magnetic permeability, the current density $\mathbf{J}$ (A/m²) is related to the electric field $\mathbf{E}$ (V/m) by the conductivity, and the dielectric displacement field $\mathbf{D}$ (C/m²) is related to the electric field by the permittivity. Any deviation from linearity is usually included by making ϵ , μ , or σ field dependent. For anisotropic media, ϵ , μ , or σ is a second-rank tensor as opposed to just a scalar function of frequency or simply a constant. For inhomogeneous media, ϵ , μ , or σ is a function of spatial coordinates. Material dielectrics that are linear, isotropic, and homogeneous when placed in an electric field at one frequency may not be isotropic or homogeneous when placed in an electric field at another frequency or under different temperature or pressure conditions. Similarly, dielectrics that behave linearly when placed in weak electric fields may not be linear in strong fields (or at high temperatures).

Anisotropy

When a dielectric is placed in an electric field $\mathbf{E}$, the material becomes polarized, and the dielectric displacement field is often

written

$$\mathbf{D} = \epsilon_0 \mathbf{E} + \mathbf{P} \quad (3)$$

where $\mathbf{P}$ is defined as the electric polarization of the material (dipole moment per unit volume), and is related to the electric field as

$$\mathbf{P} = \epsilon_0 \chi \mathbf{E} \quad (4)$$

The proportionality constant χ is called the electric susceptibility, and the factor ϵ_0 (free-space permittivity equal to 8.854×10^{-12} F/m) is included in Eq. (3) to make χ dimensionless. Then Eq. (2) becomes

$$\mathbf{D} = \epsilon_0(1 + \chi) \mathbf{E} \quad (5)$$

or

$$\mathbf{D} = \epsilon_0 \epsilon_r \mathbf{E} \quad (6)$$

where $\epsilon_r = 1 + \chi$ is called the complex permittivity of the medium relative to a vacuum. The presence of a dielectric always affects the ratio of $\mathbf{D}$ to $\mathbf{E}$ by a factor of ϵ_r . For *linear* materials the dipole moment induced in a dielectric by an external field $\mathbf{E}$ is directly proportional to $\mathbf{E}$. As long as the electric properties of the dielectric are independent of direction of the applied electric field, it is *isotropic*; that is, $\mathbf{P}$ and $\mathbf{E}$ are collinear. For an *anisotropic* material, however, the polarization (or charge separation) obtained when an electric field is applied along one coordinate axis will be different from that produced by the same field applied along a different coordinate axis. Quantitatively, this can be expressed by writing

$$\mathbf{P} = \epsilon_0 \bar{\bar{\chi}} \cdot \mathbf{E} \quad (7)$$

where $\bar{\bar{\chi}} = \chi_x \mathbf{i}\mathbf{i} + \chi_y \mathbf{j}\mathbf{j} + \chi_z \mathbf{k}\mathbf{k}$ and χ_x, χ_y, χ_z are the principal components of the electric susceptibility tensor expressed in dyadic form. For isotropic materials $\chi_x = \chi_y = \chi_z$, and Eq. (7) reduces to Eq. (4). Equation (7) shows that $\mathbf{P}$ and $\mathbf{E}$ are not collinear when $\chi_x \neq \chi_y = \chi_z$ or when $\chi_x = \chi_y \neq \chi_z$ or when $\chi_x \neq \chi_y \neq \chi_z$ (for two- or three-dimensional anisotropy), so that the electric susceptibility tensor may, in general, be viewed as an operation that takes a vector $\mathbf{E}$ and converts it into a new vector $\mathbf{P}$ that is not collinear with $\mathbf{E}$.

Polar versus Nonpolar Materials

Dielectric materials may also be divided into one of two categories: *polar* and *nonpolar*. A nonpolar material (such as inert or rare gases) is simply one that contains no (equivalent) dipoles (or separation of charge) when the material is not in an electric field. A polar material, on the other hand, possesses permanent polarization, even in the absence of an electric field, due to its molecular structure. Polar materials have permanent dipole moments at the microscopic or molecular level. A common polar molecule is the water molecule whose equivalent dipole moment results from a 104° angle between the two OH^- anions; this can be contrasted with the CO_2 molecule, in which the individual moments of each CO pair cancel, yielding a zero permanent moment.

In general, any distribution of charge may be described in terms of its multipole moments (1). The relevance of this discussion to dielectric material properties is that the existence of permanent dipole moments on the molecular level gives rise to a type of polarization mechanism when an electric field is applied that is frequency-dependent. Without an applied electric field in the case of the water molecule, the individual molecular dipole moments point in random directions, so that macroscopically their vector sum vanishes. In the presence of the applied electric field $\mathbf{E}$, though, there is a pronounced tendency of the dipoles to line up in the direction of $\mathbf{E}$, creating an *orientational* polarization whose magnitude can be computed and measured (2).

Ferroelectric materials are those in which there is spontaneous alignment of electric dipole moments at the molecular level. This occurs in ferroelectric materials at the Curie temperature. The permittivity of a ferroelectric material is field-strength dependent, which allows ferroelectric materials to be used in a variety of nonlinear devices, such as piezoelectric transducers, voltage-controlled oscillators, varactors, tunable filters, and phase shifters.

Complex Material Constituent Properties

The solution of Maxwell's equations yields all of the quantities that describe the propagation of electromagnetic waves in terms of the propagation constant $\sigma = jk$, where k is the complex wavenumber defined by

$$k^2 = \omega\mu(\omega\epsilon - j\sigma) \quad (8)$$

for $\exp(+j\omega t)$ time dependence for angular frequency ω and time t .

In general, the constituent electrical properties may be written as complex quantities; that is, for $\exp(+j\omega t)$ time dependence

$$\begin{aligned} \epsilon &= \epsilon' - j\epsilon'' = (\epsilon'_r - j\epsilon''_r)\epsilon_0 = \epsilon_r\epsilon_0 \\ \sigma &= \sigma' + j\sigma'' \\ \mu &= \mu' - j\mu'' = (\mu'_r - j\mu''_r)\mu_0 = \mu_r\mu_0 \end{aligned} \quad (9)$$

where μ_0 is the free-space permeability equal to $4\pi \times 10^{-7}$ H/m. Each component of ϵ , σ , or μ (which for anisotropic materials are tensor matrices) is, in general, a complex quantity. The imaginary part of the propagation constant contains all necessary information about energy loss in a material medium during wave propagation. If magnetic properties are ignored, we may consider only the complex form of ϵ and σ in Eq. (8):

$$\omega\epsilon - j\sigma = \omega(\epsilon' - j\epsilon'') - j(\sigma' + j\sigma'') = (\sigma'' + \omega\epsilon') - j(\sigma' + \omega\epsilon'') \quad (10)$$

Here $\omega\epsilon' + \sigma''$ may be considered an effective permittivity and $\sigma' + \omega\epsilon''$ as an effective conductivity. The term $\sigma' + j\sigma''$ physically represents carrier transport due to Ohmic and Faraday diffusion mechanisms, whereas $\epsilon' - j\epsilon''$ represents dielectric relaxation mechanisms. From Eq. (10), the loss tangent is simply defined as

$$\tan \delta = \tan\left(\psi + \frac{\pi}{2}\right) \equiv \frac{\sigma' + \omega\epsilon''}{\sigma'' + \omega\epsilon'} \quad (11)$$

where ψ is the phase between $\mathbf{E}$ and $\mathbf{J}$. If there are no dielectric losses, $\epsilon'' \rightarrow 0$. Similarly, if there are no Faraday losses, $\sigma'' \rightarrow 0$; hence

$$\tan \delta = \frac{\sigma'}{\omega\epsilon'} \quad (12)$$

which describes losses physically due to Ohmic conductivity.

Distinction between Ohmic Conductivity (σ') and Dielectric Loss Factor (ϵ'') or between Faraday Diffusion Transport (σ'') and In-Phase Polarization Phenomena (ϵ')

It is often stated that it is artificial to make distinctions between Ohmic carrier transport phenomena and dielectric loss characteristics of a material when that material is placed in a time-varying electric field. Actual dielectric measurements are indifferent to the underlying physical processes. To the extent, however, that physical and chemical processes are understood, distinctions can be made and materials designed to have certain electromagnetic characteristics.

The lack of distinction between two loss mechanisms from only measurement data can be seen by inspection of Eq. (11). Another way to see the relation between conductivity and the imaginary part of the permittivity is to write Ampere's law,

$$\nabla \times \mathbf{H} = \mathbf{J} + \frac{\partial \mathbf{D}}{\partial t} \quad (13)$$

where $\mathbf{J}$ is the conduction current in a material medium due to an applied electric field. For sinusoidal fields, Eq. (13) can be rewritten as

$$\begin{aligned} \nabla \times \mathbf{H} &= \sigma \mathbf{E} + \epsilon \frac{\partial \mathbf{E}}{\partial t} \\ &= (\sigma + j\omega\epsilon_0\epsilon_r) \mathbf{E} \\ &= j\omega \left[\epsilon_r' - j \left(\epsilon_r'' + \frac{\sigma}{\epsilon_0\omega} \right) \right] \epsilon_0 \mathbf{E} \end{aligned} \quad (14)$$

Hence, without other physical information, a conductivity σ is equivalent to an imaginary part of ϵ given by

$$\epsilon_r'' = \frac{\sigma}{\omega\epsilon_0} \quad (15)$$

so an equivalent form of Eq. (12) is

$$\tan \delta = \frac{\epsilon''}{\epsilon'} = \frac{(\text{loss current})}{(\text{charging current})} \quad (16)$$

Time-Domain Dielectric Constitutive Equation

The permittivity ϵ in Eq. (2) is defined for a time-harmonic electromagnetic phasor field at a certain frequency ω . If the permittivity is independent of frequency, the relationship in the time domain is simply expressed by

$$\mathbf{D}(\mathbf{r}, t) = \epsilon \mathbf{E}(\mathbf{r}, t) \quad (17)$$

However, if the permittivity is a function of frequency, the

temporal relationship is a Fourier transform of the product of $\epsilon(\omega)$ and $\mathbf{E}(\omega)$ and is therefore given by the convolution integral

$$\mathbf{D}(\mathbf{r}, t) = \int_{-\infty}^t h(t - \tau) \mathbf{E}(\mathbf{r}, \tau) d\tau \quad (18)$$

where

$$h(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \epsilon(\omega) e^{j\omega t} d\omega \quad (19)$$

$$\mathbf{E}(\mathbf{r}, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \mathbf{E}(\mathbf{r}, \omega) e^{j\omega t} d\omega \quad (20)$$

The medium whose permittivity is a function of frequency $\epsilon(\omega)$ is called dielectrically dispersive. Although, strictly speaking, all media are dispersive, a medium can often be treated as nondispersive within a frequency range used for a particular problem.

If a medium is linear but varies with time, the relationship between $\mathbf{D}$ and $\mathbf{E}$ cannot be expressed as the convolution integral, Eq. (18). The general relationship should then be given by

$$\mathbf{D}(\mathbf{r}, t) = \int_{-\infty}^t h(t, t - \tau) \mathbf{E}(\mathbf{r}, \tau) d\tau \quad (21)$$

Substitution of Eq. (20) into Eq. (21) yields

$$\mathbf{D}(\mathbf{r}, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \epsilon(t, \omega) \mathbf{E}(\mathbf{r}, \omega) e^{j\omega t} d\omega \quad (22)$$

where $\epsilon(t, \omega)$ is the time-varying permittivity given by

$$\epsilon(t, \omega) = \int_0^{\infty} h(t, \tau) e^{j\omega\tau} d\tau \quad (23)$$

Time-varying media will not be discussed in this article.

Complex Refractive Index

For a nonabsorbing medium the refractive index is defined as c/u , where $c = 1/\sqrt{\mu_0\epsilon_0}$ is the velocity of propagation in free space and u is the phase velocity in the material ($c/\sqrt{\mu_r\epsilon_r}$). For a dielectrically lossy medium a *complex refractive index* $n - j\kappa$ is defined such that

$$n - j\kappa = \frac{c}{u} = \frac{ck}{\omega} \quad (24)$$

so that

$$n^2 - \kappa^2 = \epsilon_r' \mu_r' \quad (25)$$

and

$$2n\kappa = \frac{\sigma \mu_r'}{\epsilon_0 \omega} \quad (26)$$

where κ is the *absorption loss index*. The *absorption coefficient* α is related to the absorption loss index by $\alpha = 2\omega\kappa/c$. For a

nonmagnetic material, Eqs. (25) and (26) may be solved for the refractive index and absorption loss index,

$$n = \frac{1}{\sqrt{2}} \left[\sqrt{(\epsilon'_r)^2 + (\epsilon''_r)^2} + \epsilon'_r \right]^{1/2} \quad (27)$$

and

$$\kappa = \frac{1}{\sqrt{2}} \left[\sqrt{(\epsilon'_r)^2 + (\epsilon''_r)^2} - \epsilon'_r \right]^{1/2} \quad (28)$$

For small dissipation, where $\tan \delta \sim \delta$, $n \simeq \sqrt{\epsilon'_r}$, and $\kappa \simeq \delta \sqrt{\epsilon'_r}/2 = \epsilon''_r/(2\sqrt{\epsilon'_r})$.

Quality Factor of Dielectric

The *quality factor* Q of a dielectric at frequency f is defined as the inverse of the loss tangent,

$$\begin{aligned} Q &= \frac{1}{\tan \delta} = \frac{\epsilon'}{\epsilon''} = \frac{\omega \epsilon' E_0^2}{\omega \epsilon'' E_0^2} \\ &= 2\pi f \frac{\frac{1}{2} \epsilon' E_0^2}{\frac{1}{2} \sigma E_0^2} \\ &= 2\pi \frac{(\text{average energy stored per half cycle})}{(\text{energy dissipated per half cycle})} \end{aligned} \quad (29)$$

The quality factor Q is used as a descriptive characteristic of any dielectric material.

Polarization Mechanisms Intrinsic to Materials. A pulse or "signal" of any specified *initial* form can be constructed by superposition of harmonic wave trains of infinite length and duration. The velocities with which the constant-phase surfaces of these component waves are propagated depend on the propagation constant or on the parameters ϵ , μ , and σ . If the medium is nonconducting and the quantities ϵ and μ are independent of the frequency of the applied field, the phase velocity is constant and the signal is propagated without distortion. The presence of a loss mechanism, however, yields a functional relation between the frequency and phase velocity, as well as between frequency and attenuation. Hence in a lossy or absorptive medium the harmonic components suffer relative displacements in phase in the direction of propagation, and the signal arrives at a distant point in a modified form. The signal is *dispersed* and attenuated, and a medium in which the phase velocity is a function of frequency f (or in which the complex dielectric constant ϵ is a function of frequency) is said to be electrically dispersive.

The quantity $\epsilon'(f; x, y, z)$ is a measure of the polarization of the material. There can be a number of different polarizing mechanisms, each having a characteristic relaxation frequency and dielectric dispersion centered around this relaxation frequency. At the relaxation frequency there is maximal absorption. Figure 1 illustrates the dispersion of ϵ (and σ) that may be observed in materials in the frequency range 10^3 Hz to 10^{15} Hz. At the highest frequencies, the polarizing species in a material are the electrons. Electronic polarization occurs when an applied electric field causes a net displacement of the electron cloud of an atom with respect to its nucleus. At frequencies below about 10^{13} Hz, there is also a contribution from

Figure 1. Dielectric dispersion for various types of polarization.

atomic polarization. Atomic polarization occurs in structures (molecules, solutions) in which atoms do not share electrons equally and electric fields displace the electron clouds preferentially towards the stronger binding atoms. It also occurs when charged atoms are displaced with respect to each other. Dipolar polarization, that is, the orientation of polar molecules (molecules with asymmetric charge distributions), occurs at frequencies below about 10^{10} Hz.

At frequencies below about 10^5 Hz, there are various types of charge polarization that may be collectively referred to as Maxwell-Wagner mechanisms (3,4). One of these, interfacial (space-charge) polarization, occurs when migrating charge carriers are trapped or impeded in their motion by local chemical or electric potentials, causing local accumulations of charge and a macroscopic field distortion. Another low-frequency mechanism that can occur is due to mixtures of materials having differing electrical properties (such as conducting spheres embedded in a dielectric). Several different equations are available to describe the resultant properties for various geometries of the embedded conductor (5-7). The common cause of these effects is the distributions of charge that occur at conductor-dielectric boundaries and the resultant action under applied electric fields that can yield very large low-frequency dielectric constants.

Still another dispersion mechanism for dielectric behavior at low frequencies, which is often distinguished from Maxwell-Wagner effects, is that which occurs in colloidal suspensions. Maxwell-Wagner effects occur when the charge around conducting particles in a dielectric medium is a thin coating that is much smaller than the particle dimensions; the charge responds to an applied electric field independent of the charge on nearby particles. In colloidal suspensions, on the other hand, the charge layer is on the same order of thickness or larger than the particle dimensions; hence it is affected by the charge distributions of adjacent particles. Colloidal polarization responses result in far higher low-frequency dielectric constants than those resulting from typical Maxwell-Wagner mechanisms, with dielectric constants on the order of 10^5 not uncommon.

Dispersion and Relaxation Processes in Materials. Polarization occurring in material media as a result of electromagnetic wave propagation is physically damped by either resonance or relaxation. Resonance is the state of a harmonic oscillator that is driven at its preferred frequency. Relaxation, on the

Figure 2. Two differing types of dispersion and absorption processes occurring in dielectrics as a function of frequency: (a) relaxation and (b) resonance.

other hand, is the state of a critically damped or overdamped oscillator. The characteristics of ϵ' and ϵ'' for these two differing types of dispersion and absorption processes are shown in Fig. 2.

At microwave frequencies, dipolar or orientation polarization phenomena principally occur. In this case, the frequency is sufficiently low so that the rotation of polar molecules has time to take place. At a frequency of $\omega = 1/\tau$, ϵ' decreases because the individual dipoles can no longer keep in step with the applied field. The relaxation time τ represents the time required for the dipoles to revert to a random distribution. This is a diffusion process that is represented by Fig. 2(a). Atomic and electronic polarization processes take place in the infrared and optical portion of the spectrum (1 THz and above) and lead to the resonance-type dispersion and absorption phenomenon represented by Fig. 2(b). A given medium may display any or all of these characteristic polarization phenomena, depending on its composition and molecular or atomic structure.

Relaxation processes are those observed in dielectric materials at microwave frequencies and below. Relaxation models are based on the general equation of charge motion,

$$\ddot{q} + (\mu\sigma)^{-1}\dot{q} + (\mu\epsilon)^{-1}q = 0 \quad (30)$$

where q is the charge and the overdot represents differentiation with respect to time. Another relaxation model is based on the diffusion of charged ions whose concentration is spatially variable. In this case

$$\begin{aligned} & \frac{\partial^2}{\partial x^2} \overline{Q}(t; x, y, z) + \frac{\partial^2}{\partial y^2} \overline{Q}(t; x, y, z) + \frac{\partial^2}{\partial z^2} \overline{Q}(t; x, y, z) \\ &= \frac{\partial^2 \overline{Q}(t; x, y, z)}{\partial t^2} + \frac{1}{K} \frac{\partial}{\partial t} \overline{Q}(t; x, y, z) + \frac{\eta}{K} \overline{Q}(t; x, y, z) \end{aligned} \quad (31)$$

where $\overline{CTQ}$, the concentration of charged ions, is a function of spatial coordinates and time. $K(t)$ is the diffusion coefficient and η is a constant. In the latter model, spatial derivatives must be taken in determining diffusion relaxation, which, in terms of electrical circuit analogs, lead to generalized distributed impedances (as opposed to lumped impedances) and nonlinear behavior.

Debye Relaxation

Materials having single relaxation time constants are called Debye materials. The complex permittivity in a Debye material

is given by (8–10)

$$\epsilon' - j\epsilon'' = \epsilon_\infty + \frac{\epsilon_s - \epsilon_\infty}{1 + \omega^2\tau^2} - j \frac{(\epsilon_s - \epsilon_\infty)\omega\tau}{1 + \omega^2\tau^2} \quad (32)$$

where τ is the relaxation time, ϵ_s is the relative dielectric constant at zero frequency ($\epsilon_{dc} = \epsilon_s\epsilon_0$) and ϵ_∞ is the relative dielectric permittivity at infinite frequency. In general, apart from liquid dielectrics, single relaxations are seldom observed. Multiple relaxations or distributions of relaxations are instead found.

Generalized Relaxation Distributions

A generalized expression for material media in which multiple relaxations are found may be written as (11)

$$\epsilon' - j\epsilon'' = \epsilon_\infty + (\epsilon_s - \epsilon_\infty) \int_0^\infty \frac{D(\tau)(1 - j\omega\tau)}{1 + \omega^2\tau^2} d\tau \quad (33)$$

where $D(\tau)$ is the time-constant distribution function, normalized such that

$$\int_0^\infty D(\tau) d\tau = 1 \quad (34)$$

One of the most commonly observed simple relaxation distributions in lossy media is the Cole–Cole distribution. In the Cole–Cole distribution Eq. (33) reduces to

$$\epsilon' - j\epsilon'' = \epsilon_\infty + \frac{\epsilon_s - \epsilon_\infty}{1 + (j\omega\tau)^{1-m}} \quad (35)$$

where $0 \leq m \leq 1$. The loss tangent for the Cole–Cole distribution is

$$\tan \delta = \frac{\epsilon''}{\epsilon'} = \frac{\theta(\omega\tau)^{1-m} \sin \left[(1-m) \frac{\pi}{2} \right]}{1 + \theta + (2 + \theta)(\omega\tau)^{1-m} \cos \left[(1-m) \frac{\pi}{2} \right] + (\omega\tau)^{2(1-m)}} \quad (36)$$

where $\theta = (\epsilon_s - \epsilon_\infty)/\epsilon_\infty$. The $m = 0$ case corresponds to a Debye material (single relaxation). The $m = 1$ case corresponds to an infinitely broad continuous distribution (one having no relaxation). In the latter case the imaginary part of the complex permittivity disappears, and the real part becomes frequency independent.

Figure 3. ϵ'' versus ϵ' plots for (a) Debye and (b) Cole–Cole materials.

The Cole–Cole distribution corresponds to a symmetric distribution of relaxation times of width m . Whereas a Debye material yields a plot of ϵ'' (ϵ') that is a semicircle whose center lies on the $\epsilon'' = 0$ axis, a Cole–Cole ϵ'' (ϵ') plot is a semicircle whose center lies below the horizontal $\epsilon'' = 0$ axis, on a line drawn from ($\epsilon' = \epsilon_\infty$, $\epsilon'' = 0$) that makes an angle of $m\pi/2$ with the horizontal axis. This is shown in Fig. 3. In addition to the Cole–Cole expression, there are other empirical relations commonly used to describe a non-Debye response. These are the Cole–Davidson (12), the combined Cole–Cole, and the Williams–Watkins (13) expressions. A characteristic feature of all these empirical relations, besides being based on Eq. (30), is that at frequencies away from the (dominant) relaxation frequency, they reduce to expressions showing a power-law dependence (14) on frequency for both ϵ' and ϵ'' .

Generalized Relation between Permittivity and Dielectric Loss Index

A generalized relation between ϵ' and ϵ'' for linear dielectric materials possessing an arbitrary number of relaxation times may be derived by regarding the permittivity as a system function characterizing the electrical properties of a material with the applied electric field as input and the displacement field as output. In the time domain the material permittivity is simply the transient (causal) system response, which can always be decomposed into the sum of an even and odd function whose Fourier transforms yield the (real) permittivity and (imaginary) dielectric loss index. The real permittivity and dielectric loss index are then related by the following Hilbert transforms, also known as the Kramers–Krönig relations,

$$\epsilon''(\omega) = \frac{1}{\pi} P \int_{-\infty}^{\infty} \frac{\epsilon'(v)}{\omega - v} dv \quad (37)$$

and

$$\epsilon'(\omega) = \epsilon_\infty - \frac{1}{\pi} P \int_{-\infty}^{\infty} \frac{\epsilon''(v)}{\omega - v} dv \quad (38)$$

where P denotes the Cauchy principal value. The application and limitations of Eqs. (37) and (38) for band-limited measurement data have been described in Ref. 11, as well as the use of an inverse power law of the distribution function for predicting expected changes in the dielectric loss tangent from measured changes in permittivity at two selected frequencies.

Effect of Temperature Changes

A classical statistical thermodynamic model using a double potential well was used (11) to describe the dispersive dielectric behavior for a bistable dielectric as a function of temperature and frequency in terms of the dipolar polarizability $\alpha_D = Np_E^2/k_B T$, the activation energy U , and the high-frequency (optical) permittivity at temperature T , where N is the total number of bistable dipoles in the material having dipole moment p_E . The results are

$$\epsilon'(\omega, T) = \epsilon_\infty(T) + \frac{\alpha_D}{1 + \omega^2 \tau^2} \quad (39)$$

and

$$\tan \delta(\omega, T) = \frac{\alpha_D \omega \tau}{\alpha_D + \epsilon_\infty(T)(1 + \omega^2 \tau^2)} \quad (40)$$

where $\tau = e^{-U/k_B T}/2A$ and A is a constant that may or may not depend on temperature describing the number of dipoles within the dielectric jumping per unit time from one potential energy state to a higher state. Equations (39) and (40) are limited to dielectric materials for which interaction between individual dipoles can be neglected and for conditions in which $p_E E \ll k_B T$ (nonsuperconducting states).

Langevin considered the electrostatic case of interacting molecules from a Maxwell–Boltzmann statistical ensemble average of the angular alignment with an applied electric field E of point dipoles having equal dipole moments in thermal equilibrium at temperature T . He derived the well-known Langevin function shown in Fig. 4,

$$\langle \cos \theta \rangle = \coth y - 1/y \quad (41)$$

where θ is the angle between field and dipole and y is $p_E E/(k_B T)$. The ensemble average $\langle \cos \theta \rangle$ increases with increasing y ; for high values of E/T , the orienting action of the electric field dominates over the disorienting action of the temperature. Implicit in the derivation of the Langevin function are the assumptions that the molecules are *point* dipoles that have *isotropic* polarizability, that ergodicity holds, and that the system obeys the classical Maxwell–Boltzmann statistics.

Additional discussion on relaxation models is to be found in the classical texts of Von Hippel (15) and Böttcher (16). The use of these physical relaxation models provides insight into what dispersive permittivity and dielectric loss tangents might be expected both as a function of temperature and frequency.

Figure 4. Behavior of Langevin function versus $p_E E/k_B T$.

However, their applicability and validity must be examined by accurate measurements.

PERMITTIVITY AND DIELECTRIC-LOSS-ANGLE MEASUREMENTS

Low-Frequency Complex Impedance Measurements

The use of a plane-parallel capacitor having a vacuum capacitance $C_0 = \epsilon_0 S/h$, where S and h are, respectively, the surface area of the electrode plates and separation of the plates, is commonly used for low-frequency dielectric measurements. If a low-frequency voltage $V = V_0 e^{j\omega t}$ is applied to this capacitor, a charge $Q = C_0 V$ appears on the electrodes that is in phase with the applied voltage. The nondissipative displacement current in the external circuit is then given by

$$I = \dot{Q} = j\omega C_0 V \quad (42)$$

which is 90° out of phase with the applied voltage. If the volume between the electrodes is filled with a lossless, nonpolar insulating material, the capacitor has a capacitance $C = \epsilon'_r C_0$. In this case the new displacement current is

$$I_{\text{diel}} = \dot{Q}_{\text{diel}} = j\omega C V = \epsilon'_r I \quad (43)$$

The capacitance is larger than the vacuum capacitance, but remains 90° out of phase with respect to the applied voltage. For lossy dielectric materials, the current is not 90° out of phase with the voltage since there is a small conduction GV due to charge motion in phase with the applied voltage. If the charges are free, the conductance G is independent of frequency. However, if the charges are bound, G is frequency dependent, and the dipole relaxation phenomena previously described become relevant. In general,

$$I = (j\omega C + G)V \quad (44)$$

where $G = \sigma S/h$ (if G is the conductance due to free charges) and $C = \epsilon'_r S/h$. Whenever dissipation is not exclusively due to free charges, but is also due to bound charges, the conductivity is itself a complex frequency-dependent quantity and a distinction cannot be made between Ohmic conductivity and dielectric loss factor or between Faradaic diffusion transport and in-phase polarization.

Free-Space Measurement

Free-space measurements of the complex permittivity and complex permeability usually involve placing a plate specimen orthogonal to the axis between the transmitting and receiving antennas. A plane electromagnetic wave is passed through the specimen. The complex permittivity or permeability can then be evaluated from measurements of the propagation constant $\gamma_s = jk_s = j\omega \sqrt{\mu_0 \epsilon_0 \epsilon_{r,s} \mu_{r,s}}$ of the plane electromagnetic wave propagating in the specimen or from the measured impedance $Z_s = \sqrt{\mu_0 \mu_{r,s} / \epsilon_0 \epsilon_{r,s}}$ of the specimen. The accuracy of free-space measurements depends on the appropriate choice of a theoretical model best representing the experimental measurement system and the accuracy of the measurement system.

Figure 5. Reflection and transmission coefficients for an electromagnetic plane wave normally incident on an infinite dielectric plate specimen.

Solid Dielectric Specimens. For a normally incident transverse electromagnetic (TEM) wave on the specimen surrounded by air (see Fig. 5) the transmission and reflection coefficients, T_0 and R_0 , are given by

$$T_0 = \frac{4\gamma_s \gamma_0}{(\gamma_0 + \gamma_s)^2 e^{-\gamma_s h} - (\gamma_0 - \gamma_s)^2 e^{\gamma_s h}} \quad (45)$$

$$R_0 = \frac{(\gamma_0^2 - \gamma_s^2) e^{-\gamma_s h} - (\gamma_0^2 - \gamma_s^2) e^{\gamma_s h}}{(\gamma_0 + \gamma_s)^2 e^{-\gamma_s h} - (\gamma_0 - \gamma_s)^2 e^{\gamma_s h}} \quad (46)$$

where $\gamma_0 = j2\pi/\lambda_0$ and $\gamma_s = j2\pi \sqrt{\epsilon_{r,s} \mu_{r,s}}/\lambda_0$. Equations (45) and (46) may be solved for the complex permittivity and permeability of a magnetic plane-parallel plate. If the specimen is nonmagnetic, the transmission coefficient may be solved for ϵ_r . A common reflection technique for complex permittivity evaluation is to place a conducting plate (short) behind the specimen and measure the reflection coefficient. In this case,

$$R_{0|\text{short}} = \frac{(\gamma_0 - \gamma_s) e^{-\gamma_s h} - (\gamma_0 + \gamma_s) e^{\gamma_s h}}{(\gamma_0 + \gamma_s) e^{-\gamma_s h} - (\gamma_0 - \gamma_s) e^{\gamma_s h}} \quad (47)$$

Generally, complex permittivity evaluations are more accurate in reflection (one-port scattering parameter) measurements when the specimen is surrounded by air, whereas permeability evaluations are most accurate from reflection measurements when the specimen is backed by a shorting plane.

Liquid, Gas, or Plasma Specimens. The preceding free-space experimental setup is used mainly for measuring solid dielectric specimens that have plane-parallel plate geometries. For liquids, gases, or plasmas that must be held in containers whose walls are transparent to probing electromagnetic waves, the (two-dimensional) analysis becomes somewhat more complicated (see Fig. 6). In this case the amplitude reflection and transmission coefficients are given by (17),

$$R_0 = \frac{m \left(\frac{Z_s + Z_w}{Z_s - Z_w} + e^{2\gamma_w d} \frac{Z_w + Z_0}{Z_w - Z_0} \right) + n \left(1 + e^{2\gamma_w d} \frac{Z_s + Z_w}{Z_s - Z_w} \frac{Z_w + Z_0}{Z_w - Z_0} \right) e^{2\gamma_s h}}{m \left(\frac{Z_s + Z_w}{Z_s - Z_w} \frac{Z_w + Z_0}{Z_w - Z_0} + e^{2\gamma_w d} \right) + n \left(\frac{Z_w + Z_0}{Z_w - Z_0} + e^{2\gamma_w d} \frac{Z_s + Z_w}{Z_s - Z_w} \right) e^{2\gamma_s h}} \quad (48)$$

Figure 6. Free-space model for measuring liquids, gases, or plasmas in transparent container.

and

$$T_0 = \left\{ \cosh(\gamma_s h) \left[\cosh^2(\gamma_w d) + \sinh^2(\gamma_w d) - \frac{1}{2} \left(\frac{Z_0}{Z_w} + \frac{Z_w}{Z_0} \right) \sinh(2\gamma_w d) \right] + \frac{1}{2} \sinh(\gamma_s h) \left[\left(\frac{Z_s}{Z_w} + \frac{Z_w}{Z_s} \right) \sinh(2\gamma_w d) - \left(\frac{Z_s}{Z_0} + \frac{Z_0}{Z_s} \right) \cosh^2(\gamma_w d) - \left(\frac{Z_w^2}{Z_0 Z_s} + \frac{Z_0 Z_s}{Z_w^2} \right) \sinh^2(\gamma_w d) \right] \right\}^{-1} \quad (49)$$

where

$$m = \left(\frac{Z_0}{Z_s} + 1 \right) \cosh(\gamma_w d) - \left(\frac{Z_0}{Z_w} + \frac{Z_w}{Z_s} \right) \sinh(\gamma_w d) \quad (50)$$

$$n = \left(\frac{Z_0}{Z_s} - 1 \right) \cosh(\gamma_w d) - \left(\frac{Z_0}{Z_w} - \frac{Z_w}{Z_s} \right) \sinh(\gamma_w d) \quad (51)$$

and Z_0 is the free-space impedance, $Z_w = Z_0/\sqrt{\epsilon_{r,w}} = \gamma_0 Z_0/\gamma_w$ is the container wall impedance, and $Z_s = Z_0/\sqrt{\mu_{r,s}\epsilon_{r,s}} = \gamma_0 Z_0/\gamma_s$ is the impedance of the medium under test.

Waveguide Transmission-Line Methods

The use of waveguide transmission and reflection techniques for evaluating complex permittivity and complex permeability has a long history, and the literature describing various techniques is extensive (18–37). Transmission-line techniques, usually made in rectangular or coaxial waveguides, are the simplest of the relatively accurate ways of measuring permeability and permittivity. Coaxial lines are broadband in the TEM dominant mode and therefore are attractive for spectral characterization of lossy magnetic materials, despite the problems of measurement uncertainty in complex permittivity determination introduced by potential air gaps between the sample and the coaxial line center conductor. Details of two-port, reference-plane invariant scattering parameter relations that can be used for determining permittivity and permeability are given elsewhere (37). One set of equations for dielectric and magnetic measurements of a single sample, in terms of two-port scattering parameters that can be taken with an automatic network

analyzer, is

$$S_{11}S_{22} - S_{21}S_{12} = \exp(-2\gamma_0(L_{\text{air}} - L)) \frac{R^2 - T^2}{1 - R^2T^2} \quad (52)$$

and

$$(S_{12} + S_{21})/2 = \exp[-\gamma_0(L_{\text{air}} - L)] \frac{T(1 - R^2)}{1 - R^2T^2} \quad (53)$$

where

$$R = \frac{\mu\gamma_0 - \mu_0\gamma}{\mu\gamma_0 + \mu_0\gamma} \quad (54)$$

$$T = \exp(-\gamma L) \quad (55)$$

$$\gamma_0 = \sqrt{\left(\frac{2\pi}{\lambda_c}\right)^2 - \left(\frac{\omega}{c_{\text{lab}}}\right)^2} \quad (56)$$

$$\gamma = \sqrt{\left(\frac{2\pi}{\lambda_c}\right)^2 - \frac{\omega^2\mu_r\epsilon_r}{c_{\text{vac}}^2}} \quad (57)$$

c_{vac} and c_{lab} are the speed of light in vacuum and laboratory, ω is the angular frequency, λ_c is the cutoff transmission-line wavelength, ϵ_r and μ_r are the specimen relative complex permittivity and permeability relative to vacuum, and L_{air} and L are air-line and specimen lengths. Equations (52) and (53) may be solved either explicitly or implicitly as a system of nonlinear scattering equations at each frequency or by using a nonlinear regression model over the entire frequency range. The total attenuation loss α_{TEM} of a sample under test for TEM mode structure in a coaxial transmission line is given by

$$\begin{aligned} \alpha_{\text{TEM}} &= \text{Re}(\gamma) \\ &= \text{Re} \left(j \frac{\omega}{c_{\text{vac}}} \sqrt{(\epsilon'_r - j\epsilon''_r)(\mu'_r - j\mu''_r)} \right) \\ &= \frac{\sqrt{2}\omega}{2c_{\text{vac}}} \sqrt{\epsilon'_r\mu'_r[(1 + \tan^2\delta_e)^{1/2}(1 + \tan^2\delta_m)^{1/2} + \tan\delta_e \tan\delta_m - 1]} \end{aligned} \quad (58)$$

where $\tan\delta_e = \epsilon''_r/\epsilon'_r$ and $\tan\delta_m = \mu''_r/\mu'_r$. One disadvantage of microwave measurements of the complex permittivity in waveguide is that specimens have very small tolerances in properly machined dimensions. If the specimen does not fill the entire cross section of the waveguide perfectly, corrections must be made for air gaps. For high-permittivity samples in either

rectangular or coaxial transmission lines, air gaps can lead to dielectric depolarization, which yields severe underestimates of actual specimen permittivity.

Thin Film Specimens

Techniques useful for the evaluation of the dielectric properties of thin film structures are important for various applications, such as dynamic random access memory (DRAM) cells and high-frequency bypass on-chip capacitors for monolithic microwave integrated circuits (MMICs). The dielectric properties of thin film structures, commonly 8 nm to 100 nm thick, on semiconductor substrates often differ appreciably from their bulk counterparts. For example, the real permittivities of thin films are usually smaller and dielectric losses significantly larger than those of corresponding bulk materials. These differences may be due to nonuniform strain arising from film-substrate lattice mismatches, film compositional inhomogeneities, film conductivity, or other structural imperfections.

Above 1 GHz, little is known about thin film capacitive characteristics. At these frequencies measurements become more difficult as a result of stray admittance effects around the thin film deposited structures. One technique outlined in (38–40) is based on an equivalent circuit model of the capacitive on-chip test structure. The equivalent circuit is expressed by lumped elements of intrinsic capacitor admittance Y_c , and parallel and series parasitic admittance Y_p and Y_s . The measured thin film test structure has an admittance Y_t which is corrected for Y_p and Y_s to obtain the intrinsic admittance of the thin film Y_c . The parasitic admittances Y_p and Y_s are evaluated by measuring the open- and short-test circuit device admittances, Y_{open} and Y_{short} . These admittances may be determined with microwave probe station scattering parameter reflection coefficient (S_{11}) measurements. The intrinsic admittance is calculated from

$$Y_c = (Y_t - Y_{open})(Y_{short} - Y_{open}) / (Y_{short} - Y_t) = G + j\omega C \quad (59)$$

where G and C are the conductance and capacitance of the intrinsic thin-film capacitor determined by the real and imaginary part of Y_c .

The dielectric loss tangent is given by

$$\tan \delta = G / (\omega C) \quad (60)$$

Resonance Methods

Resonant methods employing either closed and open cavities or dielectric resonators provide the highest measurement accuracy for evaluating complex permittivity and dielectric-loss tangent of low-loss materials at microwave frequencies (41–43). Generally, the (real) permittivity is calculated from the measured resonant frequency of one of the dominant modes of the resonant measurement system and the dimensions of the resonant structure. As long as specimen losses are low, they do not affect resonant frequencies. Exact relations between permittivity, sample dimensions, and resonant frequency exist only for simple rectangular, cylindrical, or spherical resonant structure geometries and when any permittivity inhomogeneity in the measurement fixture varies in only one of the principal coordinate directions. Resonant fixtures commonly used in practice for cylindrically shaped disk or rod specimens are shown

Figure 7. Typical cylindrical cavities and dielectric rod resonators used for complex permittivity measurements for which closed-form solutions are available: (a) TE_{01p} mode cavity, (b) TM_{010} mode cavity, (c) TE_{011} mode dielectric resonator.

in Fig. 7. An eigenvalue relationship, derived from Maxwell's equations and application of boundary conditions for the particular fixture of interest, always exists for a specific mode family that gives a transcendental equation relating permittivity, resonant frequency, and sample or fixture dimensions,

$$F(f_r, \epsilon_r', \text{dimensions}) = 0 \quad (61)$$

The permittivity is a numerical root of Eq. (61) for a given f_r and sample and fixture dimensions. Although there is more than one (mathematical) root to the eigenvalue equation, it is usually possible to pick the correct root, since many roots are non-physical or the permittivity is approximately known. It is also possible, in principle, to obtain a unique solution by using two independent measurements with different mode field configurations or by using two samples having different dimensions. The resonant fixtures shown in Fig. 7 may be practically used, when properly dimensioned, for complex permittivity evaluations of low- and medium-loss materials over the frequency range 1 GHz to 50 GHz.

Several resonant fixtures of practical use possess geometries for which analytical solutions are not available. These fixtures may be analyzed with numerical mode-matching, Rayleigh–Ritz, or finite-element methods. All these techniques allow accuracy improvements by incorporating more terms in field expansions or by mesh refinement. Mode-matching (44,45) is one of the most accurate methods for computation of resonant frequencies of axially symmetric resonant fixtures. In radial mode-matching, a resonant structure is first subdivided into cylindrical regions having dielectric inhomogeneity only along the axial direction. The electromagnetic field components are then separately expanded into series modal expansions in each region. Boundary conditions that are applied at the interfaces between adjacent regions yield a system of matrix equations (with respect to the field expansion coefficients) that have nonzero solutions only when the determinant vanishes. The resonant frequencies are the values that make the determinant of the square matrix vanish.

Generally, measurement uncertainties for (real) permittivity depend on

- Presence of air gaps between the specimen and conducting parts of the resonant structure that cause depolarization [some structures are not sensitive to air gaps, such as those in Figs. 7(a) and 7(c)]

- Computational inaccuracies
- Uncertainties from physical dimensions of specimen and resonant structure

Air gaps limit the measurement accuracy of high-permittivity solid materials when the electromagnetic field structure in the measurement system has an electric field component normal to the sample surface. In these cases, a discontinuity in the normal electric field leads to depolarization. When the applied electric field is continuous across a specimen boundary, such as with cylindrical samples in TE_{0np} or quasi- TE_{0np} ($TE_{0\delta v}$) mode resonant fixtures (45,46), high measurement accuracies are generally achieved. In the latter case, air gaps do not play a significant role. The depolarizing effects of air gaps can be mitigated by metallization of the sample surface contacting the fixture conductors. This added procedure improves real permittivity measurement accuracy, but can substantially degrade measurement accuracy of the dielectric loss factor. When the depolarizing effects of air gaps are either not important or have been mitigated, and the numerical method used for field analysis is sufficiently accurate, real permittivity measurement uncertainty depends only on the uncertainties associated with the physical dimensions of the sample under test and the measurement system.

Evaluation of the dielectric loss index or dielectric loss tangent is always based on the expression

$$Q_u^{-1} = p_{es} \tan \delta_s + p_{ed} \tan \delta_d + R_s/G + Q_r^{-1} \quad (62)$$

Equation (62) is valid for any resonant system containing isotropic dielectric materials. It defines the unloaded Q factor of the resonant system, Q_u , in terms of the sample partial electric energy filling factor p_{es} and sample dielectric loss tangent $\tan \delta_s$, the electric energy filling factors of the dielectric supports p_{ed} having relative real permittivity ϵ'_d and loss tangent $\tan \delta_d$ inside the resonant measurement system, the surface resistance R_s of any conducting shields, the geometrical factor G of the resonant system, and any radiation Q factor Q_r of the measurement fixture. The sample electric energy filling factor is defined as

$$p_{es} = \frac{W_{es}}{W_{et}} = \frac{\int_{V_s} \epsilon'_{r,s} \mathbf{E} \cdot \mathbf{E}^* dv}{\int_V \epsilon'_r(v) \mathbf{E} \cdot \mathbf{E}^* dv} \quad (63)$$

where W_{es} is the electric energy stored in the sample, W_{et} is the total electric energy stored in the resonant measurement fixture, $\epsilon'_{r,s}$ is the relative real permittivity of the sample, $\epsilon'_r(v)$ is the relative spatially dependent permittivity in the resonant structure, and the asterisk denotes complex conjugate. The electric energy filling factor for the dielectric support is given by

$$p_{ed} = \frac{W_{ed}}{W_{et}} = \frac{\int_{V_s} \epsilon'_{r,d} \mathbf{E} \cdot \mathbf{E}^* dv}{\int_V \epsilon'_r(v) \mathbf{E} \cdot \mathbf{E}^* dv} \quad (64)$$

where W_{ed} is the electric energy stored in the dielectric support. The geometrical factor is defined by

$$G = \frac{\omega \int_V \mu_0 \mathbf{H} \cdot \mathbf{H}^* dv}{\int_S \mathbf{H}_t \cdot \mathbf{H}_t^* dS} \quad (65)$$

Figure 8. $TE_{01\delta}$ mode dielectric resonator measurement fixture.

where H_t is the magnetic field tangential to any conducting shield having surface area S .

For highest accuracy in dielectric-loss tangent measurements, the first term on the right-hand side of Eq. (62) must dominate, or the last three terms on the right-hand side of Eq. (62) should be minimized and well-characterized. Evaluation of conductor losses and those due to dielectric materials other than the sample under test within the measurement system (such as dielectric supports) often requires the rigorous use of numerical computation methods. The surface resistance of metal shields must also be well-characterized at the measurement frequency and temperature of interest. If an open resonator is used, radiation losses must be considered. For most resonant measurement fixtures used in practice, uncertainties in dielectric-loss-tangent evaluations are limited by conductor losses. Conductor losses decrease as the surface resistance becomes small and as the geometric factor increases. One common procedure to minimize conductor losses is to situate the dielectric specimen in a position away from the conductor walls as shown in Fig. 8 (47–52). Usually quasi- TE_{011} modes of this structure (often called $TE_{01\delta}$ modes) are used for dielectric-loss-tangent measurements. For this mode, geometric factors [approach] a maximum when dimensions of the metal shield increase. The optimal value of the geometric factor (optimal positioning of the specimen relative to metal shielding) depends on sample permittivity. If the distance of the metal shield from the specimen becomes greater than the optimum value, the electric energy filling factor of the sample decreases rapidly, and the field distribution becomes essentially the same as in an empty TE_{011} cavity. With optimal shield dimensions and a metal surface resistance equal to 30 mΩ (that of copper at 10 GHz and 297 K), the Q factor due to conductor losses can be large (2×10^5 for a sample having a relative real permittivity equal to 30). Sample dielectric losses should be at least 10% of the overall losses in Eq. (62) for accurate dielectric loss measurements. Hence the lower bound on the dielectric-loss-tangent measurement is about 5×10^{-7} (for sample permittivities greater than or equal to 30) when using a $TE_{01\delta}$ mode dielectric resonator with optimal shielding conditions. For this resolution, the geometric factor must be accurately known. Another way to minimize conductor losses is to employ high-temperature superconductors as the shielding material (53–55); however, this can only be done at cryogenic temperatures.

The most effective way to decrease conductor losses (or increase the geometric factor) for accurate dielectric-loss-tangent measurements is to use higher-order hybrid modes having high azimuthal mode numbers. These hybrid modes, called *whispering-gallery modes*, are excited in cylindrical specimens (56) as shown in Fig. 9. Conductor losses decrease very rapidly with increasing azimuthal mode numbers for

Figure 9. Whispering-gallery mode resonant structure.

whispering-gallery modes. Therefore they can be used for high-resolution dielectric-loss-tangent measurements of ultralow-loss materials. In addition, this method can be used for measurements of low-dielectric-loss materials up to frequencies of 100 GHz.

The most commonly used dielectric materials in the electronics industry are those used for printed wiring board substrates. Typically these dielectric materials exhibit losses in the range, $10^{-4} < \tan \delta < 10^{-2}$. Because printed wiring board substrates are relatively thin dielectric sheets, the resonant measurement techniques described previously are not applicable. For these samples the most convenient measurement technique is the split (tuned) dielectric post resonator illustrated in Fig. 10. This nondestructive method can be used practically at all frequencies from 1 GHz to 10 GHz.

When measurement frequencies lower than 1 GHz are of interest, dimensions of the resonant structures described thus far become impractically large. One of the commonly used resonant structures when dielectric measurements are required in the frequency range between 100 MHz and 1 GHz is the reentrant cavity, which is shown in Fig. 11. Advantages in the use of the reentrant cavity are relatively small sample size and, because of the axially directed electric field, a permittivity measurement normal to the substrate laminar surfaces. However, the reentrant cavity technique is sensitive to the presence of air gaps between the sample and the central metal posts, so that without metallization of the top and bottom surfaces of the specimen, it is only useful for measurements of low- to medium-permittivity materials.

At frequencies above 50 GHz, the dimensions of the resonant structures become impractically small. At these frequencies, a typical method (see Fig. 12) for complex permittivity measurements is the semiconfocal Fabry–Perot type resonator (56), although for very-low-loss materials, the whispering-gallery mode technique could also be used (57). Free-space transmission and reflection techniques previously described can also

Figure 10. Split post-dielectric resonator.

Figure 11. Doubly reentrant cavity.

be used to characterize materials from 50 GHz to visible-light frequencies.

Complex Permittivity Measurements of Anisotropic Materials.

Many materials, including some single crystals, exhibit dielectric anisotropy. For dielectrically anisotropic materials the complex permittivity is not independent of direction. The general (diagonalized) form of the electric susceptibility tensor is given in Eq. (7).

Anisotropy is usually related to the internal structure of the material. It can also be enforced by external factors, such as an external static magnetic field or mechanical stress. For anisotropic materials the relationship between the electric field intensity vector $\mathbf{E}$ and electric flux density vector $\mathbf{D}$ takes the form

$$\mathbf{D} = \bar{\epsilon} \cdot \mathbf{E} = \begin{bmatrix} \epsilon_{11} & \epsilon_{12} & \epsilon_{13} \\ \epsilon_{21} & \epsilon_{22} & \epsilon_{23} \\ \epsilon_{31} & \epsilon_{32} & \epsilon_{33} \end{bmatrix} \begin{bmatrix} E_1 \\ E_2 \\ E_3 \end{bmatrix} \quad (66)$$

where the complex permittivity $\bar{\epsilon}$ is a second-rank tensor. The permittivity tensor may generally be expressed as a sum of symmetric and antisymmetric tensors

$$\bar{\epsilon} = \bar{\epsilon}^{(S)} + \bar{\epsilon}^{(A)} \quad (67)$$

Figure 12. Fabry–Perot semiconfocal resonator.

For the symmetric tensor, $\epsilon^{(S)}_{ij} = \epsilon^{(S)}_{ji}$ and for the antisymmetric tensor, $\epsilon^{(A)}_{ij} = -\epsilon^{(A)}_{ji}$. The Hermitian and anti-Hermitian parts of the permittivity tensor are

$$\bar{\epsilon}' = \frac{1}{2}(\bar{\epsilon} + \bar{\epsilon}_t^*) \quad (68)$$

$$\bar{\epsilon}'' = \frac{1}{2}j(\bar{\epsilon} - \bar{\epsilon}_t^*) \quad (69)$$

where $\bar{\epsilon}_t$ represents the complex conjugate of the transposed tensor. The Hermitian part of the permittivity tensor is associated with electric energy stored in the dielectric while the anti-Hermitian part represents power dissipation in the dielectric. Most dielectric materials are described by a symmetric tensor only and dielectric losses by the imaginary components of a symmetric tensor. For a symmetric tensor there is always a coordinate system in which the permittivity tensor may take the diagonalized form,

$$\bar{\epsilon} = \begin{bmatrix} \epsilon_{11} & 0 & 0 \\ 0 & \epsilon_{22} & 0 \\ 0 & 0 & \epsilon_{33} \end{bmatrix} \quad (70)$$

When single crystals are measured, the coordinate axes are associated with the principal axes of the crystal lattice. When two of the three components of the permittivity tensor are equal, the material is said to be uniaxially anisotropic.

The easiest approach to measuring complex permittivity of anisotropic materials is to use measurement fixtures in which there is only one component of the electric field in the sample under test. For example, in the reentrant cavity and TM_{010} cylindrical cavity, there is only an axial electric field component in the specimen. In coaxial transmission line, only a radial electric field component is present when operating in dominant TEM mode field structure and in a TE_{01n} cavity, there is only an azimuthal electric field component in the specimen. If the specimen is properly oriented using one of these measurement techniques, measurement data can be obtained for evaluation of all tensor permittivity components.

For uniaxially anisotropic materials, a cylindrical specimen is first oriented so that the cylinder axis is parallel to the anisotropy axis of the material. Then a reentrant cavity can be used to evaluate the complex permittivity parallel

to the anisotropy axis. If the sample specimen is measured in a TE_{01n} mode cavity, the permittivity perpendicular to the anisotropy axis can be determined. For general (orthogonal) three-dimensional anisotropy, a rectangular waveguide sample may be fabricated so that the principal anisotropy axes are parallel to the Cartesian axes, or three cylindrical specimens can be fabricated the cylindrical axes of which are oriented parallel to each of the different anisotropy axes. In general, three independent measurements are required for evaluation of the permittivity tensor. This can be accomplished with two or three differently oriented samples or with the use of two or three different modes using only one sample. It is preferable, but not necessary, that only one permittivity tensor component be excited by the electric field structure in the measurement fixture. However, this is not always possible, since other factors, such as sensitivity and measurement accuracy, must also be considered.

Many single crystals have extremely low dielectric loss at low temperature (58–62). It is possible to evaluate dielectric losses in these extremely low-loss materials only by using resonant fixtures in which conductor losses are very small. For these measurements the whispering-gallery mode technique is appropriate. Whispering-gallery modes can always be classified into modes symmetric (S) or antisymmetric (N) to a plane of symmetry in a measurement fixture. In fact, since for these modes the electromagnetic fields are well confined to the dielectric specimen, this classification can still be made relative to the specimen's equatorial plane even if the resonant fixture does not have a symmetry plane. To evaluate the principal permittivity components of a uniaxially anisotropic dielectric resonator, a specimen whose cylindrical axis is along a principal direction of anisotropy is first obtained. Then two whispering-gallery mode resonances that exhibit a quasi-TE (H mode) and quasi-TM (E mode) field structure are identified and measured. Finally, a system of two nonlinear determinant equations are solved with respect to the two unknown permittivity tensor components,

$$\begin{aligned} F_1(f^{(H)}, \epsilon_{\perp}, \epsilon_{\parallel}) &= 0 \\ F_2(f^{(E)}, \epsilon_{\perp}, \epsilon_{\parallel}) &= 0 \end{aligned} \quad (71)$$

where $f^{(H)}$ and $f^{(E)}$ are the measured resonant frequencies for the quasi-TE (H) and the quasi-TM (E) whispering gallery

Table 1. Electric energy filling factors, geometric factors and measured loss tangents using several quasi-TM (N1) and quasi-TE (S2) modes of the sapphire resonator. Sapphire specimen, having diameter of 50.02 mm and height of 30.03 mm, in metallic shield having 80 mm diameter and 50 mm height. Computed permittivity tensor components: $\epsilon_{\perp} = 9.27$ and $\epsilon_{\parallel} = 11.35$ at 4.2 K and $\epsilon_{\perp} = 9.40$ and $\epsilon_{\parallel} = 11.59$ at 296.5 K.

Type	m	$p_{e\perp}$	$p_{e\parallel}$	$G(\Omega)$	tan δ	
					4.2 K	296.5 K
N1	11	0.0470	0.9341	6.77×10^6		5.0×10^{-6}
	12	0.0402	0.9423	1.63×10^7	5.0×10^{-9}	4.8×10^{-6}
	13	0.0350	0.9488	3.92×10^7	1.0×10^{-9}	4.8×10^{-6}
	14	0.0303	0.9538	9.42×10^7	7.0×10^{-10}	5.0×10^{-6}
S2	10	0.9548	0.0103	6.04×10^6	5.0×10^{-9}	9.0×10^{-6}
	11	0.9607	0.0064	1.60×10^7	4.0×10^{-9}	9.0×10^{-6}
	12	0.9620	0.0081	4.20×10^7	2.0×10^{-9}	7.0×10^{-6}
	13	0.9585	0.0106	1.10×10^8	9.0×10^{-10}	7.0×10^{-6}

modes and $\epsilon_{\perp}$ and $\epsilon_{\parallel}$ are the real parts of the permittivity tensor components normal and parallel to the anisotropy axis. The eigenvalue equations represented by F_1 and F_2 result from application of variational or mode-matching methods. Once the real permittivities are evaluated from Eq. (71), dielectric-loss tangents can be computed as solutions to

$$\begin{aligned} Q_E^{-1} &= p_{e\perp}^{(E)} \tan \delta_{\perp} + p_{e\parallel}^{(E)} \tan \delta_{\parallel} + R_s/G^{(E)} \\ Q_{(H)}^{-1} &= p_{e\perp}^{(H)} \tan \delta_{\perp} + p_{e\parallel}^{(H)} \tan \delta_{\parallel} + R_s/G^{(H)} \end{aligned} \quad (72)$$

where $\tan \delta_{\perp}$ and $\tan \delta_{\parallel}$ are the dielectric-loss tangents perpendicular and parallel to the anisotropy axis; $p_{e\perp}^{(H)}$, $p_{e\parallel}^{(H)}$, $p_{e\perp}^{(E)}$, $p_{e\parallel}^{(E)}$ are the electric energy filling factors perpendicular and parallel to the anisotropy axis of the dielectric resonator for quasi-TM whispering-gallery modes (superscript E) and quasi-TE whispering gallery modes (superscript H); and $G^{(E)}$ and $G^{(H)}$ are the geometric factors for quasi-TM and quasi-TE whispering-gallery modes.

Table 1 shows permittivity and dielectric-loss-tangent-measurement results for single-crystal sapphire at room temperature and at 4.2 K using whispering-gallery modes. The electric energy filling factors in Table 1 show that both N1 and S2 mode families can be treated as quasi-TM and quasi-TE modes. The geometric factor calculations demonstrate that conductor losses are considerably smaller than dielectric losses for large azimuthal mode numbers and can be neglected in most cases. Hence the dielectric-loss tangents can be approximated as the reciprocals of the unloaded Q factors for quasi-TM and quasi-TE whispering-gallery modes. Permittivities were evaluated accounting for thermal expansion coefficients (63,64). At 4.2 K, conductor losses for the copper metal shield used in experiments can be neglected only for azimuthal mode numbers $m > 13$. Conductor losses for whispering-gallery mode dielectric resonators can be made negligible by either performing measurements on higher-order azimuthal modes or by simply enlarging the enclosing metal shield.

WAVELENGTH METER

BASIC INFORMATION

Definition of Wavelength for a Monochromatic Source

Wavelength meters are instruments designed to measure the wavelength of an electromagnetic wave. Electromagnetic waves are the classical way to represent modifications of the space surrounding a moving electrically charged body. Time-varying electric and magnetic fields are produced and can be sensed. Wavelength is a well-established parameter when considering a monochromatic (single-frequency) plane wave propagating in vacuum. It is the distance between two planes, measured along the direction of propagation of energy, where the phase and its derivatives have the same values. For the purpose of electromagnetic wave propagation, vacuum is a homogeneous, linear, isotropic, and nondispersive medium. This implies that the reaction of the medium to the electromagnetic wave's presence is instantaneous and does not depend on the location of the observation or on the amplitude and direction of propagation of the wave.

Nonconducting materials, like gases, ceramics, or polymers, are called dielectrics. They have electric charges but the charges are not allowed to move freely within the medium.

When an electromagnetic wave moves through such a medium, it stimulates the charges to oscillate around their equilibrium positions. These oscillating charges radiate an electromagnetic field that adds up to the impinging field. The resulting field is the field propagating in the medium. The reaction of the medium will then change the conditions of propagation when compared to those of vacuum. In general, a real medium is nonhomogeneous, nonlinear, nonisotropic, and dispersive. This implies that the reaction will be dependent on location in the medium and the amplitude and direction of propagation of the field, that it will not be instantaneous, and that some of the wave energy will be transferred to other spectrum bands (harmonic generation). In a first approximation, it is useful to reduce the complexity of the medium reaction to something close to that of the vacuum, taking only into account a reduction of the propagation speed associated with the summing action. The speed of the wave in a perfect dielectric material is less than that in vacuum, and the ratio of the speed value in vacuum to the speed value in the medium is the index of refraction. It is then possible to reconsider the propagation of infinite plane waves and use the same definition for the wavelength. Since the speed of propagation is less in the medium than in vacuum, the distance between the planes will be less, which implies that the wavelength in the material is less than that for vacuum. Consequently, the wavelength value is dependent on the medium in which the wave is propagating.

Wavelength or Frequency?

Wavelength is measured along the space (position) axis. But if we measure the field associated with a monochromatic electromagnetic wave at a fixed position, we observe that this field oscillates regularly with time. The rate of this oscillation per unit of time is the frequency. The frequency is then measured along the time axis. The wavelength (λ) times the frequency (ν) is equal to the speed of light in the medium (v).

The two measurements, wavelength and frequency, are dual quantities. They reveal two aspects of the same physical interaction. The wavelength is related to the “wave” aspect of electromagnetic energy while the frequency is related to the “corpuscular” aspect, the photon or quantum of energy. The wavelength is helpful for evaluating the probability of finding photons, which are the unit of exchange of electromagnetic energy with the surroundings during an interaction. The energy E of each photon is $E = h\nu$, where h is the Planck constant. The frequency ν is not dependent on the medium of propagation. The measurement of frequency is preferred by signal engineers, while wavelength is the preferred choice for opticians.

Spectral Distribution

Another important aspect of wavelength measurement is the distribution of optical energy as a function of the wavelength. When a pure monochromatic wave is considered, there is no problem with the definition of wavelength because all the energy is concentrated on a single value. But this is not realistic. Such a distribution would be generated by a noise-free source that evidently does not exist. This brings up a point related to the spectral distribution of the electromagnetic energy for which wavelength has to be measured.

Generally speaking the energy emitted by a source is distributed over a given range of wavelengths or frequencies. This is called the *spectral distribution* of the source. If the

spectral distribution is a symmetrically decreasing function around a central wavelength value, this value is defined as the nominal wavelength. If the distribution is not symmetrical and/or reveals many intense peaks, the wavelength definition is more complex. Giving a specific value of nominal wavelength is then somewhat arbitrary and must be justified by stating the prevailing conditions for the selection. In the next section, wavelength (or frequency) definitions will be given more in detail.

Particular cases that will require specifications are modulated and pulsed sources. According to the Fourier analysis of such signals, a periodically modulated source will produce a number of sidelobes, each being the replica of the unmodulated original source while a pulse has a broad spectrum whose width is related to the reciprocal of its time duration.

Instruments Used for Wavelength Measurement

In the subsequent sections, we describe different instruments performing wavelength measurements. First, we present a brief overview of the principle of operation of the two most commonly used instruments, which are the spectrometer-based and the interferometer-based wavelength meters.

If the source has a broad spectrum, spectrometers are the instruments commonly used. The spectrum of the source is first analyzed using a dispersive element such as a prism or a grating. The intensity and central wavelength are then recorded by an appropriate detector for a number of dispersive element settings. This method results in a spectral analysis from which a nominal wavelength can be identified if the instrument has been previously calibrated.

Since wavelength is defined in the space domain, its accurate measurement will be done essentially through interferometric phenomena. Let us first consider a monochromatic source. The source signal is first split into space, allowing the various parts to travel different trajectories and recombine to produce interference patterns. Calibrated measurement of the periodicity revealed in the pattern gives an indication on the wavelength. We will later describe in detail the principle of operation of the most commonly used type of interferometers used to measure wavelengths: Michelson, Fizeau, and Fabry–Perot interferometers.

Before we proceed with the description of the different wavelength meters encountered in research laboratories and in the industry, the next section gives some information regarding basic electromagnetic wave theory as well as useful wavelength-measurement definitions.

BASIC ELECTROMAGNETIC WAVE THEORY AND USEFUL WAVELENGTH-MEASUREMENT DEFINITIONS

Theoretical Background

The resolution of Maxwell's equations in vacuum gives rise to plane electromagnetic waves. Such waves are characterized by an electric field (units of volts per meter) and a magnetic field (units of amperes per meter), mutually oriented in perpendicular directions, which are themselves perpendicular to the direction of propagation of the plane wave, given by the direction of the Poynting vector (units of watts per square meter). The latter is defined as the cross-product between the electric and magnetic fields. The modulus of the Poynting vector represents

the instantaneous intensity of the light beam. Since both fields are perpendicular to the direction of propagation, such waves are called transverse electromagnetic (TEM) waves. Practical collimated laser beams are often well described by plane waves.

Fluctuating Electric Field

We define a Cartesian component of the electric field labeled $E^{(r)}(\mathbf{r}, t)$, which is a real field variable at a point represented by a position vector $\mathbf{r}$, at a time t . For any real light beam $E^{(r)}(\mathbf{r}, t)$, will be a fluctuating function of time. For example, laser fields exhibit intensity noise as well as phase noise.

In order to simplify the present analysis, we do not use the real field variable $E^{(r)}(\mathbf{r}, t)$. We rather consider its corresponding analytic signal $E(\mathbf{r}, t)$, which has only spectral components for the positive frequency part of the spectrum. This complex field is defined as

$$E(\mathbf{r}, t) = \frac{1}{2}E^{(r)}(\mathbf{r}, t) + j\frac{1}{2}H\{E^{(r)}(\mathbf{r}, t)\} \quad (1)$$

where $H\{E^{(r)}(\mathbf{r}, t)\}$ denotes the Hilbert transform of the real field.

The field intensity at the position $\mathbf{r}$ and at time t is defined as

$$I(\mathbf{r}, t) = E^*(\mathbf{r}, t)E(\mathbf{r}, t) \quad (2)$$

The field intensity gives the beam power distribution over the beam shape.

We are usually concerned with stationary fields, in which case the statistical properties are independent of the origin of time. Such a field could be characterized by the correlations of the field at two space-time points,

$$\Gamma(\mathbf{r}_1, \mathbf{r}_2, \tau) = \langle E^*(\mathbf{r}_1, t)E(\mathbf{r}_2, t + \tau) \rangle \quad (3)$$

where $\langle \rangle$ denotes an ensemble average. Since the field is stationary, this ensemble average does not depend on t . This function is also called the mutual coherence function (1, Ch. 4). When evaluated at the same position, it gives the autocorrelation function of the field $\Gamma(\mathbf{r}, \mathbf{r}, \tau)$ at position $\mathbf{r}$. Moreover, it follows that the autocorrelation function evaluated for a zero delay gives the ensemble average of the field intensity at position $\mathbf{r}$,

$$\Gamma(\mathbf{r}, \mathbf{r}, 0) = \langle I(\mathbf{r}, t) \rangle \quad (4)$$

The intensity is constant over time for stationary fields.

According to the generalized Wiener-Khintchine theorem, the cross-spectral density is defined as the Fourier transform of the mutual coherence function,

$$W(\mathbf{r}_1, \mathbf{r}_2, \nu) = \mathcal{F}\{\Gamma(\mathbf{r}_1, \mathbf{r}_2, \tau)\} \quad (5)$$

The spectral density, also called the spectrum of the light beam at position $\mathbf{r}$, is then the Fourier transform of its autocorrelation function,

$$W(\mathbf{r}, \mathbf{r}, \nu) = \mathcal{F}\{\Gamma(\mathbf{r}, \mathbf{r}, \tau)\} \quad (6)$$

So the spread of the spectral density is directly related to the decorrelation time. Short decorrelation time gives rise to broad

spectrum and vice versa. Upon proper normalization, the field spectral density could be related to the measured power spectrum.

Usually the spectral density of the field has important components only over a frequency range much narrower than the frequencies of interest. This case is called quasimonochromatic light. For such situations the spectral density of the field is often characterized by two global parameters: one giving the position of the spectrum and the other one estimating its width.

Parameter Definitions

The center frequency could be defined in many ways. We could use the median frequency ν_m , which is the frequency for which half the power of the signal is distributed on each side, so

$$\int_0^{\nu_m} W(\mathbf{r}, \mathbf{r}, \nu) d\nu = \int_{\nu_m}^{\infty} W(\mathbf{r}, \mathbf{r}, \nu) d\nu \quad (7)$$

A common way of specifying the position of the spectrum is the most probable frequency ν_{mp} , which is the frequency at which the spectral density of the field is maximum. Finally the usual frequency value used and measured is the mean frequency, which is

$$\bar{\nu} = \frac{\int_0^{\infty} \nu W(\mathbf{r}, \mathbf{r}, \nu) d\nu}{\int_0^{\infty} W(\mathbf{r}, \mathbf{r}, \nu) d\nu} \quad (8)$$

The other parameter is the linewidth of the spectral density of the field. We could define the half-power bandwidth $\Delta\nu_{hp}$ as the symmetrical range around the median frequency containing half the power of the light,

$$\int_{\nu_m - \Delta\nu_{hp}/2}^{\nu_m + \Delta\nu_{hp}/2} W(\mathbf{r}, \mathbf{r}, \nu) d\nu = \frac{1}{2} \int_0^{\infty} W(\mathbf{r}, \mathbf{r}, \nu) d\nu \quad (9)$$

The root mean square (rms) width of the spectrum is also often encountered,

$$\Delta\nu_{rms}^2 = \frac{\int_0^{\infty} (\nu - \bar{\nu})^2 W(\mathbf{r}, \mathbf{r}, \nu) d\nu}{\int_0^{\infty} W(\mathbf{r}, \mathbf{r}, \nu) d\nu} \quad (10)$$

Usually we use a more experimentally convenient definition, which is the full width at half maximum (FWHM) width. This width gives the frequency range over which the spectral density exceeds half its maximum value,

$$\Delta\nu = \nu_2 - \nu_1, \quad W(\mathbf{r}, \mathbf{r}, \nu_{1,2}) = \frac{1}{2} W(\mathbf{r}, \mathbf{r}, \nu_{mp}) \quad (11)$$

For quasimonochromatic light, the effective width of its power spectrum is much smaller than the mean frequency,

$$\frac{\Delta\nu}{\bar{\nu}} \ll 1 \quad (12)$$

All these definitions also apply to wavelength and to wave number ($\sigma = \nu/\nu$).

Interference

Let us introduce the concept of interference through a simple experiment. Consider a light beam incident on an opaque screen having two distinct pinholes at positions r_1 and r_2 . The light emerging from these pinholes is observed on a second screen distant from the first one. The electric field at a position r on the second screen is the sum of two components,

$$E_s(r, t) = K_1 E(r_1, t - t_1) + K_2 E(r_2, t - t_2) \quad (13)$$

where K_1 and K_2 are constant factors and t_1 and t_2 are the propagation delays from the pinholes,

$$t_1 = |r_1 - r|/c \quad \text{and} \quad t_2 = |r_2 - r|/c \quad (14)$$

The average intensity observed on the second screen is

$$\begin{aligned} \langle I_s(r, t) \rangle &= |K_1|^2 \langle I(r_1, t - t_1) \rangle + |K_2|^2 \langle I(r_2, t - t_2) \rangle \\ &\quad + 2 \operatorname{Re}[K_1^* K_2 \Gamma(r_1, r_2, t_1 - t_2)] \end{aligned} \quad (15)$$

This intensity differs from the sum of the intensities of the distinct components. A supplementary term arises, which takes into account the “correlation” between the two beams. This phenomenon is called interference.

For quasi-monochromatic beams, the mutual coherence function could be expressed as

$$\Gamma(r_1, r_2, \tau) = g(r_1, r_2, \tau) e^{j2\pi\bar{\nu}\tau} \quad (16)$$

where $g(r_1, r_2, \tau)$ is a slowly varying function of τ , since its bandwidth is much smaller than the mean frequency of the field. In this case, the observed intensity on the second screen is

$$\begin{aligned} \langle I_s(r, t) \rangle &= |K_1|^2 \langle I(r_1, t - t_1) \rangle + |K_2|^2 \langle I(r_2, t - t_2) \rangle \\ &\quad + 2|K_1 K_2| |g(r_1, r_2, t_1 - t_2)| \cos[2\pi\bar{\nu}(t_1 - t_2)] \\ &\quad + \angle(K_1^*, K_2) + \angle g(r_1, r_2, t_1 - t_2) \end{aligned} \quad (17)$$

where $\angle$ is defined as the angle. Thus, as we move along the second screen, the intensity varies sinusoidally at the spatial frequency $\bar{\nu}/c$. This variation is the interference fringe pattern. Fringe contrast is measured through their visibility, defined as

$$V(r) = \frac{\langle I_s(r, t) \rangle_{\max} - \langle I_s(r, t) \rangle_{\min}}{\langle I_s(r, t) \rangle_{\max} + \langle I_s(r, t) \rangle_{\min}} \quad (18)$$

where the extreme values are evaluated in the neighborhood of the position r .

When the mutual coherence function vanishes, the visibility is 0. This represents complete incoherence. The other extreme case is called complete coherence. In this case,

$$|\Gamma(r_1, r_2, \tau)| = \sqrt{\langle I(r_1, t) \rangle \langle I(r_2, t) \rangle} \quad (19)$$

which corresponds to the following visibility:

$$V(r) = \frac{2|K_1 K_2| \sqrt{\langle I(r_1, t) \rangle \langle I(r_2, t) \rangle}}{|K_1|^2 \langle I(r_1, t) \rangle + |K_2|^2 \langle I(r_2, t) \rangle} \quad (20)$$

The visibility is 1 if the intensities associated with each beam are equal. Otherwise, perfect contrast is not achieved for complete coherence. In the general case, we experiment partial coherence, so the resulting visibility does not reach 1.

SPECTROMETER-BASED WAVELENGTH METERS

In the next section, we describe instruments based on spectrometers using prism or diffraction gratings. We discuss their performances and limitations and explain their use as wavelength meters.

Basic Properties of Spectrometers

Spectrographs or Monochromators?. The difference between the two types of instrument is related to the detection of diffracted/dispersed light: in a spectrograph, a photographic plate or a charge-coupled device (CCD) array is placed in the output focal plane and records the entire spectrum. In a monochromator, a slit and a photodetector are used so that only a portion of the output spectrum is recorded. It is therefore necessary to move the detection system in the output focal plane, or to rotate the dispersive/diffractive element, to obtain the complete spectrum. Both instruments are often referred to as spectrometers in the literature.

Spectral Resolving Power and Rayleigh's Criterion. The spectral resolving power R is defined by

$$R = \frac{\lambda}{\Delta\lambda} = \frac{\nu}{\Delta\nu} \quad (21)$$

where $\Delta\lambda = \lambda_1 - \lambda_2$ is the smallest separation between two wavelengths λ_1 and λ_2 that the instrument is able to resolve. According to Rayleigh's criterion, illustrated in Fig. 1, two lines are resolved when the intensity profile corresponding to λ_1 has its maximum in coincidence with the minimum of the intensity profile corresponding to λ_2 . The interval $\Delta\lambda$ between two resolved wavelengths, known as the resolution limit, can also be expressed in terms of frequency $\Delta\nu$ or wave number $\Delta\sigma$.

The achievable resolving power of a spectrometer is in direct relation with the slit width and its linear dispersion $dx/d\lambda$,

Figure 1. Rayleigh criterion for the definition of the spectral resolving power: two lines are resolved when the intensity profile corresponding to λ_1 has its maximum in coincidence with the minimum of the intensity profile corresponding to λ_2 . The interval $\Delta\lambda$ between two resolved wavelengths is the resolution limit.

which is given by

$$\frac{dx}{d\lambda} = f \frac{d\theta}{d\lambda} \quad (22)$$

where f is the lens focal length and $d\theta/d\lambda$ the angular dispersion. If the entrance slit width is ϵ_1 , the slit image in the focal plane of the focusing lens will be

$$\epsilon_2 = \frac{f_2}{f_1} \epsilon_1 \quad (23)$$

where f_1 and f_2 are, respectively, the focal length of the collimating and focusing lenses of the spectrometer. If we want to be able to resolve two lines at λ_1 and λ_2 , the separation of their image

$$\Delta x = f_2 \frac{d\theta}{d\lambda} \Delta\lambda = \frac{dx}{d\lambda} \Delta\lambda \quad (24)$$

must be greater than $2\epsilon_2$. It is therefore possible to increase the resolving power by decreasing the input slit width (at the expense of decreasing the amount of light to be detected). However, it will be limited because of diffraction due to the finite aperture a of the dispersive element. When the collimated beam is incident on the prism or grating, it experiences Fraunhofer diffraction resulting in an intensity distribution in $\sin^2(\gamma)(\sin(\pi\gamma)/\pi\gamma)$ with γ the diffraction angle. The central lobe of the distribution has a width equal to $2\lambda/a$ and contains 90% of the incident intensity. The distance between the two maxima in the output plane will be $f_2\lambda/a$ so that the condition for resolving λ_1 and λ_2 becomes

$$\Delta x \geq f_2 \frac{\lambda}{a} \quad \text{or} \quad \frac{\lambda}{\Delta\lambda} \leq a \frac{d\theta}{d\lambda} \quad (25)$$

giving the corresponding resolving power. One must notice that the spectral resolving power is limited by diffraction effects due to the finite aperture a (determined by the size of the prism or diffraction grating) and not by the entrance slit width. When taking into account the entrance finite slit width ϵ_1 , the condition is

$$\Delta x \geq \left(f_2 \frac{\lambda}{a} + \epsilon_1 \frac{f_2}{f_1} \right) \quad \text{or} \quad \Delta\lambda \geq \left(\frac{\lambda}{a} + \frac{\epsilon_1}{f_1} \right) \left(\frac{d\theta}{d\lambda} \right)^{-1} \quad (26)$$

However, there is a lower limit for ϵ_1 (2) resulting in a practical resolving power

$$R = \frac{\lambda}{\Delta\lambda} = \frac{1}{3} a \frac{d\theta}{d\lambda} \quad (27)$$

Free Spectral Range. In the case of a spectrometer, the free spectral range is the wavelength region where the instrument has a one-valued relation between the wavelength and the position $x(\lambda)$ in the focal plane of the focusing lens. For prism spectrometers, it corresponds to the whole wavelength range of the instrument, while for grating spectrometers it is related to the diffraction order m .

Prism Spectrometers

Principle of Operation. A typical arrangement for a prism spectrometer is given in Fig. 2. The entrance slit S illuminated

Figure 2. Typical configuration for a prism spectrometer: the light source illuminates the entrance slit S which is placed in the focal plane of a collimating lens L_c . The prism P diffracts the incident collimated beam and a focusing lens L_f images the entrance slit so that the position $x(\lambda)$ of the focal point in the x plane is wavelength dependent.

by the light source is placed in the focal plane of a collimating lens L_c . The prism P diffracts the incident collimated beam with an angle dependent on the wavelength. As shown in Fig. 3(a), the angle θ , relative to the incident direction, depends on the prism angle α , the angle of incidence of the beam θ_1 , and the refractive index of the prism material $n(\lambda)$. A focusing lens L_f is used after the prism to image the entrance slit so that the position $x(\lambda)$ of the focal point in the x plane is a function of λ . A wavelength scan can be done either by rotating the prism while keeping the output slit fixed, or the contrary.

Angular and Linear Dispersion. When the prism is used at the minimum deviation [Fig. 3(a)], we have

$$\frac{1}{2} \sin(\theta + \alpha) = n \sin(\alpha/2) \quad (28)$$

Then, it is possible to derive the angular dispersion $d\theta/d\lambda$ by first evaluating $d\theta/dn$. We have

$$\frac{d\theta}{dn} = \frac{2 \sin(\alpha/2)}{\cos[(\theta + \alpha)/2]} = \frac{2 \sin(\alpha/2)}{\sqrt{1 - n^2 \sin^2(\alpha/2)}} \quad (29)$$

The angular dispersion is given by

$$\frac{d\theta}{d\lambda} = \frac{2 \sin(\alpha/2)}{\sqrt{1 - n^2 \sin^2(\alpha/2)}} \frac{dn}{d\lambda} \quad (30)$$

Figure 3. (a) Illustration of a diffraction prism used at minimum deviation: the beam exits the prism with an angle θ verifying the equation $\frac{1}{2} \sin(\theta + \alpha) = n \sin(\alpha/2)$, where α is the prism angle and n is its refractive index. (b) The limiting aperture a of the prism d and on the incident angle θ_1 following the equation $a = d \cos \theta_1 = b[(\cos \theta_1)/2 \sin(\alpha/2)]$.

We see that dispersion increases with the prism angle α (and so does the size of the prism) but does not depend on the prism size. Therefore, small prisms can be used for small laser beams while keeping the same angular dispersion. However, the prism must be chosen large enough to prevent diffraction problems and to achieve a large spectral resolving power. An equilateral prism with $\alpha = 60^\circ$ is usually chosen as the best compromise. In that case

$$\frac{d\theta}{d\lambda} = \frac{1}{\sqrt{1 - (n/2)^2}} \frac{dn}{d\lambda} \quad (31)$$

For values of n around 1.4 to 1.6, the angular dispersion reduces to

$$\frac{d\theta}{d\lambda} \cong n \frac{dn}{d\lambda} \quad (32)$$

The linear dispersion $dx/d\lambda$ depends directly on the prism material dispersion $dn/d\lambda$ and on the focal length f of L_f . It is given by

$$\frac{dx}{d\lambda} = f \frac{d\theta}{d\lambda} \quad (33)$$

Spectral Transmission and Dispersion of Prism Materials. The transparent spectral range for fused silica prisms is 180 nm to 3000 nm. For shorter wavelengths (VUV region), lithium or calcium fluoride can be used, while for longer wavelengths CaF_2 , KBr, or NaCl are transparent up to 30 μm .

The spectral dispersion $dn/d\lambda$ increases greatly near a region of absorption, making glass (e.g., BK7) an attractive material in the visible and near-ultraviolet regions while quartz is more interesting for the ultraviolet region.

Performance and Limitations. If the collimating and focusing lenses L_c and L_f are not achromatic, their focal length will decrease with wavelength. This effect can be compensated by tilting the image plane so that it matches the focal point for every wavelength. If the plane is tilted by an angle ϕ , the linear dispersion will be increased by a factor $1/\cos \phi$.

The resolving power is

$$R = \frac{1}{\lambda} a \frac{d\theta}{d\lambda} \quad (34)$$

where the limiting aperture of the prism a is given by [see Fig. 3(b)]

$$a = d \cos \theta_1 = b \frac{\cos \theta_1}{2 \sin(\alpha/2)} \quad (35)$$

with d the height of the input face of the prism and b the length of its base. At minimum deviation, we have

$$n \sin(\alpha/2) = \sin \theta_1 \quad (36)$$

so that

$$\frac{\lambda}{d\lambda} = b \frac{dn}{d\lambda} \quad (37)$$

is only limited by the size of the prism base and the dispersion. For example, if the prism material has a dispersion $dn/d\lambda$ of

500 cm^{-1} at 633 nm and the prism has a base $b = 50 \text{ mm}$, then $R \leq \frac{1}{3} \times 2500$. A spectrometer with such a prism is then able to resolve two lines separated by $\Delta\lambda = 0.75 \text{ nm}$ at 633 nm.

A prism spectrometer is interesting because it allows an unambiguous determination of wavelengths due to the nature of the equation $x(\lambda)$. Its cost can be low when using a small prism and it is simple to make and to adjust. However, as its spectral resolution is limited, it is mainly used for wavelengths scans over large spectral regions as a preliminary survey work.

Grating Spectrometers

Principle of Operation. Many configurations have been demonstrated for grating spectrometers. One possibility is to use an arrangement similar to the prism spectrometer (Fig. 2) and replace the prism by a diffraction grating used in transmission. Another way is to use the diffraction grating in reflection. Plane diffraction gratings can be used in a Littrow mounting [Fig. 4(a)] or in the Ebert mounting with a concave mirror [Fig. 4(b)]. A variation of the Ebert mounting is the Czerny–Turner mounting where two adjacent concave mirrors are used. Many configurations have also been demonstrated using concave diffraction gratings (3).

The input light is first collimated by a lens or a concave mirror. It is then diffracted by the grating that separates the different wavelengths. The refracted light is focused in the detection plane. If an aperture is used, its width determines the wavelength resolution of the spectrometer.

In every case, the diffraction grating acts as a wavelength-selective reflector, by reflecting light into well-defined directions for each incident wavelength. The different reflected beams correspond to the orders of the grating. The general equation for the grating is

$$d(\sin \alpha \pm \sin \beta) = m\lambda \quad (38)$$

where d is the groove dimension, α and β are the incidence and reflection angles relative to the grating normal, m is the grating order, and λ the wavelength [see Fig. 5(a)]. The amplitude of the wave reflected in the detection β is the superposition of the amplitudes reflected by all the grooves illuminated. The

Figure 4. (a) Grating spectrometer using a Littrow mounted grating: the light exiting the input slit is first reflected by the prism and diffracted by the grating. The diffracted light is imaged on the output plane. Note that the slit and the prism are placed in a different plane from the grating so that the light reflected by the grating does not pass twice in the prism. (b) Grating spectrometer using the Ebert mounting configuration: the light exiting the slit is collimated by a concave mirror, diffracted by the grating and imaged in the output plane after a second reflection on the concave mirror.

Figure 5. (a) The diffraction of a beam by a diffraction grating follows the equation $d(\sin \alpha \pm \sin \beta) = m\lambda$, where d is the groove dimension, α and β are the incidence and reflection angles relative to the grating normal, m is the grating order and λ the wavelength. (b) Intensity distribution of the reflected beam for $N = 10$. The amplitude of the wave reflected in the direction β results from the interference of the beams reflected by all the grooves illuminated. The corresponding intensity is $I = R_g I_0 \sin^2(N\phi/2)/\sin^2(\phi/2)$.

corresponding intensity is

$$I = R_g I_0 \frac{\sin^2(N\phi/2)}{\sin^2(\phi/2)} \quad (39)$$

where R_g is the reflectivity of the grating, I_0 the intensity of the incident wave on each groove, N the number of grooves illuminated, and

$$\phi = \frac{2\pi}{\lambda} d(\sin \alpha \pm \sin \beta) \quad (40)$$

is the phase difference between two adjacent grooves. Figure 5(b) shows I as a function of ϕ for $N = 10$. Each maximum occurs when $\phi = 2k\pi$. In terms of β , the line profile has a base half width of

$$\Delta\beta = \frac{\lambda}{Nd \cos \beta} \quad (41)$$

We can evaluate the angular dispersion from the grating equation to obtain

$$\frac{d\beta}{d\lambda} = \frac{m}{d \cos \beta} = \frac{\sin \alpha \pm \sin \beta}{\lambda \cos \beta} \quad (42)$$

which only depends on α and β and not on the number of grooves. The angular dispersion is reduced to

$$2 \tan \alpha / \lambda \quad (43)$$

in the case of a Littrow mounted grating ($\alpha = \beta$).

Possible Monochromator Configurations

A double monochromator is a combination of two single monochromators placed in cascade. This configuration improves the dynamic range, but the wavelength span is reduced and the losses are increased, degrading the sensitivity. Another possible configuration is the double-pass monochromator, which provides the dynamic range of a double monochromator while keeping the sensitivity and compactness of a single one.

Performance and Limitations. The resolving power R can be expressed from

$$\Delta\lambda = \Delta\beta \left(\frac{d\beta}{d\lambda} \right)^{-1} \quad (44)$$

so that

$$R = \frac{Nd(\sin \alpha \pm \sin \beta)}{\lambda} = mN \quad (45)$$

R depends on the number of illuminated grooves N and on the diffraction order m used. If the finite slit width and diffraction effects are considered we have:

$$R = \frac{1}{3}mN \quad (46)$$

R is limited physically by the dimensions of the grating. It is advantageous to use a high-order m but the grating reflectivity might decrease drastically. For example, a 5 cm $\times$ 5 cm grating with 1200 grooves/mm used to first order has a practical resolving power of 2×10^4 . When used at 1550 nm, it is capable of resolving $\Delta\lambda = 0.075$ nm.

The main disadvantage of grating spectrometers is the possible ambiguity in interpreting the output spectrum as the different orders will overlap for different wavelengths. A solution consists in using wavelength-selective filters in order to isolate one particular order of diffraction. However, the resolving power is much better than that obtained with a prism spectrometer. It can be increased by using a double-pass configuration where the beam is diffracted once by the grating, then passes into an aperture and diffracted again before being detected.

Wavelength Measurement Using Spectrometers. Both prism and grating spectrometers can be used as wavelength meters. To do so, it is necessary to tune the instrument over the unknown light-source spectrum. Another important aspect is to perform an accurate calibration for the wavelength determination.

One possibility for tuning monochromators is to rotate either the prism or the grating, which causes a different wavelength to be focused on the output slit, placed in front of a detector. Another possibility is to keep the prism or grating fixed and move the slit and photodetector in the output plane. In both cases,

the prism or grating angle or the slit–photodetector movement must be controlled precisely and in a repeatable way to allow accurate tuning from measurement to measurement (4).

In the case of spectrographs (no moving parts), the spectrum is recorded at once using a photodetector array, and it is only necessary to know the wavelength calibration along the photodetector array. In order to make sure that the wavelength is correctly assigned, a calibration procedure is required for spectrometers as they do not have an internal wavelength reference. It is necessary to have external reference sources such as spectral lamps or lasers stabilized to atomic or molecular absorption lines. For an accurate calibration, the use of several wavelength references (at least three) is recommended and they should be distributed over the whole spectral range of the instrument. Some commercial instruments now include internal references based on the use of molecular resonances, such as acetylene, to perform internal calibrations (see Table 1).

INTERFEROMETER-BASED WAVELENGTH METERS

The next section describes wavelength meters using interference phenomenon, including Michelson, Fizeau, and Fabry–Perot interferometers.

Classification of Interferometers

Optical interferometers can be used to perform a wide variety of precision measurements such as measurement of length, studies of surface structure, measurement of temperature, pressure, and particle velocities. Those measurements are based on the interference phenomena produced by light waves. Wavelength measurement can also be realized with very high precision. In fact, interferometers are the most accurate instruments for measuring the wavelength of an optical source.

Interferometers can be classified as two-beam interferometers or multiple-beam interferometers according to the number

of interfering beams. The most common type of two-beam interferometers used to measure wavelength are the Michelson and Fizeau interferometers. The Fabry–Perot interferometer is the most usual type of multiple-beam interferometers.

Wavelength meters based on interference phenomena can be subdivided in two categories; dynamic and static wavelength meters. The former relies on the displacement of an element. It is the most accurate type of instrument but it can only perform wavelength measurement on continuous wave (CW) sources. On the other hand, static wavelength meters have no moving parts and can be used to measure wavelength of CW or pulsed sources.

Michelson-Based Wavelength Meters

The principle of operation of the Michelson interferometer is presented in Fig. 6. The incident beam is first divided by a 50-50 beam splitter that can be either a partially reflecting metal mirror or dielectric film on a transparent substrate. The two beams are next recombined by the same beam splitter on a detector (or a screen). Since the second beam passes only one time through the beam splitter, a compensating plate may be used in the second arm to equalize the optical path followed by the two beams, but is not always necessary for small collimated beams.

If the mirror M_2 is moved by Δx , the intensity of the interference pattern on the detector changes sinusoidally. A complete cycle is observed when the optical path difference between the two arms of the interferometer corresponds to one wavelength of the incident light beam. Thus, when a mirror displacement of $\lambda/2$ is performed, a complete cycle is observed.

The wavelength of the incident light beam can be deduced if the interference maxima frequency is measured when the mirror M_2 is displaced at constant speed

$$\lambda = \frac{2v_m}{f} \quad (47)$$

Figure 6. Principle of operation of a Michelson interferometer. An incident beam is divided by a 50–50 beam splitter. The two beams are next recombined by the same beam splitter on a detector. If the mirror M_2 is moved, the intensity of the interference pattern on the detector changes sinusoidally. The wavelength of the incident light beam is deduced if the interference maxima frequency is measured when the mirror M_2 is displaced at constant speed.

where v_m is the displacement speed of moving mirror M_2 and f is the frequency of apparition of interference maxima.

The main problem with the previously described Michelson-based wavelength meter resides in the determination and the accuracy of the displacement speed of the moving mirror. For that reason, Michelson interferometers are rarely used in that configuration unless low accuracy ($\sim 1 \times 10^{-4}$) is sufficient.

The most common type of Michelson-based wavelength meter uses a two-beam interferometry process (5). In that configuration, a two-beam scanning Michelson interferometer compares the number of fringes obtained by both a reference laser for which the wavelength is known very accurately and an unknown laser. Absolute wavelength measurement of CW sources can then be performed. For the two beams, the optical path d is changed by the same and known amount. A typical

optical configuration for that type of interferometer is presented in Fig. 7.

With this type of wavelength meter, the wavelength of the unknown laser can be determined by the following relation:

$$\lambda_U = \frac{N_R n_U \lambda_R}{N_U n_R} \quad (48)$$

where N_R and N_U are the number of fringes counted on the reference and input photodetectors (corresponding to the reference and unknown laser), n_R and n_U are the refractive index of the media at the reference and unknown wavelengths, and λ_R is the wavelength of the reference laser. From that equation, it is clear that all parameters in Eq. (48) must be known very accurately. The maximum relative uncertainty of the unknown wavelength λ_U is the sum of the relative uncertainty of each relevant parameter, which are the wavelength reference, number of fringes, the ratio of the refractive indexes, beam misalignment, and wave-front distortion (2, Ch. 4).

The measurement accuracy can be greatly enhanced by improving the wavelength reference's own accuracy. Wavelength references found in current laboratory instruments are relatively simple He–Ne gas lasers with about 10^{-7} absolute accuracy. A more accurate I_2 -stabilized He–Ne laser is often used in laboratory installations where size is of minor concern but is somewhat difficult to implement in a portable instrument. Those type of lasers are calibrated with an uncertainty smaller than 10^{-10} . Recently, some progress has been made in replacing He–Ne lasers at 633 nm by semiconductor lasers, providing a more compact and reliable source for the reference laser (6).

Other sources of error for wavelength determination come from the number of fringes seen by the input and reference detectors. One way to improve the accuracy is to count as many fringes as possible; this can be done by increasing the retroreflector mirror displacement. Unfortunately, this also increases the size of the instrument which for a commercial instrument is not suitable. Usually, this technique is implemented in a laboratory environment where space is not a concern. The maximum retroreflector mirror displacement is limited by the coherence length l_c of the reference and unknown laser sources.

Figure 7. Commercially available two-beam scanning Michelson-based wavemeterTM (courtesy of Burleigh).

After a displacement corresponding to one coherence length, no interference pattern can be observed (7). The coherence length is related to the spectral width of the source and is given by

$$l_c = c/\Delta\nu \quad (49)$$

where c is the speed of light in vacuum and $\Delta\nu$ is the spectral width of the source. From that relation, it is clear that the frequency of a source emitting in a very narrow band of frequency can be determined with greater precision than a broad-band source.

Another way to improve the wavelength-measurement accuracy without increasing the path displacement of the retroreflector mirror is to determine a fractional order number of interference fringes. Techniques such as phase-locking an oscillator to an exact multiple of the frequency of the ac signal from the reference laser (8) or using a vernier method in which the counting cycle starts and stops when the two signals coincide (9) have been proposed. With these techniques, fringe fractions can be determined with an uncertainty of $1/500$ of a fringe (10). Moreover, vibrations during the measurement must be reduced to a minimum in order to eliminate the frequency jitter on the fringe signal (11).

To eliminate the dispersion of air, the wavelength meter is often operated in a vacuum chamber. If the instrument is operated in air, the index of refraction depends on the wavelength, the total air pressure, the partial pressures of H_2O and CO_2 , and the temperature. All those parameters must be controlled and/or recorded with great precision. Moreover, the ratio of the refractive indices depends on the wavelength difference $\Delta\lambda = \lambda_R - \lambda_U$. The relative uncertainty on the index of refraction depends on the wavelength range. Typically for visible wavelengths, the uncertainty ranges from 10^{-11} ($\Delta\lambda = 1 \text{ nm}$) to 5×10^{-9} ($\Delta\lambda = 200 \text{ nm}$).

There are other sources of systematic errors that can influence the achievable accuracy of a two-beam scanning Michelson-based wavelength meter. One of them is the misalignment of the two beams that causes them to travel slightly different path lengths. As an example, if the two beams are slightly tilted against each other by 10^{-4} rad, the systematic relative error becomes 5×10^{-9} . In the wavelength meter proposed in Fig. 7, the corner cube retroreflector guarantees that the incoming light beam is reflected exactly parallel to its incident direction regardless of a slight misalignment.

Finally, the quality of the optical components can also limit the measurement accuracy. With a surface quality of $\lambda/10$, wavefront distortions are already visible in the interference pattern (2). Moreover, to minimize diffraction effects particularly important in the infrared region, a large beam diameter should be used. The uncertainty due to diffraction is inversely proportional to the square of the beam diameter (11).

Laboratory and Commercial Instrument. In a laboratory experiment, Ishikawa, Ito, and Morinaga demonstrated a wavelength meter with an accuracy of 4×10^{-10} (10). In that experiment, the main limitation was caused by a slight optical misalignment between the two beams. An improved version of that wavelength meter was later designed (11). That time the wavelength uncertainty was evaluated at 7×10^{-11} and was limited by the accuracy of the I₂-stabilized He–Ne laser.

For the most accurate currently available commercial instrument (Burleigh WA-1500), the wavelength of the unknown laser source can usually be determined to an accuracy of 10^{-7} . In that case, the accuracy is limited by the reference laser, which is a He-Ne gas laser stabilized on its gain curve. Temperature and pressure sensors are used to evaluate the index of refraction of air as the interferometer is not evacuated. Figure 8 presents a picture of that instrument.

Figure 8. Front view of the Burleigh WA-1500 Michelson-based wavemeter (courtesy of Burleigh).

Multiwavelength Measurement. One of the disadvantages of the previously described wavelength meter is that it can only perform a single wavelength measurement. However, the previous configuration can be modified to perform multiwavelength measurement. This task is particularly suited to dense-wavelength division multiplexing (DWDM) communication systems. The fringe pattern produced by the unknown laser can be sampled at regular intervals corresponding to the period of the reference-laser interference pattern. A Fourier transform on those data yields the complete spectrum. The resolution or the minimum frequency spacing $\Delta\lambda$ that can be measured by the instrument is directly related to the number of counted fringes (12)

$$\frac{\lambda}{\Delta\lambda} = 2N \quad (50)$$

As for the accuracy, the resolution can be improved by counting as many fringes as possible; this can be done by increasing the retroreflector mirror displacement.

A motionless Michelson interferometer with a fixed path difference Δs can also be used to measure the wavelength of pulsed sources (13). In such a wavelength meter, the incident signal enters the interferometer polarized at 45° . A phase difference $\Delta\phi = \pi/2$ is next introduced between the two polarized components. The interference signal at the exit of the interferometer is recorded separately for both polarizations. From the two interference signals obtained, it is possible to deduce the wave number $\sigma = 1/\lambda$ modulo $1/\Delta s$ since all wave numbers $\sigma_m = \sigma_0 + m/\Delta s$ ($m=1, 2, 3, \dots$) give the same interference signals. If similar interferometers having a path difference in geometric ratios are used, the wave number can be deduced without ambiguity. Since such an instrument measures the wave number it is called a *sigmometer*.

Fizeau-Based Wavelength Meters

Fizeau interferometers can be used to perform wavelength measurement (14). Those static wavelength meters have no moving parts and can measure the wavelength of CW and pulsed sources.

Fizeau interferometers consist of two plates inclined to form a wedge of angle α (see Fig. 9). When plane monochromatic light is incident on that type of interferometer, reflected light forms a series of uniformly spaced interference fringes for which the intensity will vary as

$$I(x) = \frac{1}{2} \left[1 + \cos \left(\frac{2\pi x}{\Lambda} + \phi \right) \right] \quad (51)$$

where $\Lambda = \lambda/(2\alpha)$, x is the distance along the detector array, and ϕ is the phase at $x = 0$. The fringes produced are imaged on a detector array. With a typical interferometer plate spacing of 1 mm and a wedge of 3 min, an accurate measurement of the fringe period can give a wavelength measurement accuracy of 10^{-4} . Moreover, if the phase of the interference pattern on the detector array is determined accurately (15), the accuracy can go as high as 10^{-7} .

Such an accurate measurement can only be accomplished if the wedge angle and spacing are previously calibrated. Also, the fringe pattern on the detector must approximate as much as possible the sinusoidal pattern of Eq. (51). This is done by ensuring that the incident light has plane-wave fronts. This

Figure 9. Principle of operation of a Fizeau-based wavelength meter. Fizeau interferometers consist of two plates inclined to form a wedge of angle α . When plane monochromatic light is incident on that type of interferometer, reflected light forms a series of uniformly spaced interference fringes for which the intensity will vary. The fringes produced are imaged on a detector array. The fringe period is computed and gives a wavelength measurement.

is accomplished by spatially filtering the incident light and by using interferometer plates with excellent flatness. Dispersion effects must also be taken into account for very accurate wavelength measurement. The advantage of the Fizeau wavelength meter is its simple, compact, and robust design. However, the accuracy of such a wavelength meter is usually less than a scanning Michelson-based wavelength meter.

Figure 10 presents a commercially available Fizeau-based wavelength meter. It is worth mentioning that this instrument contains a thin fused silica etalon, a precision input aperture, and a silicon CCD array. Due to the type of detector array used, this instrument can perform wavelength measurement from 400 nm to 1000 nm. The accuracy of the instrument is 10^{-5} . The instrument is wavelength calibrated at the factory using five different stabilized lasers. The calibration process allows for effective determination of the etalon thickness and to linearize the detector array signal. All the components are housed in

Figure 10. Front view of the New Focus Fizeau-based wavelength (courtesy of New Focus).

Figure 11. Principle of operation of a Fabry-Perot interferometer. This type of interferometer is made of two highly reflecting mirrors (flat or concave) uniformly spaced by air or a dielectric material. When coherent light is injected on one side of the interferometer, an interference phenomenon is created by the multiple reflections inside the cavity.

a thermally isolated enclosure. The index of refraction of air is mathematically compensated for temperature and pressure variations.

Fabry-Perot-Based Wavelength Meters

Scanning Fabry-Perot interferometers can be used to perform wavelength measurement although those instruments are usually used as optical spectrum analyzers. Figure 11 depicts the principle of operation of a Fabry-Perot interferometer. This type of interferometer is made of two highly reflecting mirrors (flat or concave) uniformly spaced by air or a dielectric material (16).

When coherent light is injected on one side of the interferometer, an interference phenomenon is created by the multiple reflections inside the cavity. For that reason, Fabry-Perot interferometers are called multiple-beam interferometers. The interference is constructive and a stationary wave is built when the distance between the two mirrors corresponds to an integer multiple of half wavelengths of the input beam. This condition is given by

$$L = \frac{m\lambda}{2n} \quad (52)$$

where L is the distance between the mirrors, m is an integer, and n is the refractive index of the material inside the cavity. When the condition in Eq. (52) is respected, light transmission through the interferometer is maximum. The frequency spacing between the transmission peaks is called the free spectral range (FSR) and is determined by the spacing between the mirrors and by the refractive index of the material inside the cavity. The FSR (in hertz) is given by

$$\text{FSR} = \frac{c}{2nL} \quad (53)$$

The transmission coefficient of an ideal Fabry-Perot interferometer is described by an Airy function (16)

$$\tau(\lambda) = \frac{I_t}{I_0} = \left[1 + \frac{4R}{(1-R)^2} \sin^2 \left(\frac{2\pi nL \cos(\theta)}{\lambda} \right) \right]^{-1} \quad (54)$$

where I_t and I_0 are the input and transmitted intensities, R and T are the mirror reflection and transmission intensity coefficients, and θ is the angle (relative to the mirror plane

Figure 12. Transmission of an ideal Fabry-Perot interferometer for different mirror reflectivities ($\theta = 0^\circ$, $L = 1.5$ mm, $n = 1$, FSR = 99.9 GHz).

inside the cavity) of the input beam (usually the input beam is perpendicular to the mirrors and this angle is 0°). Figure 12 presents the transmission of an ideal Fabry-Perot interferometer for various mirror reflectivities at $\theta = 0^\circ$.

From Fig. 12, we see that another parameter, the finesse (F), gives information about the spectral width of each transmission peak. This parameter depends on the mirror reflectivities, optical quality, and alignment. The finesse is defined by

$$F = \frac{\text{FSR}}{\Delta\nu} \quad (55)$$

where $\Delta\nu$ is the full width at half maximum of the transmission peaks. If the finesse is much larger than 1 (which is usually the case), F can be approximated by

$$F = \frac{\pi R^{1/2}}{1-R} \quad (56)$$

Let us now return to the principle of operation of a scanning Fabry-Perot interferometer. If two signals are incident on the interferometer and if the distance L between the two mirrors is changed, the interference patterns of both signals appear one after the other. For a given FSR, a high finesse allows the resolution of very closely spaced signals. The resolution is given by (12)

$$\frac{\lambda}{\Delta\lambda} = mF \quad (57)$$

where m is the mode number. The resolution can be increased if a high-order mode is used. This can be done by using a large distance L between the mirrors. In that case, the FSR is reduced; this means that the spectral range is also reduced. Depending on the application, trade-offs have to be made. As we mentioned previously, that type of instrument is mainly used to perform

high-resolution optical spectrum analysis over a relatively narrow spectral range.

However, by counting the fringes obtained by one reference and one unknown laser while the mirrors are scanned over a relatively long displacement and by using a coincidence technique similar to the vernier technique, wavelength measurement with an accuracy of 1×10^{-7} can be obtained (17). Also, by carefully calibrating the position of the mirrors against wavelength and by carefully controlling parameters such as temperature, pressure and alignment, the instrument could be turned into a wavelength meter. Today, Fabry–Perot-based wavelength meters are widely used for measuring the wavelength of pulsed lasers. In that case, a plane-mirror Fabry–Perot interferometer is operated in a static configuration (etalons). Such etalons, when illuminating with diverging light, produce a characteristic bull’s-eye fringe pattern corresponding to different angles of incidence. A CCD camera positioned across the fringe pattern is then used along with a computer to reconstruct the interferometer spectrum. The fringes of a Fabry–Perot etalon are unequally spaced; for that reason, Fizeau etalons, which produce equally spaced fringes, can be used instead of the Fabry–Perot etalon. However, Fabry–Perot etalons have better shaped fringes. Let us also mention that high-accuracy (1 ppm) wavelength measurement of pulsed laser sources can also be performed using two different fixed Fabry–Perot etalons and a reference laser for continuous calibration. In that case, the interference patterns generated by both etalons are recorded by two CCD cameras. The patterns are finally analyzed in a computer and the wavelength is deduced.

APPLICATIONS AND ADVANCED TOPICS

Applications

Scientific Measurements. With the now generalized use of the laser as a scientific investigative tool, wavelength meters have established a firm presence in research and industrial environments. Laser-based measurement techniques reach well beyond the optics field into general physics, chemistry, biology, and engineering. The extremely coherent signal emitted from a laser, whether semiconductor, solid-state, gas, or dye-based, is ideal for probing materials in order to determine their composition or properties, measure dimensions or distances accurately, and much more. In such measurements, the laser wavelength must generally be known precisely, and often the parameter of interest can actually be transformed into a reading of wavelength or wavelength offset. This is where the accuracy of modern wavelength meters as instruments plays a vital role. Wavelength meters in general can also be used for spectral analysis, which expands even further their applicability.

Optical spectroscopy, in its various forms, is useful in a vast number of applications, since it deals with the precise measurement of atomic and molecular absorption or emission features. These features reveal fundamental characteristics of virtually any material, e.g. metals, gases, organic tissue, and crystals (18). Possible wavelength ranges go from visible to infrared, which will guide the choice of a particular tunable laser, for example, semiconductor or dye (19), and of a particular wavelength meter. In a basic measurement, the frequency of an absorption feature is readily obtained by tuning the laser to it and measuring its wavelength with a wavelength meter. Simple spectral analysis can then be achieved by scanning the laser wavelength through the absorption feature and recording

Figure 13. Use of the wavelength meter in a simple absorption spectroscopy experiment. Simple spectral analysis can be achieved by scanning the laser wavelength through the absorption feature and recording the amplitude versus wavelength for each step.

the amplitude versus wavelength for each step, as depicted in Fig. 13.

A different application of spectroscopy is the light detection and ranging (LIDAR), used for monitoring aerosols in the atmosphere. A pulsed (nanosecond time scale) laser signal is sent to a target zone, from which backscattered light is captured. Detailed optical frequency/spectrum measurement of this signal yields information about the target atmosphere. Since this is a pulsed application, the typical scanned Michelson interferometer is not suitable and instruments with faster response times using Fabry–Perot or Fizeau interferometers are likely to be used. Calibrated with a reference He–Ne laser, such an instrument gives information about the absolute wavelength and spectral properties of the backscattered light, which in turn give information about the scattering medium properties.

DWDM Optical Communication. The laser has also enabled an area of significance for electrical engineering, that of optical communication, where wavelength meters find widespread use. After years of steady growth with single-wavelength systems at $0.8 \mu\text{m}$, then $1.3 \mu\text{m}$, the advent of the erbium-doped fiber amplifier (EDFA) has enabled a massive deployment of systems in the low-loss region at $1.5 \mu\text{m}$ (20). Accurate knowledge of the wavelength is generally not required in a single-wavelength system. However, technology advances coupled to the ever-increasing demand for bandwidth fueled by the Internet explosion have recently led to industrial implementation of dense wavelength division multiplexing (DWDM). In such systems, up to tens of optical channels are transmitted on a single fiber with frequency spacing currently as low as 100 GHz (about 0.8 nm at $1.55 \mu\text{m}$). Typical bit rates for individual channels in current high-capacity transport applications are 2.488 Gbit/s (Sonet OC-48) and 9.952 Gbit/s (Sonet OC-192). (Sonet is a multiplexing format and is the acronym for Synchronous Optical NETWORK.)

The 100 GHz standard channel spacing has been endorsed globally through a recommendation of the International Telecommunication Union (ITU). This recommendation actually defines precisely each channel frequency to be used: at this time, 40 channels from $\nu = 192\,100 \text{ GHz}$ to $\nu = 196\,100 \text{ GHz}$ applying to the individual transmitters and receivers. Corresponding vacuum wavelengths can be computed with $\lambda = c/\nu$, where $c = 299\,792\,458 \text{ m/s}$, the speed of light. Each frequency (or wavelength) value is in essence absolute: no particular technique for obtaining it is specified. This allows various equipment manufacturers and users worldwide to work with a common set of specifications, easing interoperability while employing potentially different technologies. The frequency tolerance around the absolute value is not standardized rigidly and is evolving as manufacturers and users refine their designs.

Current observed tolerances are in the ± 10 GHz to ± 20 GHz range for a 100 GHz channel spacing.

Since every transmitter and receiver must be designed, constructed, verified, and maintained in accordance with such tolerances, the need for accurate and easy wavelength measurements is clear. DWDM transmitters typically use distributed feedback (DFB) semiconductor lasers (21), which present a significant frequency dependence on operational parameters like temperature and current. Since typical coefficients are 10 GHz/°C and 1.5 GHz/mA, and given the tight-frequency tolerance required, it follows that transmitter emission wavelengths need to be calibrated in terms of temperature and current. These parameters also influence markedly the laser's output power, a critical parameter that must also be mapped out.

Wavelength meters as instruments now find widespread industrial use in optical telecommunication manufacturers production facilities at various instances. At the DFB fabrication and testing stage, they are used for selecting a laser operating point (temperature and current within an acceptable range) resulting in a wavelength situated within a desired channel tolerance, this at a predefined power level. Devices for which such a setpoint cannot be found are rejected. At the transmitter subsystem assembly stage, they are used for setting up and verifying the laser initial operating conditions, always ensuring an output wavelength within prescribed tolerances. At the DWDM transmission system setup stage, they are used for final verification of the multiple channel wavelengths. Meters based on FFT techniques providing a multiwavelength function are particularly useful at this point since their spectral analysis capability provides a quick view of the entire transmitted signal. See the HP 86120B instrument in Table 1.

DWDM systems must be designed for very high reliability over many years, and laser frequency aging must be taken into account in order to guarantee that transmitter wavelengths will remain within the specified tolerances. Frequency stabilization external to the laser itself is then required and various schemes have been developed (22–24). The basic approach is to compare the emitted wavelength with some active (reference laser) or passive (reference filter) wavelength standard, determine if the transmitter wavelength is adequate, and take corrective action if not. This will counteract the effect of laser wavelength aging and maintain a precise emission frequency over long periods of time. In a way, this comparison with a wavelength reference implements the wavelength meter function, although it does not necessarily return a reading of the wavelength itself. Of course, one possibility is to monitor the transmitter output with an actual wavelength meter instrument, and instruct a controller unit to slightly modify the laser operating conditions over time so as to maintain a prescribed wavelength. As represented in Fig. 14, a multiwavelength meter allows this concept to be extended simultaneously to every channel in the system (25).

DWDM receivers generally use demultiplexing filters with well-defined transmission responses that must be measured precisely. As in the electrical domain, a simple way to achieve this measurement is to send the signal from a broadband noise source through the filter and look at the transmitted shape on an Optical Spectrum Analyzer (OSA). For the 1.55 μm communication band, an easily available noise source is the amplified spontaneous emission (ASE) found at the output of an EDFA (20). The OSA, typically a grating-based monochromator-type

Figure 14. Use of a multiwavelength meter to control simultaneously the frequency of multiple laser transmitters in a DWDM communication system.

instrument, can measure wavelengths with less accuracy than a typical interferometer-based wavelength meter but offers more advanced spectral analysis capability. Again, wavelength meters with FFT-based spectral analysis capability can be used advantageously depending on the application. However, for very precise transmission versus wavelength measurements, one can revert to the fundamental spectroscopic technique of scanning the wavelength of a tunable laser (typically a laboratory instrument based on an external-cavity laser design (19, Ch. 8), recording simultaneously the transmitted power and the wavelength with, respectively, a power meter and a wavelength meter, exactly as depicted in Fig. 13.

Advanced Topics

Let us now address some foreseen or desirable avenues for improvements of the wavelength meter instrument, as well as discuss the current state-of-the art in wavelength measurement. In stand-alone instruments, one may wish to improve the resolution and accuracy of present units, in order to enable yet more precise measurements of all kinds. Improving the resolution means being able to sense a smaller wavelength change, and for the Michelson interferometer this requires a longer mirror travel. While this can be achieved easily in a laboratory interferometer setup, it is harder to realize in an actual instrument because of size, reliability and cost constraints. For example, a wavelength ratio uncertainty of 7×10^{-11} has been demonstrated in a laboratory configuration presenting a 60 cm mirror travel in vacuum and a 30 mm beam size (11). Mechanically scanned interferometers tend also to have slow update rates, which will likely be slowed down further by longer travels. Simultaneous improvements in resolution and measurement speed appear difficult, although compromises toward either parameter can certainly be achieved.

Improving the measurement accuracy rests first on improving the wavelength reference's own accuracy. Semiconductor lasers stabilized to atomic or molecular features are a foreseen development in future instruments, featuring reduced size, increased reliability, and an improvement in reference accuracy to the 10^{-10} level (23,24). Given an improved reference wavelength, one can then refine the interferometer's intrinsic design. This implies a minimization and a precise characterization of the sources of error inherent in the design, its tolerance to misalignment, and the ultimate effect on the wavelength reading. Again, in the case of a commercial instrument, cost and

reliability issues must be addressed at the same time as these refinements.

For the DWDM field, improvement paths may be oriented slightly differently, since the resolution and accuracy of commercial wavelength meters are basically sufficient for the needs of current and near-future systems. Emphasis should then be put on realizing wavelength meters which are smaller, cheaper, and more robust, particularly by developing solid-state designs with no moving parts. Resolution and accuracy may well be traded off for these considerations, depending on the particular application. Such developments might result in the ability to integrate an accurate wavelength-meter function (as well as spectrum analysis) into optical transmission subsystems. Various possibilities for solid-state wavelength meters have been investigated (25,26).

Finally, let us touch on absolute wavelength measurement. Here, the term *absolute* means that the measurement must be related directly to the universal reference for frequency and time, the cesium primary standard. The SI unit of time, that is, the second, is defined with respect to a microwave transition from the ground state of cesium, around 9.192 GHz. Cesium primary standards, or "atomic clocks," exist as standalone instruments, but the most accurate and stable ones are fairly complex installations found at various national laboratories around the world. Their output usually consists of an RF signal in the 10 MHz range. One approach for absolute optical frequency measurement is to synthesize from the cesium reference, through frequency multiplication and heterodyning, phase-locked signals at progressively higher frequencies until the unknown wavelength has been reached (24, Ch. 5). This unknown wavelength can of course be measured with less accuracy prior to the absolute measurement with the help of a standard laboratory wavelength/optical frequency meter. The final determination of frequency is done by measuring a specific RF or microwave transfer frequency at a particular point in the chain. Such an absolute optical frequency measurement can then be transformed into an absolute vacuum wavelength measurement through the basic relation $\lambda_0 = c_0/\nu$. This was enabled by the 1983 redefinition of a meter by the Bureau International des Poids et Mesures (BIPM) (27), which effectively defined the speed of light in vacuum as $c_0 = 299\,792\,458$ m/s exactly. Measurement accuracies of 10^{-12} have been obtained in the visible range and also at the well-established $3.39\,\mu\text{m}$ and $10\,\mu\text{m}$ wavelengths of metrological He-Ne and CO₂ lasers. This is to be compared with the 10^{-7} basic accuracy of the most accurate currently available commercial instrument, the Burleigh WA-1500 depicted in Fig. 8.

Optical comb generation (28), that is the generation of precisely controlled optical sidebands at RF or microwave intervals from a precise reference wavelength, can also be used for creating signals in the vicinity of the unknown signal. This technique has recently been employed for measuring accurately a series of molecular resonances of acetylene in the $1.5\,\mu\text{m}$ communication band (29). An accuracy in the 10^{-9} range was achieved.

CONCLUSION

Wavelength measurement is a fundamental and versatile function in many aspects of science and technology, as optical waves are prevalent in our everyday lives, in the scientific laboratory

and in technology-based commercial ventures. As we have seen, wavelength measurement can take various shapes depending on the particular application, and it calls upon diverse aspects of optics and both electrical and mechanical engineering.

One can use calibrated spectrometers based on prisms or gratings, or for better precision, Michelson, Fizeau, or Fabry-Perot interferometers. Each type of instrument presents advantages and limitations, so specific applications will dictate the choice of a particular configuration. Refined laboratory setups built for absolute measurements demand very accurate modeling and optical/mechanical design as well as construction, but size, complexity, and cost constraints are relaxed. Stand-alone laboratory instruments for scientific applications must be engineered so that a suitable level of performance is packaged in an easy to operate, robust, and cost-effective instrument. Finally, further improvements in the design of wavelength meters is leading the way toward the integration of this function into more and more compact subsystems, where size and cost are paramount.

REFLECTOMETERS, TIME-DOMAIN

Reflectometers are typically applied in high-frequency, microwave, millimeter, and optical circuits and systems to test discontinuities of the signal transmission channels. The first type, the frequency-domain reflectometer (FDR), determines the incident and reflected powers to compute reflection coefficients in terms of frequency. The frequency-domain measurements do not directly distinguish the location or the type of components introducing discontinuities. Some frequency-domain reflectometers measure the ratios of reflected and incident waves for known termination and for components under test within prescribed frequency ranges (1). The amplitude data points are registered and processed for each frequency to yield computed magnitudes and phases of individual reflections related to the distances along the tested components. The frequency information is then converted into time-domain pulses. The second type, the time-domain reflectometer (TDR), can measure the location and evaluate the type of the discontinuity, and also disclose multiple defects that would appear only through their accumulated effects if the time-domain relations were not available. The principles of classical time-domain reflectometry are based on observations of the reflections from the transmission

pathway superimposed on the incident wave, which is usually a fast steplike signal. Another class of time-domain reflectometry utilizes synthetic pulses forming short sinusoidal bursts (2). The reflectometers based on this idea analyze networks within desired frequency bands. The waves, incident and reflected, are acquired by high-frequency samplers, analyzed, and processed.

A typical measurement setup is composed of a fast pulse generator and a fast operating oscilloscope, usually a digitizing sampling oscilloscope to register the signals. Such a setup delivers broadband information about the behavior of the tested system. Due to the low level of high-frequency components of the pulse-step spectrum used in time-domain reflectometers certain narrowband discontinuities may not be observed. In those cases, frequency-domain reflectometry can give more reliable answers, thanks to the even distribution of frequency components in a sweeping signal.

In this article, only time-domain reflectometry (TDR) and reflectometers are discussed.

PRINCIPLES OF TIME-DOMAIN REFLECTOMETRY

Step-Pulse Time-Domain Reflectometry

Figure 1 shows the basic structure of a TDR with a high-input-impedance oscilloscope. A step generator sends its pulse into the transmission system under test. The step generator's impedance matches that of the transmission-line connection, TL, so the only reflections expected are from the circuit under test. The incident wave, which is one-half the open-circuit step voltage, is transmitted toward the circuit under test. When this signal encounters any discontinuity, including unmatched impedance of the circuit under test, a reflected voltage wave is produced, and it is propagated back to the generator and added to the incident wave. The reflected wave can be positive or negative.

The waves shown in Fig. 2 include the incident wave and the reflected wave that comes from the pure resistive load. The delay time, t_D is related to the distance between the oscilloscope connection to the transmission channel and the single reflecting discontinuity of the channel. The amplitude character of the reflection and the location of the reflecting object can be determined from the following expressions:

$$R = \frac{E_r}{E_i} = \frac{Z_L - Z_0}{Z_L + Z_0} \quad (1)$$

Figure 1. Basic structure of TDR.

Figure 2. Simplified TDR displays for nonreflective and reflective loads.

where R is the reflection coefficient, and Z_L and Z_0 are the load impedance and the transmission-line characteristic impedance respectively;

$$d = 0.5v_d t_{d0} \quad (2)$$

where d is the distance, v_d is the wave velocity, and t_{d0} is observed delay time. For a transmission line, the velocity of the wave is

$$v_d = \frac{c}{\sqrt{\mu\epsilon}} \quad (3)$$

where c is the light velocity in vacuum, μ is the magnetic permeability of the medium, and ϵ is the electric permittivity of the medium.

The waves of Fig. 2 are related to single, pure resistive discontinuities. The transmission-line reflections produced by complex loads are shown in Fig. 3.

In both cases considered so far to illustrate reflections from single discontinuities, an ideal step wave has been applied. The general shape of the waves is preserved when real step signals with finite risetimes are applied. The reflected wave transitions are smoother and the step-like sections are shorter, due to the transition parts.

Figure 3. Displays for ideal TDR and various complex loads.

Inductance effects are observed in the response of an open circuit to very sharp changes of the input signal. The response of inductance to the slow signal changes is revealed in exponential signal traces whose time constants are given by the ratios of the inductance to the resistance observed at the terminals of the inductor. Capacitance, on the other hand, creates a short-circuit connection for very sharp signal changes, while the slow changes are controlled by a time constant that is the product of the capacitance and the resistance observed at the terminals of the capacitor.

In all the time-domain test examples mentioned, it is important to define a reference plane so all distances can be measured in relation to this plane. The reference planes chosen in Figs. 2 and 3 are at the points where the oscilloscope-input terminals are connected. For simplicity of presentation the exponential parts of the waves are referred to their own origins ($t = 0$).

The information about reflections in circuits with transmission lines helps detect discontinuities in communication networks as well as determine characteristic impedances of the transmission lines. Figure 4 shows typical reflections for the case when two sections of the transmission lines are connected in such a way that the first section matches the standard impedance of the time-domain reflectometer, and the second, open-ended, produces reflections allowing one to determine its characteristic impedance. The characteristic impedance of the second section can be calculated from the second-step voltage level, which is

$$V_s = E_i \left(1 + \frac{Z_{02} - Z_{01}}{Z_{01} + Z_{02}} \right) \quad (4)$$

For example, if $E_i = 0.5$ V, $V_s = 0.6$ V, and $Z_{01} = 50 \Omega$, then $Z_{02} = 75 \Omega$ ($Z_{02} > Z_{01}$).

Usually TDRs compute desired quantities, including the discontinuity location, by analyzing the character of the reflected waves.

Short-Pulse Time-Domain Reflectometry

Short-pulse time-domain reflectometry uses very narrow pulses, and reflections are observed as waves occurring after the incident pulses are observed. The principles of the operation resemble those of radar. This type of reflectometry has found its main applications in long-distance cable tests,

Figure 4. TDR used to determine cable impedance.

including optical fiber probing, which can measure distances from millimeters to tenths of kilometers with resolution better than 1 mm. The reflectometers can also measure the losses and other parameters of the transmission communication channels.

Figure 5 shows typical waveforms with reflections when the incident and reflected pulses are close one to each other but the pulses are separated. When the two pulses are close and overlap, signal processing in the reflectometer can still separate the waves and determine the required parameters. In optical TDRs the optical signals are converted into corresponding electrical waves, which are coherently sampled and processed in a digitizing sampling oscilloscope (3). An example of waves that overlap is shown in Fig. 6. The wave, which is sent into an optical channel, is memorized before the test starts, and it is used as a reference in signal processing.

Applications of narrow test pulses are very convenient in finding faults on long transmission lines designed for telephone, television, and computer networks. High resolution in time is achieved by applying very short pulses with duration

Figure 5. Signals received and registered by an optical TDR: (a) incident and reflected waves are separated; (b) incident and reflected waves overlap.

of several nanoseconds. High resolution to detect small amplitudes of reflected waves is secured by using high-sensitivity and low-noise digitizing sampling oscilloscopes with averaging to reduce amplitude noise and jitter (4).

Figure 6. Block diagram of a TDR.

Differential Time-Domain Reflectometry

Differential time-domain reflectometry and reflectometers have been developed to investigate properties of transmission channels that are symmetric in relation to the ground plane. Two separate pulses are generated and applied to the system under test.

Two identical pulses of the same polarity are used to test reflections related to the common mode of the signal transmission. The same pulses but of opposite polarity are used to test reflections of the differential mode of the signal transmission. Both pulses must either coincide or be staggered with great precision, and then the two responses are processed separately and the results referred to the same time origin as if the time-delayed pulses were synchronous (5).

Synthetic Pulse-Domain Reflectometry

Synthetic pulse time-domain reflectometry employing controllable-band synthesized bursts has been developed to characterize microwave bandpass components. The spectrum of the testing signal is adjusted to cover the spectrum of the devices under test. This technique, supported by software signal processing, brings sufficient information to determine magnitude and phase of reflections. The synthesized signals are composed of sinusoidal signals whose amplitudes and phases can be controlled to achieve the best resolution (1).

EXAMPLES OF TIME-DOMAIN REFLECTOMETERS

TDRs can be categorized into two major groups according to their applications. The first group includes field time-domain

reflectometers applied to test cables as well as fiber-optic links. The second group includes laboratory time-domain reflectometers used to test microwave system components.

The first type, with low resolution (down to about 30 cm), uses a cosine-shaped pulse to detect discontinuities located at large distances. The pulse widths are adjustable from nanoseconds to about 1 μ s, and the distances covered can reach 17 km. The system internal impedances are 50, 75, and 100 Ω , including cable impedances of symmetric cables for television, telephone, and computers. The pulse amplitudes are about 10 V. The time resolution in such systems is usually limited by the narrowest pulse width.

A typical laboratory time-domain reflectometer system applied to test short-distance transmission line channels can be configured by connecting a fast pulse generator and a broadband digitizing sampling oscilloscope to a high-precision transmission line, which is connected to a device under test. The maximum bandwidth of the available sampling oscilloscopes reaches 50 GHz (4,6). Flat-top pulse generators, such as the HP 4015B (4) have risetimes better than 15 ps and low overshoot (less than 1%). The overall risetime of the system is close to 17 ps. The pulses, of amplitude close to 10 V are shaped by the step-recovery diodes. Some fast pulse generators generating small-amplitude pulses with the amplitudes of several hundred millivolts employ tunnel diodes. Two-channel operation allows single-ended and differential time-domain reflectometric tests. The noise levels are close to 1 mV, which determines the minimum value of the reflection coefficient that can be detected: about 1% for small pulse amplitude units, and about 0.1% for large pulse amplitudes if other pulse distortions are ignored or corrected for by digital processing.

Figure 7. Simplified diagram of a two-channel digitizing sampling oscilloscope used in a TDR system.

The digitizing sampling oscilloscopes used in the TDRs resemble the typical sampling oscilloscopes described in the article Oscilloscopes. A more detailed block diagram of a typical TDR is shown in Fig. 7. The reflectometers briefly described here can be also used as optical time-domain reflectometers if a fast-operating laser transmitter and a fast optical-to-electrical converter are supplied.

A block diagram of the converter applied in the HP 83481A unit is shown in Fig. 8 (3,5). The photodiode receives the light beam from the fiber through a lens. The light signal, converted into an electrical current, is translated into the input voltage of the low-output-impedance driver. The driver output with an added resistor matches the typical $50\ \Omega$ transmission channel and input of the sampling oscilloscope. Optical time-domain reflectometers, such as the HP 8146A (6) include lasers operating at wavelengths of 850 nm, 1300 nm, or 1550 nm. The light pulses from the laser diode are sent to the fiber optic link under test through a 3 dB optical coupler. The light passing through the link is partly reflected and scattered towards the transmitter-receiver unit (Fig. 9). The return light passes to the receiver through the coupler and is converted into electrical signal for further processing in a sampling oscilloscope (3).

A typical image observed on the screen of an optical TDR is shown in Fig. 10 for a case without reflections. The straight-line section represents continuous fiber backscatter. The slope of the line shows the amount of attenuation. Fiber reflections due to the nonideal connectors, splices, and cracks in the fiber are shown as peaks and steps modifying the straight-line part of the response, as shown in Fig. 11.

Figure 12 shows SPICE simulations illustrating operation of a synthetic pulse time-domain reflectometer. In the circuit, the input waves are synthesized using two sinusoidal signals of two different frequencies, 1.25 GHz and 2.5 GHz gated by 2 ns pulses. The shape of the signal resembles the waves applied in Ref. 1. The reflected waves, separated from the incident waves in a simple signal processor, are observed for broad and narrow band loads connected to a coaxial cable. In Figure 12, the reflected waves are delayed and inverted in phase due to low resistance of a broadband load. The narrow band loads introduce oscillatory responses when the resonance frequencies of the loads are centered within the band of the input waves.

In the reflectometer described in Ref. 1, the Hewlett-Packard Automatic Network Analyzer was used to generate harmonically related signals to 40 MHz within the range of 400 MHz to 3560 MHz. The analyzer also served as a receiver processing the received information in frequency domain, and converted it into time-domain through Fourier transformations.

BASIC CHARACTERISTICS OF THE TIME-DOMAIN REFLECTOMETERS

As mentioned before, there are two major characteristics of TDRs. First is the ability to distinguish two consecutive reflections, representing the time resolution, which is a direct function of the system risetime. Two reflected waves merge together

when they are located at a distance corresponding to less than one-half the system risetime. The computer signal processing available in most modern reflectometer systems makes it possible to incorporate the system imperfections into the compensating process to correct overall system characteristics. In this way, the measurement results approach the behavior of an ideal system, thus improving the time resolution. This characteristic

Figure 12. (Continued)

is strongly dependent upon the system noise level, observed in as jitter.

The second characteristic is the amplitude resolution, which expresses the ability to register small changes in the reflection coefficient. The amplitude resolution is limited by the signal-to-noise ratio of the system. The noise level registered in the system can be greatly reduced by analog or digital averaging or other signal processing. Obviously, the signal processing requires longer times of data collection and higher densities of sampling.

EXAMPLES OF APPLICATIONS OF TIME-DOMAIN REFLECTOMETERS

A number of examples described below illustrate how the character and the location of various discontinuities can be found. Investigation of the reflected waves yields additional information about transmission channel losses, which are more visible in systems with longer cables.

A typical example of a response of a transmission line is shown in Fig. 13. The first two plots show the response of

a lossless transmission line with a short-circuit termination. The third shows the pulse distortions introduced by the line losses. The fast changes are attenuated more by the skin effect than slower changes, which indicate the effects of low-frequency losses. The response does not allow evaluating the losses related to specific frequencies, which is possible by using FDRs. Fig. 14 shows the effects of the termination resistor leads (7). A microstrip $50\ \Omega$ transmission line is terminated with a $50\ \Omega$ resistor with long leads (2.5 cm). From the amount of reflected amplitude and the speed of the wave decay, it is possible to evaluate the lead inductance, which is about 6 nH when the estimated decay time is 0.3 ns.

The next example consists of the results of simulations and measurements of the T connection of three transmission lines, each having $50\ \Omega$ characteristic impedance. The reflections shown in Fig. 15 help locate the connection and find the length of each section. The reflection coefficient found from the ratio of the voltages yields a $25\ \Omega$ impedance terminating the center node of the transmission lines. The signals observed at the input terminals show an added reflection from the end of transmission line T_3 when the load of this line does not match

Figure 13. Effects of transmission line losses on reflected signals.

the line impedance. The second reflection reaches the input after 140 ns and represents the doubled transmission time of T_2 and T_3 . The plots of Fig. 15(b) were obtained with the help of HPVEE software (8).

The example of Fig. 16(a) illustrates reflections from different discontinuities of a strip line with a short section of narrow

Figure 14. Effects of long resistor leads.

strip and a short section of broad strip (7). If the discontinuity length is smaller than the shortest wavelength component in the spectrum of the testing pulses, then the discontinuity can be treated as a lumped element and the effects of the sections

Figure 16. Reflections in the circuit with a strip line: (a) measured, (b) simulated.

interpreted as inductive and capacitive, respectively, as shown in the simulated model of Fig. 16(b) using SPICE (9).

STANDING WAVE METERS AND NETWORK ANALYZERS

MEASUREMENT OF NETWORKS AT MICROWAVE FREQUENCIES

Determining the characteristics of electrical networks (network analysis) is an important measurement tool both for

developers of electrical circuits and systems and in production testing. The measurement of network characteristics at microwave frequencies employs different concepts than are used at lower frequencies, where measuring port voltages and currents readily allows determination of impedance (Z) or admittance (Y) parameters. At higher frequencies, neither high-impedance voltage probes nor low-impedance current measurements are feasible, because parasitic capacitance and inductance of probes (L_s and C_p in Fig. 1) cannot be made small enough. Also, the physical dimensions of microwave circuits typically are no longer small with respect to the wavelength. A cable, connecting the port of a device under test with the measurement equipment, may easily transform the intended open circuit into a short, if its length happens to be an odd multiple of $\lambda/4$. Furthermore, short- or open-circuiting network ports, invariably linked to voltage and current measurements, may alter the behavior of microwave circuits (e.g., an amplifier, operated at those impedance extremes, may oscillate). And in waveguides, voltage and current are not even defined.

The above difficulties are circumvented if the network is embedded between defined generator and load impedances Z_0 (typically real and $50\ \Omega$) and described in terms of its power transfer characteristics. The “scattering” of the incident power wave a_1 into the transmitted wave b_2 and the reflected wave b_1 fully characterizes the two-port network of Fig. 1 in the forward direction.

Conceptually, waves represent the propagation of energy along a transmission line. The incident (forward) wave $a = U_f/\sqrt{Z_0}$ travels along the line, with a portion of it ($b = U_r/\sqrt{Z_0}$) being reflected at the line's end. Adding both complex quantities along the transmission line yields a pattern that is referred to as the standing wave (Fig. 2). The ratio of its maximum to its minimum voltage is called the voltage standing wave ratio (VSWR) and is directly linked to the magnitude of the impedance Z_L , terminating the line.

$$\text{VSWR} = \frac{|U_f| + |U_r|}{|U_f| - |U_r|} = \frac{U_{\max}}{U_{\min}} = \begin{cases} \left| \frac{Z_L}{Z_0} \right|, & |Z_L| > Z_0 \\ \left| \frac{Z_0}{Z_L} \right|, & |Z_L| < Z_0 \end{cases} \quad (1)$$

The incident and reflected waves a_i and b_i at a network port (Fig. 1) are defined as linear combinations of the port currents and voltages:

$$a_i = \frac{U_i + I_i Z_0}{2\sqrt{Z_0}}, \quad b_i = \frac{U_i - I_i Z_0}{2\sqrt{Z_0}}$$

making it easy to compute the impedance Z_i at that port:

$$Z_i = \frac{U_i}{I_i} = Z_0 \frac{1 + \frac{b_i}{a_i}}{1 - \frac{b_i}{a_i}} = Z_0 \frac{1 + \Gamma_i}{1 - \Gamma_i}, \quad \Gamma_i = \frac{b_i}{a_i} \quad (2)$$

Γ is called the reflection coefficient. Similarly, the portion of the incident power transmitted from port i to port j is obtained by the transmission factor $t_{ji} = b_j/a_i$.

Figure 1. Drawbacks of voltage and current measurement versus the wave concept.

In general, a two-port network is fully characterized by its 2×2 scattering matrix,

$$\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \begin{pmatrix} a_1 \\ a_2 \end{pmatrix}$$

which is composed of

$$\begin{aligned} \text{Reflection coefficients: } S_{11} &= \left. \frac{b_1}{a_1} \right|_{a_2=0}, \quad S_{22} = \left. \frac{b_2}{a_2} \right|_{a_1=0} \\ \text{Transmission coefficients: } S_{21} &= \left. \frac{b_2}{a_1} \right|_{a_2=0}, \quad S_{12} = \left. \frac{b_1}{a_2} \right|_{a_1=0} \end{aligned}$$

The exact determination of scattering parameters, however, still requires the locus, where they are valid, to be fixed. If the measurement port at $x = 0$ in Fig. 2 is shifted to the left, the phase of incident and reflected waves changes and so does the reflection coefficient, which therefore depends on the locus. Especially at small wavelengths, measurement of S parameters stipulates the exact definition of *where* the waves are recorded, leading to the concept of *measurement* or *reference planes*. These planes are thought to perpendicularly intersect the transmission lines leading to the ports of the network, such that the phase of the waves in each plane is constant. For scattering parameter S_{ij} , the incident wave in plane j is thus the reference for the emanating wave in plane i . S_{ij} therefore describes the transmission of energy between those planes.

Since scattering parameters are ratios of emanating and incident waves, their computation does not require absolute measurement of the wave quantities. This important advantage allows the measurement of scattering parameters (with network analyzers) to inherently exhibit much higher precision than can be expected from a spectrum analyzer that relies on absolute measurement of its input power.

The remainder of this article will present a number of measurement systems for the determination of reflection coefficients (one-port network analyzer or reflectometer) and for full

characterization of two-port networks. Although the concept of S -parameters is easily extended to N -ports, measurement of networks with more than two ports will not be covered, because most commercially available hardware is built for two-port measurements and can be used to characterize N -ports by simply terminating the unused $N-2$ ports in Z_0 .

REFLECTION MEASUREMENT TECHNIQUES

The Slotted Line for VSWR and Impedance Measurements

A very old technique for measuring the VSWR on a transmission line, to determine the impedance connected at its end, makes use of a slotted transmission line of characteristic impedance Z_0 (see, for example, Ref. 1, Chap. 2, for a very detailed outline; or see Ref. 2, Chap. 4).

The slot allows a small enough probe, as not to disturb the line's field, to be moved along the x axis of the transmission line and sample its electric field. The high-frequency voltage is converted to direct current (dc) by a diode detector and brought to an instrument for readout. Since the signal level of the probe must be kept low in order to avoid loading of the line, the detector operates in its square-law region and its output is proportional to the detected *power*, or the square of the voltage. Noting the maximum and minimum values of the detector output, while varying the position of the probe, allows computation of the VSWR, provided that the slot is long enough to reach both maximum and minimum.

As indicated by Eq. (1), measurement of the scalar VSWR is not sufficient to uniquely determine the complex impedance Z_L , terminating the line. In fact, since

$$\begin{aligned} \text{VSWR} &= \frac{|U_f| + |U_r|}{|U_f| - |U_r|} = \frac{1 + \left| \frac{U_r}{U_f} \right|}{1 - \left| \frac{U_r}{U_f} \right|} = \frac{1 + \left| \frac{b}{a} \right|}{1 - \left| \frac{b}{a} \right|} \\ &= \frac{1 + |\Gamma|}{1 - |\Gamma|} \rightarrow |\Gamma| = \frac{\text{VSWR} - 1}{\text{VSWR} + 1} \end{aligned}$$

Figure 2. Standing waves along a transmission line, terminated in Z_L .

Figure 3. The slotted line measurement setup.

only the *magnitude* of the reflection coefficient Γ is available. The *phase* of Γ is obtained by noting the *position* $x_{\min}$ of the first minimum, appearing when the probe is moved away from Z_L . With the propagation constant

$$\beta = \frac{2\pi}{\lambda_{sl}}$$

of the slotted transmission line, the phase of Γ becomes

$$\varphi = 2\beta x - \pi$$

such that

$$\Gamma = |\Gamma|e^{j\varphi} = \frac{VSWR - 1}{VSWR + 1} e^{j(2\beta x - \pi)}$$

and the complex impedance Z_L may be computed from Γ using Eq. (2).

Though conceptionally simple, the slotted line technique suffers from a number of drawbacks and limitations:

1. The slotted transmission line itself is a costly precision device, exhibiting precise line impedance Z_0 , low losses, negligible loading due to the probe, and mechanical stability of the probe depth over the entire moving range.
2. Linearity errors and the limited dynamic range of the detectors reduce the accuracy when measuring large VSWRs. By modulating the RF source and selective reception of the modulation frequency, noise can be reduced, increasing sensitivity and thus measurement dynamic (the so-called "modulated frequency technique").
3. The measurement procedure requires manual interaction and, in its simple form of Fig. 3, does not allow for swept frequency impedance measurements. If, however, only the magnitude of the reflection coefficient is of

interest, Sorger (3) describes a setup that uses two slotted lines for swept frequency VSWR measurement.

Because slotted line reflection measurements are a very old technique, much research has been undertaken to alleviate the above limitations. Many ideas and extensions can be found in Ref. 2, covering the topic in more detail.

Using the Slotline with Multiple Probes

The biggest drawback of slotline measurements, the need for manual interaction, can be overcome if more than one probe taps to the field of the line in known and fixed positions. Figure 4 shows a system proposed by Caldecott (4) that uses three probes in arbitrary but known positions x_1 , x_2 , and x_3 . Caldecott proved that

$$\Gamma_L \approx \frac{P_1(e^{-j2\beta x_2} - e^{-j2\beta x_3}) + P_2(e^{-j2\beta x_3} - e^{-j2\beta x_1}) + P_3(e^{-j2\beta x_1} - e^{-j2\beta x_2})}{\sin[2\beta(x_2 - x_3)] \sin[2\beta(x_3 - x_1)] + \sin[2\beta(x_1 - x_2)]}$$

even providing complex measurability of the reflection coefficient, although only scalar power measurements ($P_1 \dots P_3$) are used.

Another interesting multiprobe reflectometer for swept frequency/swept power applications reported in Ref. 5 even provided an automatic Smith-chart display of the measured impedance.

The Six-Port Reflectometer

The idea of the foregoing section can be generalized to the so-called six-port reflectometer, developed by Hoer (6) and Engen (7) in the early 1970s. Figure 5 shows a general six-port junction, driven by a signal generator at port 5, ports 1 through 4 connected to power sensors (diode detectors, bolometers, thermocouple, etc.) and port 6 interfacing to the unknown impedance with reflection coefficient Γ_L .

As the mathematical derivation of the six-port theory is rather lengthy, the interested reader should refer to Refs. 2, 6, or 7 for details. In essence the 6×6 S -matrix of the six-port network is reduced to the form

$$b_i = Q_i a_6 + R_i b_6, \quad i = 1, \dots, 4 \quad (3)$$

by using $\Gamma_i = a_i/b_i$ to eliminate $a_1 \dots a_5$ (b_5 is also eliminated by omitting the 5th equation). The powers P_i are related to b_i by

$$P_i = |b_i|^2(1 - |\Gamma_i|^2)$$

Figure 4. The multiprobe reflectometer.

Figure 5. The six-port reflectometer.

and, using Eq. (3), can be expressed as

$$P_i = (1 - |\Gamma_i|^2) \{ |R_i|^2 |b_6|^2 + 2\text{Re}(Q_i^* R_i) \text{Re}(a_6 b_6^*) + 2\text{Im}(Q_i^* R_i) \text{Im}(a_6 b_6^*) + |Q_i|^2 |a_6|^2 \}$$

which may be written in matrix form as

$$(P_1 P_2 P_3 P_4)^T = [D] (|b_6|^2 \text{Re}(a_6 b_6^*) \text{Im}(a_6 b_6^*) |a_6|^2)^T \quad (4)$$

with $[D]$ being a real-valued 4×4 matrix. Inverting Eq. (4) gives access to its right-hand-side vector, provided that $[D]$ is known and invertible with $[C]$ being its inverse,

$$(|b_6|^2 \text{Re}(a_6 b_6^*) \text{Im}(a_6 b_6^*) |a_6|^2)^T = [C] (P_1 P_2 P_3 P_4)^T$$

such that Γ_L can be computed as

$$\begin{aligned} \Gamma_L &= \frac{a_6}{b_6} = \frac{a_6 b_6^*}{b_6 b_6^*} = \frac{\text{Re}(a_6 b_6^*) + j \text{Im}(a_6 b_6^*)}{|b_6|^2} \\ &= \frac{\sum_{n=1}^4 C_{2n} P_n + j \sum_{n=1}^4 C_{3n} P_n}{\sum_{n=1}^4 C_{1n} P_n} \end{aligned} \quad (5)$$

With just 12 of the 16 real-valued elements of $[C]$ appearing in Eq. (5), only 11 need to be computed, as Eq. (5) may be normalized to one of the 12 terms. They are determined by measuring *six known* reflection coefficients and using the complex equation [Eq. (5)] to establish a set of 12 linear, real-valued equations in the 12 unknowns.

Although such a calibration procedure to determine the elements of $[C]$ *must* be carried out before the six-port can be used for reflection measurements, it has the added advantage of providing error-corrected results. No a priori knowledge about the six-port is necessary, because the calibration sufficiently characterizes $[C]$, which reflects the properties of the six-port junction.

Further advantages of this kind of instrument are that neither the signal generator nor the power sensors need to be perfectly matched. The mismatch of the power sensors must however be constant. Because only ratios of measured powers enter the calculation of Γ_L , the power sensors do not need to be absolutely calibrated for power measurements.

However, the power sensors must be linear; and because of their broadband nature, care must be taken to suppress spurious emissions from the signal generator.

Evaluation of Eq. (5) and the determination of $[C]$ require some amount of numerical processing. Six-port reflectometers

are therefore almost always combined with microcontrollers to automate the process of calibration and measurement.

Internally, the six-port must be built such that the reduced matrix $[D]$ is invertible at all measurement frequencies. Details of the design process are outlined in Ref. 8 with a practical realization, using 0° and 90° couplers described in Ref. 9.

Reflection Measurement with the Directional Coupler

All of the impedance measurement methods described thus far evaluate the *sum* of incident and reflected waves, requiring at least two independent measurements for calculation of the reflection coefficient.

Alternatively, forward and reflected waves may be separated using a directional coupler. Such devices are common building blocks in microwave engineering and exist in a wide variety of designs, many of which are treated in Ref. 10, Chap. 8. The interested reader may also refer to Ref. 11 for some less common coupler structures and unusual applications. Figure 6 depicts the associated symbol of a directional coupler and its scattering matrix.

The important property of the directional coupler, used to separate incident and reflected wave is in its decoupled port. Figure 7 illustrates that feeding a wave a_1 into port 1 results in wave $b_2 = \tau a_1$ and $b_3 = \kappa a_1$ being emitted at ports 2 and 3 with no energy being fed to port 4, the decoupled port. Similarly, port 2 is decoupled from port 3. Driving the coupler at port 1, terminating port 3 in Z_0 , and connecting a matched power detector to port 4 allows measurement of unknown reflection coefficients connected to port 2.

Directional couplers, also called “VSWR-bridges” or “reflection coefficient bridges,” appear in various forms, with the microstrip coupler, the resistive coupler, and the Wilkinson divider (Fig. 8) being the variants most often found.

All practical realizations of directional couplers exhibit finite *directivity*, meaning that a small amount of the power fed to port 1 will leak to port 4, even if port 2 and 3 are perfectly terminated in Z_0 . The directivity of a coupler is defined as

$$d = \frac{S_{14}}{\kappa \tau}$$

Mismatch at port 2 and even at the driving port 1 will further add to erroneous reflections being indicated by the wave b_4 ,

Figure 6. The directional coupler.

Figure 7. Reflection measurement using a directional coupler.

which ideally should be a measure of the reflection of Z_L only. All these errors must be kept low if the coupler is to be used for precision reflection measurement. Narrow-band precision couplers, exhibiting more than 50 dB directivity, have been built in waveguide and broad-band couplers, typically of the resistive bridge type, and exhibit more than 36 dB directivity over a bandwidth of more than three decades. As a rule of thumb, the directivity should be at least 10 dB better than the expected reflection coefficient of the measured device under test (DUT).

ARCHITECTURES OF NETWORK ANALYZERS

In order to measure the entire scattering matrix of a two-port, some means of measuring the transmitted waves as well as the reflected waves must be provided. Because reflection measurements, nowadays, are almost always carried out with directional couplers, we will use its symbol for denoting measurement of reflected waves. As in Fig. 7, the “mixer” symbol will be used to denote a measurement point, at which the wave to be measured may be further processed in one of the following ways:

1. With power detectors, leading to scalar measurement of the wave
2. With a homodyne receiver, potentially capable of providing amplitude and phase information
3. With a heterodyne receiver (hence the mixer symbol), providing amplitude and phase information

Depending on the type of detector used, network analyzers (NAs) are classified into one of the following types of analyzer:

Scalar Network Analyzer. The simplest and most economic approach to the measurement of scattering-parameters

employs power (diode) detectors. Because these provide no phase information, only the magnitude of the S -parameters can be measured, hence the term *scalar network analyzer* (SNA). For many applications, however, the magnitude may be all that is needed. Calibration techniques, as described in the section entitled “Error Models, Calibration, and Error Correction,” however, require the phase information and consequently cannot be applied to SNAs. Instead, normalization is all that can be employed with such an instrument.

Other drawbacks of SNAs are the limited dynamic range and the broad-band nature of the power detectors. Since they record the entire power of a wave, regardless of its spectral origin, these instruments are susceptible to spurs or harmonics of the generator. If, for example, the harmonics of the radio-frequency (RF) source are suppressed by 30 dB, and the DUT has high-pass or band-stop characteristic (return loss of a filter or an antenna), the SNA will show no less than -30 dB attenuation or return loss, regardless of the DUT’s real properties.

It should be emphasized that the mere use of power detectors does not necessarily yield a scalar network analyzer. The six-port reflectometer, as described in the section entitled “The Six-Port Reflectometer,” employs four scalar detectors to determine the complex reflection coefficient; a complete vector NA can be built by using two such reflectometers (see Refs. 8, 9, and 12), retaining all vector error-correction capabilities of those instruments (13,14), as discussed in the section entitled “Error Models, Calibration, and Error Correction.”

Heterodyne (Vector) Network Analyzer. If the wave quantities are processed by heterodyne receivers, the phase information can be preserved by phase-locking the heterodyne oscillator to the RF source driving the DUT (Fig. 9), and complex measurement of the scattering parameters is possible. Besides providing a much higher dynamic range (over 120 dB for recent industry products versus 70 dB for SNAs), the ability to measure the complex S -parameters has the added benefit of allowing calibration techniques to enhance measurement accuracy. On the other hand, the inherent higher complexity of heterodyne vector network analyzers (VNAs) results in more expensive hardware. For broad-band systems, the heterodyne oscillator and its Phase Locked Loop (PLL) add considerably to the cost, because they must cover the system’s entire bandwidth.

A cost reducing alternative exists by employing “harmonic mixing” (e.g., Ref. 35). In this case the local oscillator (LO) in Fig. 9 has to cover only one octave with all higher frequencies that are needed being supplied by the LO’s harmonics. Harmonic mixing, however, leads to higher mixer conversion loss and thus also reduces the instrument’s dynamic range.

Figure 8. Some commonly used directional couplers.

Figure 9. Heterodyne receiver (LO: Local Oscillator, IF: Intermediate Frequency, BP: Bandpass filter, PFD: Phase-Frequency Detector, $H(s)$: Loopfilter).

Figure 10. Unidirectional network analyzer.

Homodyne Network Analyzers. In order to circumvent the need for a second microwave source and phase-locking circuitry, homodyne systems use the same generator for down-conversion that drives the DUT. Because the homodyne mixing process provides only the real part of the wave quantity, homodyne NAs need additional hardware (phase-shifters) to extract the complex information from two or more measurements (e.g., Ref. 15). Though relatively simple hardware concepts have been developed (16), homodyne NAs also suffer from their sensitivity to generator harmonics, limiting dynamic range. It is for that reason that homodyne systems are rarely used in the laboratory, although some realizations exist for industrial measurements.

Regardless of the kind of detector used, all practical realizations of the NA architectures introduced in the next sections should be built to provide

- Good port match, properly terminating the DUT in the system impedance Z_0
- High directivity of the directional coupler for precise reflection measurement
- Low variation of transmission losses over the bandwidth of the system

Reflection and Transmission Measurement with the Unidirectional Network Analyzer

Unidirectional network analyzers (Fig. 10) extend the capability of a simple reflectometer to measure S_{11} and S_{21} of a two-port DUT.

With the measured quantity m_1 being proportional to a_1 , m_2 presenting a measure for the reflection b_1 , and m_3 presenting a measure for the transmission b_2 , S_{11} and S_{21} can be expressed as

$$S_{11} = c_{11} \frac{m_2}{m_1}, \quad S_{21} = c_{21} \frac{m_3}{m_1} \quad (6)$$

The proportionality constants are usually obtained through normalization measurements of known reflection/transmission coefficients. Connecting a “Short” with $S_{11} = -1$ to port 1 yields

$$c_{11} = -1 \frac{m_1^S}{m_2^S}; \quad \text{and} \quad c_{21} = 1 \frac{m_1^T}{m_3^T}$$

is obtained by connecting both ports (“Through”), such that $S_{21} = 1$.

For measurement of S_{22} and S_{12} (reverse direction), the DUT must be connected to the unidirectional NA with its ports reversed.

The Three-Receiver Network Analyzer Architecture for Full Two-Port Measurements

The need for manually reversing the DUT can be eliminated if a switch and another directional coupler is introduced into the system of Fig. 11. With the switch in position I, the RF source is connected to port 1 of the DUT, m_1 is proportional to a_1 , m_2 is a measure for b_1 , and m_3 is a measure for b_2 . The second contact of the switch terminates the coupler at port 2 in Z_0 , ensuring proper port match. With the switch in position II, port 2 of the DUT is excited, the coupler connected to port 1 of the DUT is terminated in Z_0 , and m_1 is now a measure for a_2 . Since the three receivers m_1 , m_2 , and m_3 now provide different readings, depending upon the position of the switch, their measurement values will from now on be referred to as m_i^I and m_i^{II} , the superscript denoting the position of the switch. The S -parameters of the DUT are therefore determined as

$$S_{11} = c_{11} \frac{m_2^I}{m_1^I}, \quad S_{21} = c_{21} \frac{m_3^I}{m_1^I}$$

$$S_{22} = c_{22} \frac{m_3^{II}}{m_1^{II}}, \quad \text{and} \quad S_{12} = c_{12} \frac{m_2^{II}}{m_1^{II}}$$

Figure 11. Bidirectional network analyzer with three receivers.

Figure 12. Bidirectional vector network analyzer with four receivers.

with the proportionality constants resulting from normalization measurements. Using a “Short” at port 1 and port 2 and a “Through” connecting both ports yields

$$c_{11} = -1 \frac{m_1^I}{m_2^I}, \quad c_{21} = 1 \frac{m_1^I}{m_3^I}$$

$$c_{22} = -1 \frac{m_1^{II}}{m_3^{II}}, \quad \text{and} \quad c_{12} = 1 \frac{m_1^{II}}{m_2^{II}}$$

The switch should be well-matched to keep measurement errors low, must be reproducible, and must provide sufficient isolation in order not to limit the dynamic range of the instrument.

The Four-Receiver Vector Network Analyzer

There seems to be little gained in extending the above-described three-receiver NA with a fourth receiver, as outlined in Fig. 12, since the complete S -matrix of a two-port can already be measured with three receivers. For *vector* network analyzers (VNA), however, the additional receiver provides simultaneous measurement capability of all waves and makes the architecture completely symmetrical around the DUT, resulting in interesting calibration capabilities, detailed in the sections entitled “The Seven-Term Error Model for Vector Network Analyzers with Four Receivers,” “The Cross-Talk Correcting 15-Term Error Model for Four-Receiver VNAs,” and “Modern Self-Calibration Techniques for Four-Receiver VNAs.” The subtle change of moving the switch from *between* two receivers to *in front* of the receiver pairs radically alters the error model, even reducing the requirements of the switch (see section entitled “The Seven-Term Error Model for Vector Network Analyzers with Four Receivers”). For measurements *without* error correction, however, the switch must, again, be as ideal as possible with respect to match, repeatability, and isolation.

A four-receiver VNA measures the S -matrix of a two-port DUT as

$$S_{11} = c_{11} \frac{m_2^I}{m_1^I}, \quad S_{21} = c_{21} \frac{m_3^I}{m_1^I}$$

$$S_{22} = c_{22} \frac{m_3^{II}}{m_4^{II}}, \quad \text{and} \quad S_{12} = c_{12} \frac{m_2^{II}}{m_4^{II}}$$

with the proportionality factors determined through normalization measurements as described before.

ERROR MODELS, CALIBRATION, AND ERROR CORRECTION

For a long time, precision NAs required carefully designed and expensive hardware, ensuring a good port match for embedding the DUT between proper terminations and high coupler directivity for precise reflection measurement. Losses in the hardware had to be accounted for by reference measurements of devices with known characteristic. With the advent of microprocessors, however, the focus has shifted toward calibration techniques that allow the imperfections of the hardware to be taken into account and corrected mathematically. An error model is needed for this purpose, and its parameters are determined through measurement of well-known one- or two-ports (calibration). This mathematical description of the non-ideal hardware is then used to correct the measurement of the DUT.

The error models, covered in subsequent sections, are used to model and correct all the linear errors of the VNA: transmission losses between the generator, the receivers, and the DUT; port match; and coupler directivity. Theoretically, the hardware of a VNA that provides these error-correction capabilities need no longer be built to high standards. Yet, commercially available systems still strive for good hardware performance for two reasons: first, in an effort to assist the calibration through good hardware performance and achieve even better accuracy; and, second, to provide an instrument that does not depend upon time consuming calibration procedures, allowing uncorrected measurements for all those applications that can tolerate the reduced accuracy. However, there are commercially available instruments that use the calibration capabilities for a considerable extension of their usable bandwidth. When the directivity of the directional couplers decreases to unsatisfactory values below a certain frequency, a built-in error correction mathematically enhances the directivity to usable values, extending the frequency range to as low as 9 kHz.

Since all error models presented herein are linear and deterministic, there remains a stringent requirement that the VNA hardware be linear (errors due to compression of receivers cannot be corrected) and stable.

Figure 13. Four-port description of a reflectometer.

With modern equipment achieving a short-term stability in the millidecibel range, the most prominent source of error in many cases remains in the cabling between the VNA and the DUT and the associated interface contacts. These contacting errors are statistical in nature and must be minimized by proper cable and connector selection and maintenance. As the transmission phase of coaxial cables varies over temperature and may change if the cable is bent, VNAs are usually equipped with special test-port cables, optimized for phase-stability and mechanically protected against overbending.

The mathematical descriptions of the error models presented in the following sections make heavy use of matricial representations, leading to very compact expressions and similar structures for the different models. Alternatively, flow-graph techniques could be applied as in Refs. 17 and 18, leading to comparable results.

The Three-Term Error Model for Reflection Measurements

A reflectometer like the one of Fig. 13 can always be represented by a linear four-port, driven at the left port by the RF source, two ports connected to the receivers for measurement of the incident and reflected waves and the DUT placed at the port to the right. In this general form, the underlying hardware of the reflectometer becomes unimportant, much like the fact that internal structure of the six-port reflectometer was of no concern in the section entitled “The Six-Port Reflectometer.”

The waves incident to and reflected from this four-port relate to its S -matrix by

$$\begin{pmatrix} b_{m1} \\ b_{m2} \\ a_L \\ b_G \end{pmatrix} = [K] \begin{pmatrix} a_{m1} \\ a_{m2} \\ b_L \\ a_G \end{pmatrix} \quad (7)$$

The measured quantities m_1 and m_2 are proportional to the incident waves of the receivers ($m_1 = \eta_1 b_{m1}$, $m_2 = \eta_2 b_{m2}$), with the receiver constant η_i representing the entire transfer characteristics of the i th receiver, comprising mixer conversion, intermediate frequency (IF) amplification, and so on. Architectural details of the receiver are of no concern at this point. The only requirement is that η_i must be constant, implying stability of the receivers phase and amplitude response. Let r_i be the reflection coefficients of the receiver inputs such that the conditions

$$m_1 = \eta_1 b_{m1}, \quad m_2 = \eta_2 b_{m2}, \quad a_{m1} = r_1 b_{m1}, \quad a_{m2} = r_2 b_{m2} \quad (8)$$

result. Their use allows the elimination of the generator waves a_G and b_G in Eq. (7), according to the following scheme: The

third equation of Eq. (7) is solved for a_G and the result is inserted into the first two equations. In these, b_{m_i} is expressed through a_{m_i} and a_{m_i} in turn expressed by m_i , using Eq. (8). The resulting two equations relate the measured quantities m_1 and m_2 to the waves at the DUT and are arranged in matrix form as

$$\begin{pmatrix} b_L \\ a_L \end{pmatrix} = \begin{bmatrix} G_{11} & G_{12} \\ G_{21} & G_{22} \end{bmatrix} \begin{pmatrix} m_2 \\ m_1 \end{pmatrix} = [G] \begin{pmatrix} m_2 \\ m_1 \end{pmatrix} \quad (9)$$

Every element of $[G]$ evolves as a function of K_i , r_i , and η_i , which need not be explicitly known. It suffices to determine $[G]$ through a process called calibration, in order to calculate the correct waves at the DUT from the raw measurements m_i :

$$\Gamma_L = \frac{b_L}{a_L} = \frac{G_{11}m_2 + G_{12}m_1}{G_{21}m_2 + G_{22}m_1} \quad (10)$$

Interestingly, this four-port/two-port reduction with its elimination of the generator waves has freed the error model [Eq. (9)] from any influence of the RF source. Power or impedance variations do not introduce measurement errors, provided that m_1 and m_2 are measured simultaneously.

Equation (10) can be further simplified by dividing numerator and denominator by m_1 and defining

$$m_{11} = \frac{m_2}{m_1} = \frac{\eta_2 b_{m2}}{\eta_1 b_{m1}} \quad (11)$$

as the uncorrected (raw) reflection measurement [compare with Eq. (6)] such that the error-corrected reflection coefficient becomes

$$\Gamma_L = \frac{b_L}{a_L} = \frac{G_{11}m_{11} + G_{12}}{G_{21}m_{11} + G_{22}} \quad (12)$$

The importance of Eq. (11) is twofold:

1. The ratio of two measurements enters the computation of the error-corrected result. Relative, rather than absolute, measurements are therefore still sufficient if an error model and error correction are used. And with the reflected wave measurement m_2 being referenced to the incident wave measurement m_1 , the theoretically derived insensitivity of the error model to power variations of the RF source becomes obvious.
2. The ratio of η_1/η_2 appearing in Eq. (11) indicates that amplitude and phase drifts of the receivers cancel if both receivers are built equal.

Both properties are essential for the high accuracy achievable with VNAs. The use of the latter property is especially important for accurate phase measurements at high frequencies.

Calibration of the Three-Term Error Model. Before error-corrected measurements using Eq. (12) can be carried out, the error matrix $[G]$ must be determined. For this calibration procedure, a number of one-ports (calibration standards) with known reflection coefficients are needed. Since numerator and denominator of Eq. (12) may be multiplied by any complex number without altering the result, one of the error terms may arbitrarily be set to 1, with the other three remaining to be computed. Without loss of generality, let $G_{11} = 1$ and Eq. (12) can be rearranged to yield a linear equation in the three remaining error terms:

$$-G_{12} + \Gamma^i m_{11}^i G_{21} + \Gamma^i G_{22} = m_{11}^i \quad (13)$$

The superscript i denotes the i th calibration measurement with known reflection coefficient Γ^i and the corresponding measured value m_{11}^i . Performing calibration measurements with three distinct and known reflection standards yields three linear inhomogeneous and independent forms of Eq. (13), sufficient to solve for the needed error terms.

In order to maximize the independence of the three equations, the three-term calibration is typically performed with those three impedances, which are furthest apart in the reflection plane:

$$\text{Open: } \Gamma^O = 1, \quad \text{Short: } \Gamma^S = -1, \quad \text{Match: } \Gamma^M = 0$$

Three-term reflectometer calibration is therefore also referred to as OSM calibration.

The Five-Term Error Model for Unidirectional Vector Network Analyzers

Extending a single reflectometer with a third receiver for transmission measurements yields the unidirectional NA of Fig. 10. Its error model comprises two parts: The reflectometer hardware to the left of the DUT which is again represented by an error two-port $[G]$, and the hardware to the right of the DUT which constitutes a physical two-port with a corresponding 2×2 S -matrix (Fig. 14).

As in the foregoing section, the reflection coefficient r_3 and the transfer characteristics η_3 of the receiver m_3 establish the conditions

$$a_{m_3} = r_3 b_{m_3} \quad \text{and} \quad m_3 = \eta_3 b_{m_3}$$

which are used to reduce $[T]$ to an error two-port that relates

Figure 14. Hardware description of the transmission receiver m_3 .

Figure 15. Error model of the unidirectional vector network analyzer.

the waves a_2 and b_2 of the DUT to the measured value m_3 :

$$\begin{pmatrix} b_2 \\ a_2 \end{pmatrix} = \begin{bmatrix} H_{11} & H_{12} \\ H_{21} & H_{22} \end{bmatrix} \begin{pmatrix} m_3 \\ 0 \end{pmatrix} = [H] \begin{pmatrix} m_3 \\ 0 \end{pmatrix}$$

Together with the error two-port of the reflectometer

$$\begin{pmatrix} b_1 \\ a_1 \end{pmatrix} = \begin{bmatrix} G_{11} & G_{12} \\ G_{21} & G_{22} \end{bmatrix} \begin{pmatrix} m_2 \\ m_1 \end{pmatrix} = [G] \begin{pmatrix} m_2 \\ m_1 \end{pmatrix}$$

and the definition of the DUT's S -matrix

$$\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} \quad (14)$$

the error model (Fig. 15) can be expressed as

$$\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} = \begin{pmatrix} G_{11}m_2 + G_{12}m_1 \\ H_{11}m_3 \end{pmatrix} = [S] \begin{pmatrix} G_{21}m_2 + G_{22}m_1 \\ H_{21}m_3 \end{pmatrix} = [S] \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} \quad (15)$$

It is obvious that the two equations of Eq. (15) are not sufficient to solve for the entire S -matrix of the DUT. On the other hand, the "forward" S -parameters S_{11} and S_{21} cannot be error-corrected by themselves without the knowledge of S_{12} and S_{22} .

Error correction is therefore only possible if a second measurement with the DUT reversed is made. Denoting the measured values with superscripts f and r for forward and reverse measurement of the DUT, both vector equations of Eq. (15) can be combined into a matrix equation

$$\begin{bmatrix} G_{11}m_2^f + G_{12}m_1^f & H_{11}m_3^r \\ H_{11}m_3^f & G_{11}m_2^r + G_{12}m_1^r \end{bmatrix} = [S] \begin{bmatrix} G_{21}m_2^f + G_{22}m_1^f & H_{21}m_3^r \\ H_{21}m_3^f & G_{21}m_2^r + G_{22}m_1^r \end{bmatrix} \quad (16)$$

Again, Eq. (16) may be normalized to the incident waves m_1^f and m_1^r such that only the uncorrected measurement ratios

$$m_{11} = \frac{m_2^f}{m_1^f} = \frac{\eta_2 b_{m_2}^f}{\eta_1 b_{m_1}^f}, \quad m_{21} = \frac{m_3^f}{m_1^f} = \frac{\eta_3 b_{m_3}^f}{\eta_1 b_{m_1}^f}$$

$$m_{12} = \frac{m_3^r}{m_1^r} = \frac{\eta_3 b_{m_3}^r}{\eta_1 b_{m_1}^r}, \quad m_{22} = \frac{m_2^r}{m_1^r} = \frac{\eta_2 b_{m_2}^r}{\eta_1 b_{m_1}^r}$$

remain [compare with Eq. (6)]. Solving the normalized version

of Eq. (16) for $[S]$ yields the error-correction formula

$$[S] = \begin{bmatrix} G_{11}m_{11} + G_{12} & H_{11}m_{12} \\ H_{11}m_{21} & G_{11}m_{22} + G_{12} \end{bmatrix} \times \begin{bmatrix} G_{21}m_{11} + G_{22} & H_{21}m_{12} \\ H_{21}m_{21} & H_{21}m_{22} + G_{22} \end{bmatrix}^{-1} \quad (17)$$

Calibration of the Five-Term Error Model. Not all of the eight error terms contained in $[G]$ and $[H]$ are needed for error correction with Eq. (17), where H_{12} and H_{22} do not appear. Furthermore, the structure of Eq. (17) reveals its invariance to multiplication of *all* error terms with a constant. The remaining error terms may therefore be computed by rearranging Eq. (17) into a linear, homogeneous system of equations in the error terms,

$$\begin{bmatrix} -m_{11}^i & -1 & S_{11}^i m_{11}^i & S_{11}^i & 0 & S_{12}^i m_{21}^i \\ 0 & 0 & S_{21}^i m_{11}^i & S_{21}^i & -m_{21}^i & S_{22}^i m_{21}^i \\ 0 & 0 & S_{12}^i m_{22}^i & S_{12}^i & -m_{12}^i & S_{11}^i m_{12}^i \\ -m_{22}^i & -1 & S_{22}^i m_{22}^i & S_{22}^i & 0 & S_{21}^i m_{12}^i \end{bmatrix} \begin{pmatrix} G_{11} \\ G_{12} \\ G_{21} \\ G_{22} \\ H_{11} \\ H_{21} \end{pmatrix} = 0 \quad (18)$$

setting one error term to unity and solving the resulting inhomogeneous system of equations. $[S^i]$ denotes the S -matrix of the i th calibration standard. Five independent equations are needed to solve for the remaining five independent error terms, hence the name five-term error model.

The problem of *how many* two-port standards are needed and how they must be built to ensure five independent equations can be tackled in the following way: A suitable combination of standards must always comprise at least one standard with transmission ($S_{21} \neq 0$ and $S_{12} \neq 0$); otherwise, H_{11} and H_{21} cannot be determined [$S_{21} = S_{12} = 0$ implies $m_{21} = m_{12} = 0$, such that the fifth and sixth column of Eq. (18) vanish]. Numerical investigations reveal that a two-port standard exhibiting transmission contributes at least two equations and may contribute four if it is not symmetric (i.e., $S_{11} \neq S_{22}$).

Because the use of reflection standards ($S_{21} = S_{12} = 0$) implies $m_{21} = m_{12} = 0$, the second and third equation of Eq. (18) degenerate, leaving only the first and fourth equation for determination of $[G]$; and with $S_{11} = \Gamma_S$ the first equation corresponds directly to Eq. (13) (three-term calibration) with $G_{11} = 1$. Transmissionless standards therefore contribute one equation per reflection coefficient connected to port 1.

Even though the general nature of Eq. (18) allows for calibration with any set of standards that yields five independent equations, traditionally the five-term model is calibrated using the three reflection standards Open, Short, and Match (contributing three equations), together with a direct connection of both reference planes, the Through standard (furnishing the remaining two equations). Figure 16 depicts this commonly used set of standards. Another name for this commonly used procedure is SOLT, which stands for Short, Open, Load, and Through.

Of course, care must be taken as to build the calibration standards such that their S -matrix or reflection coefficients match the postulated values used in the calibration process. All deviations of the standards' *real* values from the postulated *ideal* of Fig. 16 lead to inconsistencies in the equations of Eq. (18). Keeping these inconsistency errors small requires a smart choice and precisely built or modeled standards.

Because the Through standard requires a direct connection of both measurement ports, it is typically a very easy standard to realize in coaxial media. The same holds for the Short, which is easily manufactured to high precision ($<1^\circ$ deviation at 20 GHz) in coaxial media. However, care must be taken as to ensure that the Short is connected directly to the reference plane, which is a potential problem if sexed connectors (N, SMA, K) are used. Bridging same-sexed connectors with adapters introduces a phase shift $2\beta l$ into the reflection coefficient, which must be known in order to substitute the shorts reflection coefficient by $-1e^{-2\beta l}$. The same holds if offset shorts with electrical length $2\beta l$ are used. For a frequency band where $2\beta l$ is between 40° and 320° , the latter can replace the open standard, which typically suffers from fringing capacities and radiation losses. Therefore, the open standards contained in commercially available calibration kits come with detailed information on those imperfections, modeling the frequency dependence of the open's capacitance by a polynomial to enhance accuracy. For the absolute impedance reference, the Match standard, precision crafting is needed for precision measurements.

The 10-Term Error Model for Vector Network Analyzers with Three Receivers

For all practical purposes, the applicability of the five-term error model is somewhat impaired by the need for manually reversing the DUT in order to obtain error-corrected results. If a switch is incorporated into the VNA, as depicted in Fig. 11, this manual interaction can be automated, easing error-corrected measurements considerably.

In essence, the error model of the resulting bidirectional VNA with three receivers (see section entitled "The Three-Receiver Network Analyzer Architecture for Full Two-Port Measurements") consists of *two* five-term error models (Fig. 17). Because of the switch being located *between* m_1 and m_2 and m_1 and m_3 , respectively, different error two-ports are needed for either position of the switch.

With the switch in position I, the reflectometer comprising m_1 and m_2 can be represented by an error two-port $[G^I]$ and the reflectometer terminated in Z_0 and comprising m_3 by an error two-port $[H^I]$. In the second state of the switch, the four-port comprising m_1 and m_3 can be reduced to the error two-port $[G^{II}]$ and the reflectometer terminated in Z_0 and comprising m_2 by an error two-port $[H^{II}]$ with

$$\begin{pmatrix} b_1 \\ a_1 \end{pmatrix} = [G^I] \begin{pmatrix} m_2^I \\ m_1^I \end{pmatrix}, \quad \begin{pmatrix} b_2 \\ a_2 \end{pmatrix} = [H^I] \begin{pmatrix} m_3^I \\ 0 \end{pmatrix}$$

$$\begin{pmatrix} b_1 \\ a_1 \end{pmatrix} = [H^{II}] \begin{pmatrix} m_2^{II} \\ 0 \end{pmatrix}, \quad \begin{pmatrix} b_2 \\ a_2 \end{pmatrix} = [G^{II}] \begin{pmatrix} m_3^{II} \\ m_1^{II} \end{pmatrix}$$

$$\text{Through: } [S^T] = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad \text{Open: } S_{11}^O = 1, \quad \text{Short: } S_{11}^S = -1, \quad \text{Match: } S_{11}^M = 0$$

Figure 16. Calibration standards for the TMSO five-term procedure.

Figure 17. Error model of the bidirectional vector network analyzer with three receivers.

Using these relations together with Eq. (14) yields a vector equation for either state of the switch which can be combined into a matrix equation, very similar to Eq. (16):

$$\begin{bmatrix} G_{11}^I m_2^I + G_{12}^I m_1^I & H_{11}^{II} m_2^{II} \\ H_{11}^I m_3^I & G_{11}^{II} m_3^{II} + G_{12}^{II} m_1^{II} \end{bmatrix} = [S] \begin{bmatrix} G_{21}^I m_2^I + G_{22}^I m_1^I & H_{21}^{II} m_2^{II} \\ H_{21}^I m_3^I & G_{21}^{II} m_3^{II} + G_{22}^{II} m_1^{II} \end{bmatrix}$$

Normalization to the incident waves m_1^I and m_1^{II} now yields

$$\begin{bmatrix} G_{11}^I m_{11} + G_{12}^I & H_{11}^{II} m_{12} \\ H_{11}^I m_{21} & G_{11}^{II} m_{22} + G_{12}^{II} \end{bmatrix} = [S] \begin{bmatrix} G_{21}^I m_{11} + G_{22}^I & H_{21}^{II} m_{12} \\ H_{21}^I m_{21} & G_{21}^{II} m_{22} + G_{22}^{II} \end{bmatrix} \quad (19)$$

with

$$m_{11} = \frac{m_2^I}{m_1^I} = \frac{\eta_2 b_{m_2}}{\eta_1 b_{m_1}}, \quad m_{21} = \frac{m_3^I}{m_1^I} = \frac{\eta_3 b_{m_3}}{\eta_1 b_{m_1}}$$

$$m_{12} = \frac{m_2^{II}}{m_1^{II}} = \frac{\eta_2 b_{m_2}}{\eta_1 b_{m_1}}, \quad m_{22} = \frac{m_3^{II}}{m_1^{II}} = \frac{\eta_3 b_{m_3}}{\eta_1 b_{m_1}}$$

where comparison with the five-term error model shows that m_{12}^{II} and m_{13}^{II} have switched their position as have the error terms for the second state of the switch, a consequence of the switch now reversing the DUT and the error two-ports.

With error correction according to the 10-term error model applied, the requirements of the switch as detailed in the section entitled “The Three-Receiver Network Analyzer Architecture for Full Two-Port Measurements” become somewhat relaxed, because its mismatch errors and transmission losses are now accounted for. However, repeatability and leakage errors (finite isolation) are not contained in the error model.

Calibration of the 10-Term Error Model. As was the case with the five-term model, not all 16 error terms appear in Eq. (19). H_{12}^I , H_{22}^I , H_{12}^{II} , and H_{22}^{II} are not needed for error correction and cannot be determined by the calibration procedure.

Rearranging Eq. (19) as a linear homogeneous system of equations in the remaining error terms, as demonstrated in the section entitled “Calibration of the Five-Term Error Model,” finds the four equations to be decoupled: Two equations depend solely upon error terms of $[G^I]$ and $[H^I]$, and the other two

equations depend only upon $[G^{II}]$ and $[H^{II}]$:

$$\begin{bmatrix} -m_{11}^I & -1 & S_{11} m_{11}^I & S_{11} & 0 & S_{12} m_{21}^I \\ 0 & 0 & S_{21} m_{11}^I & S_{21} & -m_{21}^I & S_{22} m_{21}^I \end{bmatrix} \mathbf{e}^I = 0,$$

$$\mathbf{e}^I = (G_{11}^I, G_{12}^I, G_{21}^I, G_{22}^I, H_{11}^I, H_{21}^I)^T$$

$$\begin{bmatrix} 0 & 0 & S_{12} m_{22}^I & S_{12} & -m_{12}^I & S_{11} m_{12}^I \\ -m_{22}^I & -1 & S_{22} m_{22}^I & S_{22} & 0 & S_{21} m_{12}^I \end{bmatrix} \mathbf{e}^{II} = 0,$$

$$\mathbf{e}^{II} = (G_{11}^{II}, G_{12}^{II}, G_{21}^{II}, G_{22}^{II}, H_{11}^{II}, H_{21}^{II})^T$$

With one of the error terms of both $\mathbf{e}^I$ and $\mathbf{e}^{II}$ set to 1 (e.g., $G_{11}^I = G_{11}^{II} = 1$), two sets of five independent equations must be supplied by the calibration measurements in order to solve the resulting inhomogeneous system for the remaining 10 error terms.

A similar reasoning (compared with the section entitled “Calibration of the Five-Term Error Model”) as to how many and what kind of standards are needed is applicable here. At least one standard with transmission ($S_{21} \neq 0$ and $S_{12} \neq 0$) is needed in order to determine $[H^I]$ and $[H^{II}]$. Because of the different error terms, such a standard will supply a total of four equations for both positions of the switch. Reflection two-ports ($S_{21} = S_{12} = 0$), on the other hand, still contribute one equation for each of their two reflection coefficients S_{11} and S_{22} .

The same standards as with the five term error model (referred to as TMSO, Through-Match-Short-Open, or SOLT, Short-Open-Load-Through) are commonly used to calibrate the 10-term model, with the reflection standards now being reflection two-ports.

Because of the decoupled nature of Eq. (19), the reflection two-ports may be realized as one-ports by first connecting the calibration impedance to port 1 and noting the measurement values with the switch in position I. Then the appropriate calibration impedance is connected to port 2 and the measurements are taken with the switch in the second position [since these standards do not exhibit transmission, the corresponding transmission receiver (m_{13}^I , m_{12}^{II}) need not be considered]. With respect to the commonly used TMSO standards, this sequential procedure eliminates the need for two identical reflection standards but allows usage of one physical match—short and open—as reflection one-ports.

The Cross-Talk Including 12-Term Error Model for Three-Receiver VNAs

A number of commercially available VNAs provide a 12-term calibration capability (17), expanding the above-described 10-term error model by two error terms that characterize forward and reverse isolation. Their inclusion aims at extending the dynamic range for measurements where finite isolation

$$\begin{aligned} \text{Through: } [S^T] &= \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, & \text{Open: } [S_O^I] &= \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \\ \text{Short: } [S^S] &= \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}, & \text{Match: } [S^M] &= \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} \end{aligned}$$

Figure 18. Calibration standards for the TMSO (SOLT) 10-term procedure.

of the switch or coupling over the DUT adversely affects measurement accuracy at high insertion loss levels of the DUT.

For that purpose an additional isolation standard (no transmission) with, for now, arbitrary reflection coefficients r_1 and r_2

$$[S^X] = \begin{bmatrix} r_1 & 0 \\ 0 & r_2 \end{bmatrix} \rightarrow [M^X] = \begin{bmatrix} m_{11}^X & m_{12}^X \\ m_{21}^X & m_{22}^X \end{bmatrix}$$

must be measured (alternatively the transmission measurement of one of the reflection standards may be exploited). The transmission terms m_{12}^X and m_{21}^X of its measurement matrix are a measure of the cross-talk level and can be used for correcting the measured transmission values of the DUT:

$$[S] = \begin{bmatrix} G_{11}^I m_{11} + G_{12}^I & H_{11}^I (m_{12} - m_{12}^X) \\ H_{11}^I (m_{21} - m_{21}^X) & G_{11}^I m_{22} + G_{12}^I \end{bmatrix} \times \begin{bmatrix} G_{21}^I m_{11} + G_{22}^I & H_{21}^I (m_{12} - m_{12}^X) \\ H_{21}^I (m_{21} - m_{21}^X) & G_{21}^I m_{22} + G_{22}^I \end{bmatrix}^{-1}$$

However, this simple correction scheme can only improve results if the reflection coefficients of the isolation standard match the reflection coefficients of the DUT. For well-matched DUTs, the isolation terms can be taken from the measurement of the Match standard $[S^M]$. High transmission dynamic DUTs (e.g., filters), however, typically exhibit strongly varying reflection coefficients over frequency. If two identical DUTs are available, an isolation standard that satisfies the above condition can be generated by connecting the first DUT with port 1 to port 1 of the VNA and the second DUT with port 2 to the VNAs second port. The unused ports of the DUTs are terminated in Z_0 . Consequently the isolation measurement must be repeated with a suitable isolation standard whenever DUTs with differing reflection coefficients are to be measured.

Considering the above limitations, the cross-talk reduction with the 12-term model should be regarded as a cross-talk *normalization* rather than a *calibration*.

In the section entitled “The Cross-Talk Correcting 15-Term Error Model for Four-Receiver VNAs,” it will be shown that for an error model to correctly include cross-talk, eight error terms are needed for its characterization.

The Seven-Term Error Model for Vector Network Analyzers with Four Receivers

The addition of a fourth receiver to independently measure all four waves at the DUT, as depicted in Fig. 12, leads to very interesting instrument properties and calibration possibilities.

Figure 19. Seven-term error model of the bidirectional vector network analyzer with four receivers.

The DUT is now embedded in a symmetrical test set, consisting of two reflectometers, each of which can be represented by an error two-port (see section entitled “The Three-Term Error Model for Reflection Measurements,” which discusses four-port/two-port reduction).

The subtle but far-reaching advantages of this architecture and the accompanying error-model are:

1. The error model (Fig. 19) is valid for *either* position of the switch, reducing the number of error terms to eight and the number of two-port calibration standards required to three.
2. The four-receiver architecture provides redundant information in the calibration measurements that can be exploited to allow calibration with *partially unknown* standards. The section entitled “Modern Self-Calibration Techniques for Four-Receiver VNAs” details these important and powerful techniques.
3. The switch is no longer part of the error two-ports. Instead it has been moved into the generator port of the reflectometers, whose waves were eliminated during the four-port/two-port reduction. Therefore, the imperfections of the switch no longer influence the quality of an error-corrected measurement. The switch may be mismatched, may exhibit transmission losses and finite isolation, and does not even need to be repeatable.

The mathematical derivation of the seven-term error model unfolds in the usual way. With

$$\begin{aligned} \begin{pmatrix} b_1 \\ a_1 \end{pmatrix} &= [G] \begin{pmatrix} m_2 \\ m_1 \end{pmatrix}, & \begin{pmatrix} b_2 \\ a_2 \end{pmatrix} &= [H] \begin{pmatrix} m_3 \\ m_4 \end{pmatrix}, & \text{and} \\ \begin{pmatrix} b_1 \\ b_2 \end{pmatrix} &= [S] \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} \end{aligned} \quad (20)$$

vector equations for both positions of the switch (I and II) are obtained and combined into a matrix equation:

$$\begin{bmatrix} G_{11}m_2^I + G_{12}m_1^I & G_{11}m_2^{II} + G_{12}m_1^{II} \\ H_{11}m_3^I + H_{12}m_4^I & H_{11}m_3^{II} + H_{12}m_4^{II} \end{bmatrix} = [S] \begin{bmatrix} G_{21}m_2^I + G_{22}m_1^I & G_{21}m_2^{II} + G_{22}m_1^{II} \\ H_{21}m_3^I + H_{22}m_4^I & H_{21}m_3^{II} + H_{22}m_4^{II} \end{bmatrix} \quad (21)$$

The eight measurement values contained in Eq. (21) can be

condensed to four by expanding Eq. (21) as

$$\begin{bmatrix} G_{12} & 0 \\ 0 & H_{12} \end{bmatrix} \begin{bmatrix} m_1^I & m_1^{II} \\ m_4^I & m_4^{II} \end{bmatrix} + \begin{bmatrix} G_{11} & 0 \\ 0 & H_{11} \end{bmatrix} \begin{bmatrix} m_2^I & m_2^{II} \\ m_3^I & m_3^{II} \end{bmatrix} \\ = [S] \left\{ \begin{bmatrix} G_{22} & 0 \\ 0 & H_{22} \end{bmatrix} \begin{bmatrix} m_1^I & m_1^{II} \\ m_4^I & m_4^{II} \end{bmatrix} + \begin{bmatrix} G_{21} & 0 \\ 0 & H_{21} \end{bmatrix} \begin{bmatrix} m_2^I & m_2^{II} \\ m_3^I & m_3^{II} \end{bmatrix} \right\}$$

and right-multiplying both sides with the inverse measurement matrix of the first and fourth receiver. The result is much simplified error-model representation

$$\begin{bmatrix} G_{12} & 0 \\ 0 & H_{12} \end{bmatrix} + \begin{bmatrix} G_{11} & 0 \\ 0 & H_{11} \end{bmatrix} [M] \\ = [S] \left\{ \begin{bmatrix} G_{22} & 0 \\ 0 & H_{22} \end{bmatrix} + \begin{bmatrix} G_{21} & 0 \\ 0 & H_{21} \end{bmatrix} [M] \right\} \quad (22)$$

with a 2×2 measurement matrix

$$[M] = \begin{bmatrix} m_2^I & m_2^{II} \\ m_3^I & m_3^{II} \end{bmatrix} \begin{bmatrix} m_1^I & m_1^{II} \\ m_4^I & m_4^{II} \end{bmatrix}^{-1} = \begin{bmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{bmatrix}$$

With the measurement values pertaining to the incident waves m_1^I and m_1^{II} residing on the main diagonal of the right submatrix and the off-diagonal elements being small, the matrix is guaranteed to be invertible. For $m_4^I = m_1^I = 0$ (three receiver analogy) the entries of $[M]$ are normalized with respect to the incident waves m_1^I and m_1^{II} . The measurement matrix $[M]$ is therefore attributed S -parameter character. Furthermore, the computation of $[M]$ provides a first level of error correction, because finite isolation of the switch is eliminated. This is achieved by the fourth receiver, which precisely measures the level of the switch's leakage signals through m_1^I and m_1^{II} .

Equation (22) is easily returned to the structure of Eq. (21), with the four measurement values now being direct counterparts of the corresponding error-corrected S -parameters of the DUT:

$$\begin{bmatrix} G_{11}m_{11} + G_{12} & G_{11}m_{12} \\ H_{11}m_{21} & H_{11}m_{22} + H_{12} \end{bmatrix} \\ = [S] \begin{bmatrix} G_{21}m_{11} + G_{22} & G_{21}m_{12} \\ H_{21}m_{21} & H_{21}m_{22} + H_{22} \end{bmatrix} \quad (23)$$

It may be interesting to note that $[G]$ and $[H]$ are of the cascading *transfer matrix* type. This type of matrix also appears in all the other error models introduced in this section. The fact that transfer matrices exhibit a singularity if the underlying network has zero transmission can safely be ignored as far as error two-ports of practical reflectometer or network analyzer realizations are concerned. Those networks *must* exhibit transmission in order to perform the desired function. The device under test, however, may be perfectly isolating and should therefore always be represented by its S -matrix (the section entitled "The General TAN Procedure" introduces *pseudo-transfer matrices* to work around that singularity).

Calibration of the Seven-Term Error Model. With Eq. (23) being of the same structure as the five-term model [Eq. (16)] and the 10-term model [Eq. (19)], the determination of the error terms proceeds in the same way. Equation (23) is rearranged into a linear homogeneous system of equations

$$\begin{bmatrix} -m_{11}^i & -1 & S_{11}^i m_{11}^i & S_{11}^i & 0 & 0 & S_{12}^i m_{21}^i & 0 \\ 0 & 0 & S_{21}^i m_{11}^i & S_{21}^i & -m_{21}^i & 0 & S_{22}^i m_{21}^i & 0 \\ -m_{12}^i & 0 & S_{11}^i m_{12}^i & 0 & 0 & 0 & S_{12}^i m_{22}^i & S_{12}^i \\ 0 & 0 & S_{21}^i m_{12}^i & 0 & -m_{22}^i & -1 & S_{22}^i m_{22}^i & S_{22}^i \end{bmatrix} \mathbf{e} = 0, \\ \mathbf{e} = (G_{11}, \dots, G_{22}, H_{11}, \dots, H_{22})^T$$

with every calibration measurement i contributing four equations. One error term is set to 1, and seven independent equations are required to solve for the remaining seven error terms. It turns out that the eight equations stemming from the measurement of two calibration two-ports are not sufficient to provide the necessary rank of 7. Measurement of a third calibration two-port is needed such that a total of 12 equations exist.

The resulting surplus in information can be used in one of the following ways:

1. The linear system with all 12 equations is solved in the least-squares sense (e.g., see Ref. 19), using the extra equations to minimize residual errors (contacting or repeatability errors).
2. Even though contacting errors cannot be accounted for due to their statistical nature, in Ref. 20 the extra information is used to assess these errors by deriving error bounds. As these techniques are not yet widely used, they will not be further treated here.
3. The calibration standards can be permitted to have unknown parameters (13,21), which are determined using the extra information contained in the additional equations. Because the construction of standards, which do not have to be fully known, can result in considerable savings, this "self-calibration" technique is of much practical importance. The section entitled "Modern Self-Calibration Techniques for Four-Receiver VNAs" has the details.

Performing a seven-term calibration with completely known standards is most easily done using the TMS procedure, where the three calibration two-ports

$$\text{Through: } [S^T] = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad \text{Match: } [S^M] = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} \\ \text{Short: } [S^S] = \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}$$

are used. Comparison with the 10-term and the 5-term model shows that the third reflection standard is no longer needed. Using a short, instead of an open, as the third standard is in many cases the more convenient choice, because shorts can be manufactured to higher precision in coaxial media or waveguides (see section entitled "Calibration of the Five-Term Error Model"). At low frequencies, however, using an open may be the more advantageous choice, as the test port itself serves as a comparatively good open up to about 100 MHz.

The computed error terms are used for error correction by simply solving Eq. (23) for $[S]$:

$$[S] = \begin{bmatrix} G_{11}m_{11} + G_{12} & G_{11}m_{12} \\ H_{11}m_{21} & H_{11}m_{22} + H_{12} \end{bmatrix} \times \begin{bmatrix} G_{21}m_{11} + G_{22} & G_{21}m_{12} \\ H_{21}m_{21} & H_{21}m_{22} + H_{22} \end{bmatrix}^{-1}$$

Calibration of the Seven-Term Error Model using an Unknown Through. For applications where a Through standard of known properties is not available, the seven-term error model may be calibrated by performing simple reflectometer calibrations for the error two-ports $[G]$ and $[H]$, according to the section entitled “Calibration of the Three-Term Error Model,” and using a transmission standard whose only known property is its reciprocity (e.g., $S_{21} = S_{12}$).

Such a calibration method may, for instance, be desirable for on-wafer measurements where nonaligned measurement ports render a known Through difficult to build (22). Calibration without an unknown Through was first introduced in Ref. 23 and is very simple to derive if the cascade structure of the error model (Fig. 19) is written using transfer matrices. With the error two-ports $[G]$ and $[H]$ already in that notation [Eq. (20)], the difference to Eq. (22) is in the description of the DUT

$$\begin{pmatrix} b_1 \\ a_1 \end{pmatrix} = [\Sigma] \begin{pmatrix} a_2 \\ b_2 \end{pmatrix} = \frac{1}{S_{21}} \begin{bmatrix} -\Delta S & S_{11} \\ -S_{22} & 1 \end{bmatrix} \begin{pmatrix} a_2 \\ b_2 \end{pmatrix} \quad (24)$$

and in the evolving measurement matrix

$$\begin{bmatrix} m_1^I & m_1^{II} \\ m_2^I & m_2^{II} \end{bmatrix} \begin{bmatrix} m_3^I & m_3^{II} \\ m_4^I & m_4^{II} \end{bmatrix}^{-1} = [P] = [G]^{-1}[\Sigma][H]$$

with the latter now also being a transfer matrix.

Performing reflectometer calibrations, as described in the section entitled “Calibration of the Three-Term Error Model,” for both error two-ports establishes three of the four error terms in $[G]$ and $[H]$, leading to the preliminary error matrices $[\tilde{G}]$

and $[\tilde{H}]$, with one error term normalized to 1. Without loss of generality, let us assume $\tilde{G}_{11} = \tilde{H}_{11} = 1$. This knowledge of $[G]$ and $[H]$, except for a common factor, can be expressed as

$$[P] = [G]^{-1}[\Sigma][H] = \frac{1}{K_G} [\tilde{G}]^{-1}[\Sigma]K_H[\tilde{H}] = \alpha [\tilde{G}]^{-1}[\Sigma][\tilde{H}]$$

$$\alpha = \frac{K_H}{K_G}$$

The still unknown term α can be regarded as the seventh error term, still needed for a full two-port calibration. As the determinant of the transfer matrix of a reciprocal two-port is unity, using such a device for calibration produces the equation

$$\det[P^{\text{reci}}] = \alpha^2 \det[\tilde{G}]^{-1} \det[\Sigma^{\text{reci}}] \det[\tilde{H}] = \alpha^2 \frac{\det[\tilde{H}]}{\det[\tilde{G}]}$$

which is solved for α :

$$\alpha = \pm \sqrt{\frac{\det[\tilde{G}]}{\det[\tilde{H}]} \det[P^{\text{reci}}]} \quad (25)$$

According to Ref. 23, the correct root in Eq. (25) is most easily found using

$$S_{21}^{\text{reci}} = \frac{\alpha}{P_{22}^{\text{reci}}}$$

if the phase of the reciprocal transmission-factor is known to $\pm 90^\circ$.

The Cross-Talk Correcting 15-Term Error Model for Four-Receiver VNAs

Whenever energy emanating from the measurement planes finds a path to leak around the DUT or a coupling path between the reflectometers of the VNA exists (Fig. 20), the error models of the sections entitled “The Five-Term Error Model for Unidirectional Vector Network Analyzers,” “The 10-Term Error Model for Vector Framework Analyzers with Three Receivers,” “The Cross-Talk Including 12-Term Error Model for

Figure 20. Eight-port hardware representation of the vector network analyzer, including coupling of the reflectometers.

Figure 21. Fifteen-term error-model of the four-receiver vector network analyzer.

Three-Receiver VNAs,” and “The Seven-Term Error Model for Vector Network Analyzers with Four Receivers” cannot adequately handle the associated cross-talk error. On-wafer measurements typically suffer from this kind of leakage error, due to the small separation of the measurement planes and the radiation of the probe tips.

An error model, capable of accounting for those leakage errors was first detailed in Ref. 24 and is also termed *full-model* (14). It can be derived by describing the four-receiver VNA's hardware as a general eight-port. The coupling between the reflectometers may be arbitrary and nonreciprocal but must be linear and not affected by the parameters of the DUT. Comparable to the four-port/two-port reduction, introduced in the section entitled “Calibration of the Five-Term Error Model,” the reflection coefficients and conversion constants of the four receivers are used to eliminate the reflected waves at the receivers and the generator waves a_G and b_G .

The resulting error four-port $[C]$ (Fig. 21) relates the measured values m_i ($i = 1, 2, 3, 4$) to the waves a_1, a_2, b_1, b_2 at the DUT such that its S -matrix can be computed from the measurement data and $[C]$. Because the switch is not part of the error network and the waves of the RF source are eliminated in Eq. (26), the properties of the switch have no influence on the quality of error correction, and the same error network may be used for either state of the switch.

The mathematical formulation of the error model is derived by partitioning the 4×4 matrix $[C]$ into four 2×2 matrices. With

$$\begin{pmatrix} b_1 \\ b_2 \\ a_1 \\ a_2 \end{pmatrix} = [C] \begin{pmatrix} m_1 \\ m_4 \\ m_2 \\ m_3 \end{pmatrix} = \begin{bmatrix} [G] & [E] \\ [F] & [H] \end{bmatrix} \begin{pmatrix} m_1 \\ m_4 \\ m_2 \\ m_3 \end{pmatrix} \quad (26)$$

the two vector equations

$$\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} = [G] \begin{pmatrix} m_1 \\ m_4 \end{pmatrix} + [E] \begin{pmatrix} m_2 \\ m_3 \end{pmatrix}$$

$$\begin{pmatrix} a_1 \\ a_2 \end{pmatrix} = [F] \begin{pmatrix} m_1 \\ m_4 \end{pmatrix} + [H] \begin{pmatrix} m_2 \\ m_3 \end{pmatrix}$$

can be derived to express the waves at the DUT as

$$[G] \begin{pmatrix} m_1 \\ m_4 \end{pmatrix} + [E] \begin{pmatrix} m_2 \\ m_3 \end{pmatrix} = [S] \left\{ [F] \begin{pmatrix} m_1 \\ m_4 \end{pmatrix} + [H] \begin{pmatrix} m_2 \\ m_3 \end{pmatrix} \right\}$$

An equation of this type is obtained for measurement in either position of the switch, and combining both vector equations into a matrix equation yields

$$[G] \begin{bmatrix} m_1^I & m_1^{II} \\ m_4^I & m_4^{II} \end{bmatrix} + [E] \begin{bmatrix} m_2^I & m_2^{II} \\ m_3^I & m_3^{II} \end{bmatrix} = [S] \left\{ [F] \begin{bmatrix} m_1^I & m_1^{II} \\ m_4^I & m_4^{II} \end{bmatrix} + [H] \begin{bmatrix} m_2^I & m_2^{II} \\ m_3^I & m_3^{II} \end{bmatrix} \right\}$$

which simplifies to

$$[G] + [E][M] = [S]\{[F] + [H][M]\} \quad (27)$$

by introduction of the measurement matrix

$$[M] = \begin{bmatrix} m_2^I & m_2^{II} \\ m_3^I & m_3^{II} \end{bmatrix} \begin{bmatrix} m_1^I & m_1^{II} \\ m_4^I & m_4^{II} \end{bmatrix}^{-1} = \begin{bmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{bmatrix}$$

Comparison with the formulation of the seven-term model [Eq. (22)] reveals the very close relationship, because their structure and even the measurement matrix are identical. In fact, the seven-term error model evolves as a special case of the more general 15-term model. Consequently, the eight off-diagonal error terms that default to zero in Eq. (21), where no leakage is assumed, are needed in the 15-term model to correctly describe the cross-talk.

Calibration of the 15-Term Error Model. Determination of the 16 error terms in the error quadrants $[G]$, $[E]$, $[F]$, and $[H]$ is achieved by expanding Eq. (27) into a system of four linear equations in the error terms per calibration measurement (25). One error term may be arbitrarily set to one, and the resulting inhomogeneous system may be solved for the remaining 15 error terms. Care must be taken to choose one of the error terms *on* the diagonal of the error-quadrants for this normalization, because the *off*-diagonal elements vanish in the case of a leakage-free error four-port.

It turns out that at least five completely known and distinct calibration two-ports must be measured to determine the 15 error terms (25,26). With five calibration measurements, 20 equations in the 15 unknowns exist, but only 15 are needed. Analogous to the section entitled “The Seven-Term Model for Vector Network Analyzers with Four Receivers” either five suitable equations may be neglected or, alternatively, the system of 20 equations in 15 unknowns is solved in the least-squares sense. Use of partially unknown standards and their determination through self-calibration is the third option and is outlined in the section entitled “Self-Calibration for the 15-Term Error Model.”

An especially well-suited combination of standards for the 15-term model, first mentioned in Ref. 25, consists of a Through two-port and the three reflection one-ports *match*, *short*, and *open*, combined to yield four reflection two-ports such that calibration is performed with the five two-ports of Fig. 22.

Contrary to the 7-term, 5-term, or 10-term error-models, the 15-term model does not allow reflection two-ports to be measured sequentially, by separating the reflection measurements at both ports. Due to the presence of cross-talk that must be precisely measured, both ports need to be terminated

$$S^T = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad S^{MS} = \begin{bmatrix} 0 & 0 \\ 0 & -1 \end{bmatrix}, \quad S^{OM} = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}, \quad S^{SO} = \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}, \quad S^{OS} = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}$$

Figure 22. Calibration standards for the 15-term Tms0-procedure.

in the prescribed impedance while performing the calibration measurement. Cyclically interchanging the three reflection one-ports to create the calibration standard lets this Tms0 procedure get by with one match-, short-, and open standard. Lowercase letters are used to indicate that match, short, and open are one-ports and need to be combined to form the necessary calibration two-ports.

Once all error terms are known, the measured values of an arbitrary DUT are to be error-corrected. Contrary to the calibration process, error correction is performed with every measurement. Numerical efficiency is therefore in demand.

Equation (27) is easily solved for the S -matrix $[S]$ of the DUT

$$[S] = \{[G][M] + [E]\}\{[H][M] + [F]\}^{-1}$$

and devises a very simple algorithm for the error-correction process. Only 2×2 matrices need to be manipulated.

Figure 23 (taken from Ref. 27) demonstrates the capabilities of the 15-term procedure in the presence of an artificial leakage error between the measurement planes. Figure 24 depicts the setup. The DUT is a 20 dB attenuator, and the cross-talk is modeled by a second 20 dB attenuator in parallel to the DUT.

While the presence of the leakage error corrupts the result in a way that the uncorrected data bears no resemblance with the transfer characteristics of the DUT, correcting the data according to the 15-term procedure recovers the attenuation value with good precision, even though the amount of cross-talk is of the same magnitude as the DUT's transmission.

MODERN SELF-CALIBRATION TECHNIQUES FOR FOUR-RECEIVER VNAs

Calibration of four-receiver VNAs according to the 7-term or the 15-term error model yields five redundant equations that are not needed for the computation of the error terms. Using this extra information for the determination of unknown parameters of the calibration standards is a very powerful technique that allows the calibration to be performed with *partially known* standards. Besides reducing the cost of standards, self-calibration techniques also enhance the accuracy of the calibration as inconsistency errors are reduced.

Figure 23. Transmission measurement of a 20 dB attenuator (corrected/uncorrected). (From Ref. 27, with permission.)

One of the most popular self-calibration representative, introduced in 1979 by Engen and Hoer (13) for the double six-port reflectometer (seven-term error model), is the TLR procedure. It allows calibration with the following standards:

- (T)hrough (direct connection of both measurement planes)
- (L)ine (a line of unknown electrical length, between 20° and 160° , perfectly matched)
- (R)eflect (unknown, but symmetrical reflection standard)

The L standard and the R standard are only partially known, with no requirements imposed upon the reflect, except that the same reflect has to be used on both measurement planes. Its value and the exact electrical length of the line are determined through the self-calibration process. Different methods can be employed for the determination of the unknown parameters of the standards, three of which are as follows:

1. The *linear* system of equations in the error terms [Eqs. (23) and (27)] is treated as a *nonlinear* system in the error terms *and* the unknowns of the standards. This nonlinear system is solved iteratively (28) or, where possible, analytically, providing a simultaneous solution of error terms and unknowns of the standards (17,18,29).
2. For a unique solution of the error terms to exist, five of the 12 (respectively 20) equations must be linearly dependent. If the 12×8 (20×16) coefficient matrix of the homogeneous linear system of equations [Eqs. (23) and (27)] can be *analytically* brought to tridiagonal form, the last five lines are required to vanish, resulting in five equations in which only measurement values and parameters of the standards appear. It may be argued that the analytical reduction of a 20×16 or even a 12×8 matrix to tridiagonal form is impracticable. However, Eqs. (23) and (27) are sparse enough to render the derivation of self-calibration equations according to this scheme feasible, even for the 15-term error model (30). Once the unknown parameters of the standards are determined, the standards are completely known and so are all nonzero entries of the tridiagonal matrix, which is then used to compute the error terms by a backsubstitution process (19, p. 37).

Figure 24. Measurement setup of a network analyzer with artificial cross-talk.

3. The formulation of the error model is rearranged to yield relations between the standards' S -parameters and the measured values, eliminating the error terms. These relations are exploited to solve for the unknown parameters of the calibration standards which are then completely known and can be used to solve the linear system of equations [Eqs. (23) and (27)] for the error terms. In the following sections, this method, which is based on similarity transformations (21,27), will be presented for the 7-term and the 15-term error model.

Self-Calibration for the Seven-Term Error Model

Elimination of the error parameters to arrive at a relation between the standards' parameters and the measurement values was first described by Eul and Schiek (21) and is most easily achieved by using transfer parameters to describe the cascade structure of the error model (Fig. 19). See Eq. (24) in the section entitled "Calibration of the Seven-Term Error Model Using an Unknown Through."

As transfer parameters exhibit a singularity for transmissionless two-ports ($S_{21} = 0$), this representation of the error model is less suited for the computation of the error terms, which is why the S -parameter representation [Eq. (22)] was chosen in the section entitled "The Seven-Term Error Model for Vector Network Analyzers with Four Receivers." The seven-term error model, however, may as well be written using Eq. (24) with the three calibration measurements yielding three such equations.

Solving the i th calibration measurement for $[H]$.

$$[H] = [\Sigma_i]^{-1}[G][P_i]^{-1} \quad (28)$$

and substituting Eq. (28) into the remaining calibration measurements j and k yields

$$\begin{aligned} [P_j][P_i]^{-1} &= [G]^{-1}[\Sigma_j][\Sigma_i]^{-1}[G] \quad \text{and} \\ [P_k][P_i]^{-1} &= [G]^{-1}[\Sigma_k][\Sigma_i]^{-1}[G] \end{aligned} \quad (29)$$

Recognizing Eq. (29) as similarity transformations, the equality of the eigenvalues of the similar matrices is equivalent to the equality of their determinants and traces, hence

$$\begin{aligned} [A] &= [X][B][X]^{-1} \Rightarrow \det[A] = \det[B] \\ \text{trace}[A] &= a_{11} + a_{22} = \text{trace}[B] = b_{11} + b_{22} \end{aligned}$$

which yields the four equations

$$\begin{aligned} \det\{[P_j][P_i]^{-1}\} &= \beta_1 = \det\{[\Sigma_j][\Sigma_i]^{-1}\}, \\ \text{trace}\{[P_j][P_i]^{-1}\} &= \beta_2 = \text{trace}\{[\Sigma_j][\Sigma_i]^{-1}\} \\ \det\{[P_k][P_i]^{-1}\} &= \beta_3 = \det\{[\Sigma_k][\Sigma_i]^{-1}\}, \\ \text{trace}\{[P_k][P_i]^{-1}\} &= \beta_4 = \text{trace}\{[\Sigma_k][\Sigma_i]^{-1}\} \end{aligned} \quad (30)$$

The combination of both equations in Eq. (29) leads to a fifth condition for the standards' parameters:

$$\text{trace}\{[P_j][P_i]^{-1}[P_k][P_i]^{-1}\} = \beta_5 = \text{trace}\{[\Sigma_j][\Sigma_i]^{-1}[\Sigma_k][\Sigma_i]^{-1}\} \quad (31)$$

These five equations in Eqs. (30) and (31), in which only the transfer parameters of the standards and measurement values appear, can be used to compute a maximum of five unknown parameters of the standards.

The General TAN Procedure. One possibility to distribute the five unknowns among the three calibration standards is the general TAN procedure, where a Through standard (of known transmission factor t), a well-matched Attenuator (with unknown forward and reverse attenuation k_f and k_r), and a symmetrical, but not necessarily reciprocal, Network standard (with unknown reflection r and unknown transmission coefficients u_f and u_r) are used for calibration:

$$[\Sigma_T] = \begin{bmatrix} t & 0 \\ 0 & 1/t \end{bmatrix}, \quad [\Sigma_A] = \begin{bmatrix} k_r & 0 \\ 0 & 1/k_f \end{bmatrix}$$

$$[\Sigma_N] = \frac{1}{u_f} \begin{bmatrix} u_f u_r - r^2 & r \\ -r & 1 \end{bmatrix}$$

The inclusion of the known parameter t is for convenience if connector sex dictates the use of a nonzero length Through.

Since the A -standard may also turn into a well-matched Line standard (L) with $k_f = k_r = e^{-\gamma l}$, or into a double Match standard (M) with $k_f = k_r = 0$, and since the N standard may degenerate to a Reflection standard (R) with $u_f = u_r = 0$, the general TAN procedure also covers the most popular TLR and TMR self-calibration procedures.

However, the singularity of the transfer matrices $[\Sigma_A]$ and $[\Sigma_N]$ and the accompanying measurement matrices $[P_A]$ and $[P_N]$ for the case of vanishing transmission (M , R standard) must be taken care of. For that purpose, pseudo-transfer matrices are introduced (31) by separating the matrix of the measured quantities $[P]$ from its determinant Δm , which may be zero. The residual part of the matrix is denoted $[\tilde{P}]$

$$[P] = \begin{bmatrix} m_1^I & m_1^{II} \\ m_2^I & m_2^{II} \end{bmatrix} \frac{1}{m_3^I m_4^{II} - m_3^{II} m_4^I} \begin{bmatrix} m_4^{II} & -m_3^{II} \\ -m_4^I & m_3^I \end{bmatrix} = \frac{1}{\Delta m} [\tilde{P}] \quad (32)$$

with

$$\Delta m = m_3^I m_4^{II} - m_3^{II} m_4^I \quad \text{and} \quad [\tilde{P}] = \begin{bmatrix} m_1^I & m_1^{II} \\ m_2^I & m_2^{II} \end{bmatrix} \begin{bmatrix} m_4^{II} & -m_3^{II} \\ -m_4^I & m_3^I \end{bmatrix}$$

Combination of the determinant of the measurement matrix with the transfer matrix of the standard belonging to it yields the pseudo-transfer matrices

$$\begin{aligned} \Delta m_A [\Sigma_A] &= \frac{\Delta m_A}{k_f} \begin{bmatrix} k_r k_f & 0 \\ 0 & 1 \end{bmatrix} = \begin{bmatrix} k_r & 0 \\ 0 & 1/k_f \end{bmatrix} = [\Sigma_A^P] \\ \Delta m_N [\Sigma_N] &= \frac{\Delta m_N}{u_f} \begin{bmatrix} u_f u_r - r^2 & r \\ -r & 1 \end{bmatrix} = \frac{1}{\mu_f} \begin{bmatrix} \mu_f \mu_r - \rho^2 & \rho \\ -\rho & 1 \end{bmatrix} \\ &= [\Sigma_N^P] \end{aligned}$$

with

$$\begin{aligned} \kappa_f &= \frac{k_f}{\Delta m_A}, & \kappa_r &= k_r \Delta m_A, \\ \mu_f &= \frac{u_f}{\Delta m_N}, & \mu_r &= r_r \Delta m_N, & \rho &= r \end{aligned} \quad (33)$$

and modifies Eqs. (30) and (31) as

$$\begin{aligned} \det\{[\tilde{P}_A][P_T]^{-1}\} &= \beta_1 = \det\{\Delta m_A[\Sigma_A][\Sigma_T]^{-1}\} \\ &= \det\{[\Sigma_A^p][\Sigma_T]^{-1}\} \\ \text{trace}\{[\tilde{P}_A][P_T]^{-1}\} &= \beta_2 = \text{trace}\{\Delta m_A[\Sigma_A][\Sigma_T]^{-1}\} \\ &= \text{trace}\{[\Sigma_A^p][\Sigma_T]^{-1}\} \\ \det\{[\tilde{P}_N][P_T]^{-1}\} &= \beta_3 = \det\{\Delta m_N[\Sigma_N][\Sigma_T]^{-1}\} \\ &= \det\{[\Sigma_N^p][\Sigma_T]^{-1}\} \\ \text{trace}\{[\tilde{P}_N][P_T]^{-1}\} &= \beta_4 = \text{trace}\{\Delta m_N[\Sigma_N][\Sigma_T]^{-1}\} \\ &= \text{trace}\{[\Sigma_N^p][\Sigma_T]^{-1}\} \\ \text{trace}\{[\tilde{P}_A][P_T]^{-1}[\tilde{P}_N][P_T]^{-1}\} &= \beta_5 \\ &= \text{trace}\{[\Sigma_A^p][\Sigma_T]^{-1}[\Sigma_N^p][\Sigma_T]^{-1}\} \end{aligned} \quad (34)$$

Because at least one standard must exhibit transmission, this property is, without loss of generality, attributed to the T standard, which therefore may be represented by a regular transfer matrix.

With β_i being nonsingular complex values, computed from the measurement values of the four receivers, according to Eq. (32), the first two equations of Eq. (34) can be used to determine the transmission coefficients of the A standard,

$$\frac{\kappa_r}{\kappa_f} = \beta_1, \quad \frac{\kappa_r}{t} + \frac{t}{\kappa_f} = \beta_2$$

which compute as

$$\kappa_r = t \left(\frac{\beta_2}{2} \pm \sqrt{\frac{\beta_2^2}{4} - \beta_1} \right) \quad \text{and} \quad \kappa_f = \frac{\kappa_r}{\beta_1} = \frac{t^2}{t\beta_2 - \kappa_r} \quad (35)$$

Similarly, the other parameters may be derived from the remaining equations in Eqs. (34) as

$$\mu_f = \frac{t^2 - \kappa_f \kappa_r}{t\kappa_f(\beta_5 - \kappa_r \beta_4)}, \quad \mu_r = \mu_f \beta_3 \quad (36)$$

$$\rho = \pm \sqrt{\mu_f \mu_r - \frac{\beta_4 \mu_f}{t} + \frac{1}{t^2}} \quad (37)$$

Using Eq. (33), the parameters of the transfer matrices of the standards $[\Sigma_A]$ and $[\Sigma_N]$ are computed from the above-derived pseudo-transfer parameters.

The root ambiguity in Eq. (35) is solved with a priori knowledge of the A standard's transmission factor. If the standard exhibits attenuation ($|k_r| < 1$), the root whose magnitude is below 1 will be chosen, since the standard is passive. If a line standard with $|k_f| = |k_r| \approx 1$ is used, the phase of the line's

transmission factor must be known to $\pm 90^\circ$ in order to select the correct root.

The root choice in Eq. (37) requires the same kind of information about the phase of the N standard's reflection coefficient, which must be known to $\pm 90^\circ$.

Equations (35) to (37) allow the computation of the calibration standards for the general TAN calibration procedure, also accounting for the special cases of the TMN, TMR, TAR, TLN, and TLR procedures, where the second and/or third standard are double one-ports without transmission.

Calibrating with TMN standards ($k_f = k_r = 0$), for instance, reduces Eqs. (35) to (37) to

$$\mu_f = \frac{\beta_2}{\beta_5}, \quad \mu_r = \frac{\beta_2 \beta_3}{\beta_5}, \quad \rho = \pm \sqrt{\mu_f \mu_r - \frac{\beta_4 \mu_f}{t} + \frac{1}{t^2}}$$

TAR (TLR), on the other hand, has arbitrary k_f and k_r with $\mu_f = \mu_r = 0$, reducing the set of unknowns to

$$\begin{aligned} \kappa_r &= t \left(\frac{\beta_2}{2} \pm \sqrt{\frac{\beta_2^2}{4} - \beta_1} \right), & \kappa_f &= \frac{\kappa_r}{\beta_1} \\ \rho &= \pm \frac{1}{t} \sqrt{1 - \frac{\beta_4(t^2 - \kappa_f \kappa_r)}{\kappa_f(\beta_5 - \kappa_r \beta_4)}} \end{aligned}$$

For the TMR procedure (32) $k_f = k_r = 0$ and $\mu_f = \mu_r = 0$. Only the unknown reflection r needs to be determined, yielding

$$\rho = \pm \frac{1}{t} \sqrt{1 - t \frac{\beta_2 \beta_4}{\beta_5}}$$

As before, the reflection coefficient must be known a priori to $\pm 90^\circ$ in order to resolve the root ambiguity. Technically this is done by choosing the solution that is closest to the estimated reflection coefficient of the R standard. Its choice as a short or an open is common practice (though not required) and provides the necessary information. Furthermore, the *true* value of r is determined by the self-calibration process and can be used to check the quality of the calibration, in those cases where the R standard is completely known.

It should be noted that the perfect match of the A , L , or M standard in the above-described procedures is the only absolute impedance standard and must always be a known quantity, determining the reference impedance of the calibration. The R standard is not required to be known exactly, and the only demand is that the same reflection is presented to both ports. By connecting the same reflection standard first to port 1 and then to port 2, this requirement is easily met. Possible inconsistencies between the phase-reference planes of the different standards, which may creep in without the use of self-calibration, can therefore not occur. The postulated symmetry of the R standard uniquely sets the phase reference at equal offsets to the test ports. These offsets are zero if the transmission factor t of the through corresponds to its true electrical length.

Besides allowing the calibration of the seven-term error model with partially known standards, self-calibration also provides an interesting means of verifying the quality of the calibration if the calibration standards are fully known. In this case, all deviations of the computed parameters of the

standards from their *known* values indicate imperfections of the calibration process.

Employing Self-Calibration for ϵ_r -Measurements

The scheme introduced above for determining the transmission factor of the *A* standard can be used in a straight-forward manner to obtain error-corrected measurements of the electrical length of an unknown line: Measurements of a through and the unknown line yield the measurement matrices $[P_T]$ and $[\tilde{P}_A]$, which, using Eq. (34) make β_1 and β_2 available. With the transmission factor of a line being

$$e^{-\gamma l} = k_f = k_r = \frac{k_r}{\Delta m_A}$$

Eq. (35) can be used to solve for γl . Furthermore, if the mechanical length l of the line is known, the complex propagation constant γ containing ϵ_r is available with very high precision, even though up to this point no calibration has been performed.

Self-Calibration for the 15-Term Error Model

Contrary to the above-presented self-calibration scheme for the seven-term error model, self-calibration formulas for the 15-term model can be derived without the need for transfer parameters and their associated singularity problems.

As was shown in the section entitled “The Cross-Talk Correcting 15-Term Error Model for Four-Receiver VNAs,” the 15-term error model is calibrated using five calibration measurements

$$[G] + [E][M_n] = [S_n]\{[F] + [H][M_n]\} \quad (n = 1, \dots, 5) \quad (38)$$

Using four of those equations, named *i*, *j*, *k*, and *l*, most of the error parameters can be eliminated, arriving at

$$\begin{aligned} &\Delta M_{j,k}^{-1} \Delta M_{i,j} \Delta M_{i,l}^{-1} \Delta M_{l,k} \\ &= ([H] + [F][M_k])^{-1} \Delta S_{j,k}^{-1} \Delta S_{i,j} \Delta S_{i,l}^{-1} \Delta S_{l,k} ([H] + [F][M_k]) \end{aligned} \quad (39)$$

with

$$\Delta S_{m,n} = [S_m] - [S_n], \quad \Delta M_{m,n} = [M_m] - [M_n] \quad (m, n = 1, \dots, 5)$$

(see Ref. 27 for a comprehensive outline of the derivation).

Equation (39) again constitutes a similarity transform, resulting in the two nonlinear relations

$$\begin{aligned} &\text{Trace}\{\Delta M_{j,k}^{-1} \Delta M_{i,j} \Delta M_{i,l}^{-1} \Delta M_{l,k}\} \\ &= b_1 = \text{Trace}\{\Delta S_{j,k}^{-1} \Delta S_{i,j} \Delta S_{i,l}^{-1} \Delta S_{l,k}\} \\ &\text{Det}\{\Delta M_{j,k}^{-1} \Delta M_{i,j} \Delta M_{i,l}^{-1} \Delta M_{l,k}\} \\ &= b_2 = \text{Det}\{\Delta S_{j,k}^{-1} \Delta S_{i,j} \Delta S_{i,l}^{-1} \Delta S_{l,k}\} \end{aligned} \quad (40)$$

between the measured values $[M_n]$ and the standards' *S*-parameters (invariance of the eigenvalues of similar matrices).

Because only four calibration measurements are used by Eq. (39), the fifth standard $[S_m]$, $[M_m]$ may be substituted into Eq. (39) to yield two more similarity transformations:

$$\begin{aligned} &\Delta M_{j,k}^{-1} \Delta M_{m,j} \Delta M_{m,l}^{-1} \Delta M_{l,k} \\ &= ([H] + [F][M_k])^{-1} \Delta S_{j,k}^{-1} \Delta S_{m,j} \Delta S_{m,l}^{-1} \Delta S_{l,k} ([H] + [F][M_k]) \end{aligned} \quad (41)$$

(*i*th standard replaced by *m*th standard) and

$$\begin{aligned} &\Delta M_{m,k}^{-1} \Delta M_{i,m} \Delta M_{i,l}^{-1} \Delta M_{l,k} \\ &= ([H] + [F][M_k])^{-1} \Delta S_{m,k}^{-1} \Delta S_{i,m} \Delta S_{i,l}^{-1} \Delta S_{l,k} ([H] + [F][M_k]) \end{aligned} \quad (42)$$

(*j*th standard replaced by *m*th standard).

Together with Eq. (40), the resulting trace and determinant equalities provide six nonlinear self-calibration equations, sufficient for computation of the maximally five unknowns that the 15-term error model allows for.

It is interesting to note that the derivation of Eq. (39) holds as long as the structure of the error model [Eq. (38)] is unchanged. The calibration standards and/or the measurement matrix $[M]$ may therefore also be expressed in *T*-(transfer) parameters or even in chain parameters, using voltages and currents instead of waves. Even the extension to the error model of an *N*-port VNA, as described in Ref. 24, is straightforward. In this case, all quadrants of the error matrix, the standards' *S*-(*T*-) matrix, and the measurement matrices are $N \times N$ matrices. The invariance of the eigenvalues of the two similar matrices in Eq. (39) yields *N* relations between the measured values and the standards.

The Tmrg Procedure. The self-calibration equations [Eqs. (39), (41), and (42)] permit construction of a multitude of self-calibration procedures, allowing calibration with the set of standards, best suited for a specific application. A particularly interesting variant, the Tmrg procedure, refining the Tmso procedure of the section entitled “The Cross-Talk Correcting 15-Term Error Model for Four-Receiver VNAs,” shall now be introduced.

Whereas Tmso requires a *perfect* match, short and open, the above-derived formalism allows the reflection coefficients of the short and open to be computed through self-calibration. Furthermore, a nonzero but known reflection coefficient may be used as the *m* standard, reducing its requirement from *perfect* to *known*.

Comparable with Fig. 22, Fig. 25 shows the five standards to be constructed from a Through (with known transmission factor *t*) and three reflection one-ports with reflection coefficients *m*, *r*, and *g*. The first four standards suffice for the determination of the unknown reflection coefficients *r* and *g*:

Substituting the standards *i*, *j*, *k*, and *l* into Eq. (39) and evaluating the product of *S*-matrix differences yield

$$\begin{aligned} &\Delta S_{j,k}^{-1} \Delta S_{i,j} \Delta S_{i,l}^{-1} \Delta S_{l,k} = [B] \\ &= \frac{1}{t^2 - rm} \begin{bmatrix} t^2 C_1 - m^2 C_2 & t(mC_2 - gC_1) \\ t(rC_1 - mC_2) & t^2 C_2 - rgC_1 \end{bmatrix} \end{aligned}$$

$$[S_{(k)}^T] = \begin{bmatrix} 0 & t \\ t & 0 \end{bmatrix}, \quad [S_{(j)}^m] = \begin{bmatrix} r & 0 \\ 0 & m \end{bmatrix}, \quad [S_{(i)}^{mg}] = \begin{bmatrix} m & 0 \\ 0 & g \end{bmatrix}, \quad [S_{(i)}^{gr}] = \begin{bmatrix} g & 0 \\ 0 & r \end{bmatrix}, \quad [S_{(mg)}^{rg}] = \begin{bmatrix} r & 0 \\ 0 & g \end{bmatrix}$$

Figure 25. Calibration standards for the 15-term Tmrg self-calibration procedure.

with

$$C_1 = \frac{r-m}{r-g}, \quad C_2 = \frac{g-r}{g-m}$$

resulting in

$$\begin{aligned} & \text{trace}\{\Delta M_{j,k}^{-1} \Delta M_{i,j} \Delta M_{i,l}^{-1} \Delta M_{l,k}\} \\ &= \text{trace}[B] = b_1 = \frac{m^2(g-m) + gr(m-r) + t^2(r-g)}{(rm-t^2)(m-g)} \end{aligned} \quad (43)$$

$$\det\{\Delta M_{j,k}^{-1} \Delta M_{i,j} \Delta M_{i,l}^{-1} \Delta M_{l,k}\} = \det[B] = b_2 = \frac{(t^2-mg)(r-m)}{(t^2-rm)(m-g)} \quad (44)$$

Equation (44) can be solved to yield a linear relation for r

$$r = \frac{b_2 t^2 (g-m) + m(gm-t^2)}{b_2 m(g-m) + (gm-t^2)} \quad (45)$$

and can be combined with Eq. (43) to form a quadratic equation for g

$$g^2 - g \frac{2mt^2 a_1 a_2}{m^2 a_3 - t^2 b_2^2} + \frac{t^4 a_3 - t^2 m^2 b_2^2}{m^2 a_3 - t^2 b_2^2} = 0 \quad (46)$$

with

$$a_1 = b_1 - 1 - 2b_2, \quad a_2 = b_2 + 1$$

$$a_3 = (b_1 - 1)(b_2 + 1) - b_2(2 + b_2)$$

Choosing the proper root for g requires knowledge about the sign of that reflection standard. Using a short for g and an open for r provides the necessary sign information and makes the standards sufficiently distinct for subsequent use as fully known calibration standards.

The only parameters that must be known are the transmission coefficient t of the T standard and the reflection m . The quantity m should be small for numerical reasons and must be known, but the standard is not required to be an *ideal* match.

Since only one set of reflection one-ports is physically required, the postulated equality of the reflection coefficients that enter the different standards is guaranteed, an important advantage over calibration procedures, which require the *same* reflection coefficient to be connected to both ports simultaneously.

OUTLOOK AND RELATED TOPICS

The continuously growing need for fast (production) and precision (laboratory) network measurements has led to the development of sophisticated instrumentation equipment (33–35) and many optimized calibration procedures. This process is expected to continue with the focus shifting toward even higher frequencies (>110 GHz), on-wafer cross-talk correction, and N -port measurements (36,37). A lot of interest is spawned by

the communication industry—for instance, in the characterization of IC packages (N -port measurements) and in high production throughput. Semiautomatic calibration procedures, avoiding the necessity of reconnecting the calibration standards for every calibration, address this need but are not covered here. The interested reader is referred to Ref. 38 for an overview. References 39 and 40 describe commercially available solutions.

Finally, Refs. 20 and 41 present statistical methods to assess errors not originally contained in the error model, like repeatability or contacting errors. Because these errors meanwhile constitute the accuracy limit of error-corrected network analyzer measurements, their inclusion is expected to further boost measurement accuracy.

MILLIMETER-WAVE MEASUREMENT

The millimeter-wavelength spectral band covers the frequency range 30 GHz ($\lambda = 10$ mm) to 300 GHz ($\lambda = 1$ mm). In the larger view, it can include a part of the submillimeter band: the extended range up to 1 THz ($\lambda = 0.3$ mm), which represents one of the least explored portions of the electromagnetic spectrum. The frontier between the millimeter–submillimeter region and the far-infrared region is arbitrary and variable. The distinction comes mainly from the detection techniques employed (coherent or incoherent detection). The millimeter spectrum is presented in Fig. 1.

In the microwave domain, the atmosphere is transparent to frequencies up to 40 GHz except for a weak water vapor absorption line at 22 GHz. However, in the millimeter domain, there are several strong absorption lines: (1) a large and complex set of oxygen lines around 55 GHz to 60 GHz, (2) a single oxygen line around 119 GHz, and (3) a water vapor line around 183 GHz. Above 300 GHz, several absorption lines exist, mainly due to the water vapor. The spectral region located in between these lines, currently called “windows,” is decreasingly transparent when the frequency increases.

Millimeter waves offer a solution to the increasing demand in frequency allocation due to the low-frequency-band saturation and the requirement for higher data rates. Moreover, a high directivity can be obtained with small antennas associated with small sized circuits which become more easily integrable. Applications are numerous, ranging from mobile communications, local area networks, and collision avoidance radars to satellite communications, radio-astronomy, radio-altimetry, and robotics.

In the millimeter-wave range up to 100 GHz, the equipment and methods of measurement have been extended from the microwave domain. The major problems in the millimeter field are due to the small size of the devices and the transmission line losses. Above 100 GHz, as an alternative, other equipment and methods of measurement, using a quasi-optic setup, have been developed or adapted from far-infrared techniques (dielectric waveguide cavity resonator, free-space methods).

MILLIMETER-WAVE AUTOMATIC NETWORK ANALYZER

The reader is invited to consult Electric noise measurement.

As all other types of automatic network analyzer (ANA), the millimeter-wave automatic network analyzer (MWANA) measures magnitudes and phases of scattering parameters (S parameters) of the device under test (DUT).

Figure 1. Atmospheric transmission in the millimeter domain.

Main Types of MWANA

Broadband Coaxial Systems. In this group, single or multiple synthesized sweeper network analyzers are commercially available (1). The single synthesized source systems perform *S*-parameter measurements up to 50 GHz using 2.4 mm coaxial accessories, and up to 67 GHz using 1.85 mm coaxial elements (V connectors). The multiple synthesized sources system may cover the 40 MHz to 110 GHz frequency range using 1 mm coaxial elements (W connectors).

Rectangular Waveguide Systems. These network analyzers perform *S*-parameter measurements in Q (33 GHz to 50 GHz), U (40 GHz to 60 GHz), V (50 GHz to 75 GHz), and W (75 GHz to 110 GHz) frequency ranges; the rectangular

waveguide standards are WR-22, WR-19, WR-15, and WR-10, respectively.

In the multiple-source network analyzer, one synthesized source provides the radiofrequency (RF) (stimulus) signal and the second provides the local oscillator (LO) signal. Figure 2 shows a simplified block diagram of this system common to all waveguide bands. This system consists of a conventional network analyzer, two microwave sources (RF and LO), and a pair of band-dependent millimeter-wave test set modules covering the frequency bands given above. The RF signal after amplification is routed to the Port 1 test set module for forward measurements (S_{11} and S_{21}) or to the Port 2 test set module for reverse measurements (S_{22} and S_{12}). Components in the millimeter-wave test set module provide frequency multiplication, signal separation to sample incident, reflected and

Figure 2. Simplified synopsis of the MWANA test set, for an HP85106D V-band system (50 GHz to 75 GHz).

Table 1. Dynamic Range of HP8510 C for Transmission Measurements as a Function of the Frequency Band

Frequency range (GHz):	33–50	40–60	50–75	75–110
Maximum power measured at port 2, nominal value:	+12 dBm	+10 dBm	+10 dBm	0 dBm
Reference power at port 1, nominal value:	0 dBm	0 dBm	0 dBm	–3 dBm
Minimum power measured at port 2:	–87 dBm	–87 dBm	–75 dBm	–79 dBm
Receiver dynamic range ^a :	99 dB	97 dB	85 dB	79 dB
System dynamic range ^b :	87 dB	87 dB	75 dB	75 dB

^a “Receiver dynamic range” is defined as the ratio of the maximum signal level at port 2 for 0.1 dB compression to the system noise floor.

^b “System dynamic range” is defined as the ratio of the maximum signal at port 1 and the system noise floor.

transmitted signals, and the harmonic mixers to accomplish the intermediate frequency (IF) conversion (generally first IF) to some MHz (e.g., 20 MHz). The second source provides the LO for the four harmonic mixers. This LO source is set such that the millimeter-wave RF test signal frequency and the appropriate LO harmonic are offset by exactly the IF (e.g., 20 MHz). For instance, in the case of the HP8510C MWANA (1) with V-band millimeter-wave test set modules, the frequency of the two microwave sources (RF and LO) can be expressed as follows:

$$\text{RF} = \frac{F_{\text{op}}}{4} \quad \text{and} \quad \text{LO} = \frac{(F_{\text{op}} + 20 \text{ MHz})}{14}$$

where F_{op} is the operating frequency.

As compared with a single-source network analyzer (coaxial), the rectangular waveguide system has inherent drawbacks. Indeed the power of the RF signal injected to the DUT cannot be controlled due to the frequency multiplication. This power may be close to 0 dBm (1 mW on 50 W system) and may be more dependent on the frequency band. This feature may induce nonlinear phenomena (compression, distortion) when the DUT is an active device (transistor, amplifier, etc.). Moreover, reactive impedance of a rectangular waveguide below its cutoff frequency may allow instability of the active DUT.

Dynamic Range of Millimeter-Wave Automatic Network Analyzer

Dynamic range, which is the key consideration in most measurement systems, relates to the ability of a receiver to accurately detect a signal over a large amplitude range. The largest input signal is usually limited by compression in the input receiver, while the smallest ones that can be detected are limited by the noise floor and other undesirable signals. Dynamic range can be improved by increasing the number of measurement averages and changing video IF bandwidth. Table 1 summarizes the dynamic range of HP8510C for transmission measurements as function of the frequency band.

On-Wafer Probing System

Commercially available coplanar probes cover the full millimeter-wave band (2). On-wafer probing in millimeter-wave measurement is by far the most precise technique, due to (1) better positioning and (2) better contact repeatability. For millimeter-wave measurement, only ground-signal-ground (G-S-G) topology is useful, since fundamental modes must only be excited at the probe tip. There are mainly two

types of coplanar probes: coaxial-to-coplanar probe tips and waveguide-to-coplanar probe tips. The former one uses the internal MWANA test set bias tee, while the latter one may include a direct-current (dc) bias tee inside the probe (Fig. 3). Typical values for return loss and insertion loss are, respectively, between 10 dB to 15 dB and 1 dB to 2 dB (2). The connection between the probe and the test set port must be kept as short as possible, and the millimeter-wave coaxial cable may easily add several decibels to the insertion loss.

Specific On-Wafer Calibration Technique

High-precision measurement relies on careful reference plane definition and on-chip parasitic access determination (4). Reference plane definition strongly correlates with the calibration used. For SOLT (short, open, load and through standards) calibration, the reference plane is defined by the coherent values declared for “short” and “open.” Through losses must be kept low, and delay declaration must be coherent with reference plane positioning. Any inconsistency will lead to poor measurement. For TRL (through, reflect, line standards) or LRM (line, reflects, match standards) calibration, the reference plane is always located in the center of the through, but may be moved to some other convenient place after calibration. When using on-chip standards, some or all of the on-chip access parasitics may be included in the calibration, while use of specific

Figure 3. Mechanical structure of the waveguide-coaxial transition and the coaxial probe. (From Ref. 3.)

standards (on alumina substrate) implies subsequent determination (deembedding) of the access parasitics. In the latter case, the reference plane is usually located under the probe tip. The main error sources are (1) bad calibration and (2) bad access parasitic determination. Advanced calibration techniques have been devised for improving calibration while use of specific on-wafer elements may improve deembedding of the access parasitic.

Advanced Calibration Technique. This technique uses more standards in order to (1) obtain better standards definition (SOLT calibration) and (2) perform vector errors correction (LRM calibration and TRL calibration). None of these techniques are implemented in ANA hardware, so specific computer programs are needed.

SOLT Enhancement. The reference plane is solely determined by the short declaration (usually 0 pH). An open-ended long line measurement is performed with an incorrect open declaration and an error model to allow finding for each frequency the open declaration error, thus leading to a better frequency dependent open declaration (5). This allows precise measurement with SOLT up to 110 GHz.

LRRM Calibration. A standard LRM calibration is performed, a new reflect is measured (a short if the calibration reflect was an open), and a new set of error vectors is calculated (6). This allows us to correct for a small probe misplacement in addition to true load deviation.

NIST Multiline Calibration. The TRL calibration technique is based only on the accurate knowledge of the characteristic impedance of transmission line standards. One of the main drawbacks of TRL is its relatively narrow operating frequency range. To perform a very broadband (up to 110 GHz) TRL calibration, a multiline calibration technique has been proposed by the National Institute of Standards and Technology (NIST) (7).

Deembedding of the Access Parasitic

The use of an on-chip-specific design may allow precise determination of all access parasitics between a reference plane and a DUT port. This is an alternative to techniques based on frequency dependence of Y and Z parameters which allow parasitic determination for transistor measurement (8). The deembedding uses direct S -parameter correction or correction through precise parasitic modeling using a specially designed on-chip test device.

Direct S -Parameter Correction. The measurement of open and short placed at the DUT port position allows direct S -parameter correction, using S to Y transformation:

$$Y_{\text{device}} = ((Y_{\text{meas}} - Y_{\text{open}})^{-1} - (Y_{\text{short}} - Y_{\text{open}})^{-1})^{-1}$$

This technique is frequently used for microwave measurement on silicon devices but is also interesting in millimeter-wave measurement. However, extreme care must be taken to compensate for open capacitance (fringing field) and short inductance (ground access) when designing the specific open and short device.

Precise Parasitic Modeling. This usually uses several short, open, and through devices. A careful modeling of all these elements allows us to find out the true access parasitic and the intrinsic device parasitic. Once the access parasitic models

are known, correction of the DUT measurement are obtained through the use of a linear simulator.

Specific Characterizations of Transistors in Millimeter Wave

In view of the increasing number of applications in the centimeter-wave range, the millimeter-wave range is now largely used. MVDS (40.5 GHz to 42.5 GHz), wireless local area networks (60 GHz WLAN), and automotive radar (77 GHz) are among the most focused millimeter-wave applications today. In addition, advanced technologies are now available for manufacturing integrated circuits used in this range. The main challenge is to design this integrated circuit accurately. To this end, reliable broadband transistor models are needed for designing a millimeter-wave integrated circuit. Linear models (or equivalent circuit) including high-frequency noise sources are usually deduced from S parameter and noise-parameter on-wafer measurements. The accuracy of each element of such models depends on the measurement accuracy. The determination of equivalent circuit elements may be difficult and inaccurate in the millimeter-wave range. The key considerations in designing a reliable equivalent circuit of transistors in the millimeter-wave range are as follows:

1. The choice of calibration technique as a function of the topology of the transistor and the nature of the substrate,
2. The choice of the equivalent circuit topology including parasitic elements.

Another solution consists in establishing an equivalent circuit of transistors from S parameters and noise parameters performed in a relatively lower frequency range (for instance, up to 50 GHz). The main advantage is that the accuracy of measurement in this frequency range is better controlled than that in the millimeter-wave range. To validate the reliability of such an equivalent circuit, we calculate the S parameters and noise parameters from the elements of the equivalent circuit and we compare these calculated data with measured ones in the millimeter-wave range.

Millimeter-Wave Cryogenic On-Wafer Measurement

There are basically two different solutions depending on the temperature range. For measurements down to 200 K, the setup is similar to that of the system used for high temperature measurement. The system works at ambient pressure, only the chuck is cold, and a local overpressure of drier air or nitrogen is used to prevent icing of wafer or probe tips. In this case, the temperature gradient is mainly located on the probe itself, so cable length at low temperatures is kept minimal. The calibration substrate may be kept at room temperature.

For measurements down to a few kelvin, the device and probes are kept under vacuum in a nitrogen or helium flow cryostat. Probe displacement under vacuum is obtained through the use of a bellow, cable length is significant, and calibration and measurement must be made at the same temperature.

VOLTAGE AND POWER RATIO TECHNIQUES: SIX-PORT NETWORK ANALYZER

The voltage and power ratio techniques and the six-port network analyzer (SPNA) are based on direct detection of the

millimeter-wave. The hardware configuration of these measurement systems is simple because it is composed of diode or thermal detectors and of directional couplers or probes. In contrast, heterodyne detection systems involve multiple frequency conversions requiring local oscillators. The complexity of the measurement system makes random and systematic errors more difficult to estimate. That is why direct detection techniques provide much of the basis for precision microwave metrology. This article deals with the measurement of the scattering parameters S_{ij} of n -port millimeter devices using a slotted line, a (tuned) reflectometer, and an SPNA.

Slotted Line

This is the oldest method for measuring the reflection coefficient S_{11} of an impedance. In the millimeter frequency range, the slotted line is realized using a piece of metallic rectangular waveguide with a slot located at the center of the broad wall of the guide. The electric field inside the guide is sampled with a wire antenna connected to a Schottky diode detector. The magnitude of S_{11} is given by the voltage standing wave ratio (VSWR). The phase of S_{11} is given by the position of the antenna for which the detected voltage is minimum. This technique has been largely replaced by an automated method.

The Tuned Reflectometer

A simple reflectometer requires one or two directional couplers and power detectors in order to measure the magnitude of S_{11} . These techniques suffer from low directivity of the couplers and from the mismatches of the source and the measurement port Γ_0 . A tuned reflectometer includes tuners in order to overcome these difficulties. The measurement system is composed of a millimeter-wave source, one coupler of directivity D , one power detector, and two tuners. The detected power P may be written as follows:

$$P = K \left| \frac{S_{11} + D}{1 - S_{11}\Gamma_0} \right|^2$$

where K is a constant characterizing the measurement system.

The measurement procedure consists of successively connecting a sliding load and a sliding short in order to null D and Γ_0 using the tuners. Thereafter, the magnitude of S_{11} is given by the power ratio

$$|S_{11}| = \frac{P}{P_{cc}}$$

where P_{cc} is the power measurement when a short circuit takes place at the DUT. For a frequency equal to 110 GHz, the uncertainty measurement (defined at 2σ) of $|S_{11}|$ using the tuned reflectometer is in the range of 0.005 to 0.06 when $|S_{11}|$ varies from 0.01 to 0.5. In metrological labs, transmission measurements (S_{21}) are performed using an IF attenuator (IF substitution method).

Six-Port Network Analyzer

The name “six-port” is due to the six-port millimeter-wave junction (Fig. 4). At its four output ports it provides power readings P_3 to P_6 which are a weighted addition of the incident a_2 and reflected b_2 waves. The complex value of S_{11} (b_2/a_2) derives from

Figure 4. Six-port measurement system. It provides the complex value of the reflection coefficient S_{11} of the load connected at the measurement port. The power detector, connected at each output port, measures the power of b_i , where $i = 3$ to 6.

the six-port equations:

$$\frac{P_i}{P_3} = K_i \left| \frac{\gamma_i a_2 + \beta_i b_2}{\gamma_3 a_2} \right|^2, \quad i = 4, 5, 6$$

where α_i and β_i are the weighted factor of the waves a_2 and b_2 at the i th port and K_i is a constant of the power detector. The four scattering parameters may be obtained by the connection of two SPNAs at the two ports of the DUT or one SPNA in the reflection or transmission mode.

Practical SPNA Junctions

Six-port theory is, in principle, applicable to arbitrary design. However, for better accuracy assessment, design objectives should be obtained:

- At one output port, the wave is proportional (α_3) to the incident wave a_2 .
- At the three remaining ports we have $|q_i| = 1.5$ and $\arg(q_i - q_j) = 120^\circ$, where $q_i = -\alpha_i/\beta_i$ for $i, j = 4, 5, 6$.

A simple six-port junction consists of one directional coupler and three voltage probes (as used in the slotted line) separated by about $\lambda/6$. A similar junction replaces the probes by a waveguide coupling structure (9). This structure contains two E-plane T junctions at the upper broad wall of the main R320 (26.5 GHz to 40 GHz) waveguide and one E-plane T junction at the lower broad wall. The distances between the T junctions are about $\lambda/6$.

Figure 5 shows a six-port junction using techniques (10) at submillimeter wave (300 GHz). Similar quasi-optical techniques have been applied in optic domains for a wavelength of $0.633 \mu\text{m}$ (11). The beam splitter may be replaced by directional couplers using a metallic waveguide or dielectric waveguide structure (94 GHz) (12).

A more wideband system (13) (75 GHz to 110 GHz) has been realized by means of connecting five 3 dB 90° hybrid couplers. It can be shown that the q_i points are frequency independent and are equal to $(-j, 1 + j, -1 + j)$ assuming identical and symmetrical couplers with a coupling factor of 3 dB. This feature is interesting in the millimeter-wave range because the phase property of commercial couplers are usually unknown.

Another technique is the multistate reflectometer. It consists of two directional couplers. The internal matched

Figure 5. Six-port millimeter-wave junction using quasioptic techniques. It comprises five horns and four dielectric sheets. Each of the dielectric sheets is a beam splitter. A metallic mirror is placed on the fourth branch of each beam splitter except the one which involves the measurement of the source signal. The distance between the mirror and the dielectric sheet gives the weight of the added signals.

termination on the fourth arm of one coupler has been replaced by a phase shifter. Three states of the phase shifter provide the three equivalent power ratios of the six-port technique. Currently, this system permits on-wafer measurement at a frequency of 140 GHz (14).

Experimental Results

Table 2 shows S_{11} measurement results obtained with different systems. The measurement results labeled “SPNA,” “HP8510,” or “AB millimeter” can be compared with the values labeled “LCIE” given by the calibration center of LCIE (Laboratoire Central des Industries Electriques en France), which are considered arbitrarily to be the references. In this case, the magnitude of S_{11} as determined with a tuned reflectometer while the phase is obtained with a slotted line. The mean standard deviation is equal to 0.01 for the magnitude and 4° for the phase. The small differences may be due to temperature effects or the nonrepeatability of the connections.

Future Trends

The six-port junction may be realized using a microwave monolithic integrated circuit (MMIC). The MMIC chips can be used as a sensor in an antenna array or integrated inside the tips of a probe station. In the latter case, the series of losses of the probe tips and the line connection do not decrease the measurement accuracy of the wafer probe station.

SOURCE-PULL AND LOAD-PULL TECHNIQUE

Large-signal millimeter-wave measurements of representative samples of semiconductor devices are of prime importance for

two main reasons: (1) accuracy and consistency check of nonlinear transistor models for CAD and (2) experimental optimization of transistor optimum operating conditions without the use of any model.

Nonlinear devices demonstrate different aspects of their behavior depending on the source and load match. Therefore, large-signal measurement systems use either computer-controlled tuners or active loads to change source and load impedances of the DUT to reach the optimum matching conditions under large-signal operation (load-pull system).

Tuner systems operating up to the W band are commercially available. They are widely used for the design of low-noise amplifiers (15), power amplifiers and oscillators (16), and mixers (17). However, such systems do not allow synthesis of impedances close to the edge of the Smith chart. This main drawback becomes more and more crucial if the operating frequency increases (millimeter wave) or if on-wafer measurements are performed. For these reasons the active source and load-pull technique has emerged. Going further in the large-signal characterization, novel measurement systems allowing the extraction of voltage/current waveforms at the DUT's ports have been developed.

Basic Considerations on the Source and Load-Pull Techniques

The principle of the large-signal characterization of any nonlinear two-port is sketched in Fig. 6. If a single-tone power source is used, the four power waves are expressed as follows:

$$a_1(t) = \sum_n A_{1n} \cos(n\omega t + \varphi_{1n}), \quad b_1(t) = \sum_n B_{1n} \cos(n\omega t + \theta_{1n})$$

$$a_2(t) = \sum_n A_{2n} \cos(n\omega t + \varphi_{2n}), \quad b_2(t) = \sum_n B_{2n} \cos(n\omega t + \theta_{2n})$$

Figure 6. Source and load-pull techniques: principle.

Table 2. Measurement Comparison Among Network Analyzers

Network Analyzer	93 GHz	94 GHz	95 GHz	96 GHz
LCIE	0.415 −100.8°	0.447 174.8°	0.479 91.4°	0.515 13°
SPNA	0.01 −0.1°	−0.013 +0.2°	0.012 −0.8°	−0.013 7°
HP8510	0.005 5°	0.002 3°	0.01 5°	0.002 3°
AB millimeter	0.006 0.1°	−0.007 −4°	0.02 −3°	0.01 −1°

A vector network analyzer (VNA) or six-port reflectometer provides the measurements of the magnitudes $|A_{in}|$, $|B_{jn}|$ ($i, j = 1, 2$) and the power wave ratios at the same frequency. From this information, powers, impedances and gains can be calculated. Unfortunately, classical VNAs do not allow the measurements of absolute phases ϕ_{in} and θ_{in} . As a consequence, time-domain waveforms cannot be extracted. A novel system allowing the measurements of time-domain waveforms will be described later.

First a conventional source and load-pull system (measurements of impedances and powers) is considered. Referring to Fig. 6, a systematic approach for performing large-signal characterization of a DUT is as follows:

1. Impose desired dc voltages or currents.
2. Tune the source and load networks.
3. Sweep the power level of the input source and measure powers, efficiency, and gain.

Then the same procedure can be repeated for different operating conditions. This implies the use of a fully automated measurement system.

Multiharmonic Active Source and Load-Pull System

Multiharmonic source and load-pull systems are very useful in designing optimized nonlinear microwave circuits. Both source and load impedances have a great influence on the performances of DUTs in terms of efficiency and linearity. The load-pull characterization has also become a key step in the whole modeling process of semiconductor devices.

Load-Pull (18). The block diagram of a multiharmonic load-pull system is shown in Fig. 7. The measurements of absolute powers and power wave ratios are performed by using a VNA

(receiver operation mode) calibrated with a TRL procedure. The synthesis of load impedances at the first three harmonics coming out of the DUT is performed by using active loops and monitoring the complex gain of each loop with attenuators and phase shifters. Once the gains are fixed, a power sweep at the input of the DUT is performed and input/output power characteristics of the DUT are measured.

Source-Pull (19). Figure 8 shows a measurement system based on the use of six-port reflectometers. This system integrates both input and output active loops to perform source and load-pull measurements. Depending on the position of switch 1, the input six-port measures either the input reflection coefficient of the DUT or the reflection coefficient of the source load presented to the DUT. For both cases the error terms found by a classical calibration procedure are valid.

Time-Domain Waveform Measurement System (20)

As previously mentioned, conventional VNAs do not allow the measurements of absolute phases of harmonically related signals. As a consequence, time-domain waveforms cannot be extracted. Therefore, different institutes have developed measurement systems to extract time waveforms in one or another way usually based on the HP microwave transition analyzer. The potential of the combination of the nonlinear network measurement system (NNMS) with active source and load-pull techniques is under study.

This NNMS is mainly composed of a four-channel broadband downconverter followed by digitizers. It uses the harmonic mixing principle to convert RF fundamental and harmonics into IF fundamental and harmonics. This instrument takes the place of the VNA in the system previously presented.

The calibration of the system is performed in three main steps:

Figure 7. Multiharmonic load-pull system block diagram.

Figure 8. Source-pull implementation with a millimeter-wave six-port junction.

1. Classical TRL calibration
2. Power calibration
3. Phase calibration

During the last step, a reference generator (step recovery diode) is connected instead of the DUT (21). The reference generator is calibrated using the nose-to-nose calibration procedure (22).

DIELECTRIC WAVEGUIDE CAVITY RESONATOR

At millimeter-waves, resonators are useful for a large number of applications in communication systems and measurements of dielectric properties. In the millimeter-wave and submillimeter-wave ranges, difficulties arise from wavelengths which are very short, and devices are difficult to machine with a large degree of accuracy. So the problem is to achieve high circuit Q for volumic or hybrid millimeter-wave integrated circuits.

Different resonator structures are used. Some of them are derived from low-frequency application, like a cylindrical metallic cavity, but other devices have been developed specially for millimeter-wave measurement. In the following subsections we present mainly the devices given in Fig. 9 which are often used.

Cylindrical Metallic Cavity

This structure presented in Fig. 9(a) is composed of a cylindrical metallic waveguide closed at the top and the bottom by a metallic plane. The resonant frequency depends on the dimensions of the cavity (diameter and height) and the mode which is excited in the structures. These modes are chosen to be TE_{01n} or TM_{01n} modes and depend on excitation line position. The unloaded Q factor of these resonators increases with the axial number n . But it is difficult to use axial numbers greater than five, because a lot of modes are excited in a frequency band and it is difficult to obtain good frequency isolation. Typically, at room temperature and with copper to realize the cavity, values of unloaded Q factor are equal to 12,000 at 30 GHz and 7000 at 100 GHz on the TE_{013} modes.

Open Resonators

The most popular of this type of resonator is the Fabry-Pérot, which is presented in Fig. 9(b) (23,24). These resonators are used from the short-microwave to the optical domains (25). The basic device is composed of two reflectors of arbitrary radius of curvature separated by a length d . At low frequencies, the dimensions of the mirror will be very large, so for this reason these devices are used essentially at very high frequencies. TEM_{plq} mode is excited in these structures, where p , l , and q are, respectively, radial, azimuthal, and axial variations of

Figure 9. Example of millimeter-wave resonators. (a) Cylindrical metallic cavity. (b) Open resonators. (c) Whispering gallery dielectric resonators.

the energy which is localized in the center between the two mirrors. In a great number of applications, the TEM_{00q} mode is used and resonant frequency of these modes are periodics along the q parameter. As in metallic cavities, the unloaded Q factor increases with the number of axial variations, and values of the Q factor greater than 10^6 are possible in millimeter-wave measurement.

Dielectric Resonators

For high frequencies the dimension of resonators excited on conventional modes becomes impractically small. A solution consists of using dielectric resonators excited on whispering gallery modes (WGMs), which are higher-order modes. The first advantage of this solution is the dimension of the resonators, which is approximatively 10 times bigger than resonator excited on conventional modes. The geometry of the resonators is a disk with a diameter greater than thickness, as shown in Fig. 9(c) (26,27). So these resonators are easy to integrate in planar circuits.

Moreover, acting on these modes, energy is confined at the periphery of the dielectric resonator, and radiation losses are negligible. Thus, unloaded Q factors are very large and only limited by dielectric losses of the material used to realize the resonators.

At room temperature and using quartz material, a measured Q factor of 30,000 has been obtained at 100 GHz. Placed in a metallic cavity and at 77 K, a Q factor of 30,000,000 has been measured at 7 GHz with sapphire.

Applications to Millimeter Devices

In millimeter-wave devices, a large number of applications use resonators circuits. These elements are used in devices such as filters or oscillators, or for material measurements to determine complex permittivity and permeability. In both cases, it is very interesting to have a high Q factor of the resonances modes.

Filtering. Insertion losses and rejection depend on Q factor of the resonators. To realize these circuits, cylindrical metallic cavity or WGM dielectric resonators are suitable because association of several resonators is possible. At high frequencies, topologies of these structures are the same as for low-frequency devices.

Oscillator. Frequency stabilization and phase noise need a high Q value of the resonant device. For millimeter-waves, dielectric resonators excited on WGM give good results and are easy to integrate in the devices. With these modes, the original topology of oscillators can be realized by using the wave propagation effect at the periphery of the resonators, which is another property of these modes.

Dielectric Material Measurement. These resonator devices are currently used because they permit good accuracy with regard to the complex permittivity of the material. For metallic cavities or open resonators, the method consists of comparing the resonant frequency and the unloaded Q factor of the empty and loaded resonators. This method is convenient if the thickness of the material under test is smaller than the wavelength. For material with a large thickness, methods using WGM are suitable. In this case, measurements of resonance frequency and Q factor are compared with results obtained by electro-

magnetic simulator. These methods can be used for anisotropic dielectric or magnetic material (28).

Future Trends

The performance of millimeter-wave resonator devices is limited by the difficulty of integration of resonators in devices (in particular, for cavity or open resonators) or by losses of metallic or dielectric materials. Over the past 10 years, with the development of new dielectric materials like sapphire in the microwave domain, performances have been improved with regard to the unloaded Q factors. Unfortunately, characteristics of these materials change with temperature, and frequency stabilization is difficult to obtain without using regulating temperature devices. In the future, with technology development, we can hope to obtain material with optimum characteristics.

FREE-SPACE METHODS: INTERFEROMETRY

Waveguide loss becomes important for millimeter waves; free-space transmission has lower loss and is good for low-noise applications as well as for high-power applications (in addition, larger area of beam spread produces a lower power density). Free-space measurement is required when contact is not possible. Such is the case in radiometry for measurement of temperature and chemical composition, as well as in interferometry and in radar detection for measurement of distance, velocity, and position.

Very often for millimeter waves, the beam diameter is a relatively small number of wavelengths; thus, diffraction must be considered. A wide variety of components and systems have been developed using quasi-optical techniques, either similar to waveguide devices or derived from infrared and optical techniques (29,30).

Quasi-Optical Techniques

Gaussian Beams. Paraxial propagation of a beam in free space is relatively simple to analyze if the transverse electric field amplitude variation has a Gaussian form:

$$E(r)/E(0) = \exp[-(r/w)^2]$$

where r is the distance from the axis of propagation, and w is called a "beam radius." A Gaussian beam is produced with, or focused to, a minimum size; this minimum beam radius w_0 called a "beam waist."

The feedhorn is the best coupling device between the Gaussian beam and the guided wave (Fig. 10). The best coupling (98%) is obtained with a scalar feedhorn pattern. Several types of planar antennas (patch, bow tie, traveling-wave slot) can also be used. An associated lens is used to obtain reasonable coupling efficiency. Several types of planar antennas (patch, bow tie, traveling-wave slot) can be used. An associated lens allows us to reduce the beam size and increase the coupling efficiency.

Quasi-Optical Components Used in Millimeter-Wave Measurement. Quasi-optical components provide a wide variety of functions used for millimeter measurements:

- Beam transformations require focusing elements like parabolic or ellipsoidal mirrors and lenses. To minimize the absorptive loss of lenses, low-loss dielectrics must be

Figure 10. Devices for millimeter-wave and submillimeter-wave beam production (horn and open-structure examples).

selected (PTFE, alumina, fused silica, etc.); and to obtain low reflection loss, a matching layer or grooves are essential, except for low-index materials.

- High Q -factor ($\gg 10,000$) resonant cavities can be formed with two spherical mirrors or one spherical and one plane mirror.
- Signal filtering can be achieved by interferometers (see below) and by plate filters: Perforated conductive plates or arrays of resonant patterns are printed on a dielectric substrate.
- Polarizing grids are usual in quasi-optical systems, often used as beam splitters for a polarized signal. These grids can be formed with free-standing wires or with dielectric-supported conducting strips. Dielectric plates are also used as beam splitters and can function as hybrids (90° phase shift between reflected and transmitted beams).
- Different types of interferometers are developed from beam splitters and reflective devices: dual-beam interferometers or Fabry–Perot interferometers.

Quasi-Optical Bench. The purpose of the quasioptical bench is to create a “beam waveguide” including a sufficient measurement area. Figure 11 shows a basic bench: The measurement area is located between a signal generator and a detector equipped with free-space coupling devices (horns and lenses). The relative positions must be finely adjustable (in three rectangular directions and two or three rotating angles) while staying extremely stable. As in coaxial or waveguide measurements, generators and detectors can use frequency multipliers and heterodyne and phase-locked systems to increase the sensitivity and stability.

Free-space measurements may use a device for analog-to-coaxial calibration set parts. The methods are identical, but special care is required to (1) decrease the multiple reflections by using absorbing shields and anechoic rooms, (2) take VSWR into account, and (3) manage external (or internal) electromagnetic interferences. Another source of error and instability is atmospheric absorption, when the measuring frequency band comes over the absorption bands of an atmospheric molecule.

Free-Space Antenna Measurement

The antenna characteristics which have to be measured in the millimetric range are mainly radiation patterns in co-

and cross-polarization. Phase center measurements of primary feeds, as well as beam efficiency, also have a great importance for reflector antenna design. Measurement techniques are much the same as at lower frequencies, but with specific difficulties and requirements (31). (See also Radiometry, Electromagnetic field measurement.)

Radiation Pattern Measurements. Far-field measurements must be performed outdoors if antenna dimensions are large compared with the wavelength, which generally is the case for reflector antennas at millimetric frequencies. However, atmospheric attenuation and geographic implementation become prohibitive when the far field exceeds 1 km. Compact antenna test ranges (CATRs) remedy this problem for medium-to-large reflector antennas in the millimetric range.

For antennas of moderate (cm) dimensions, far-field measurements can be performed indoors. Horns and printed antennas are tested in anechoic chambers. In CATRs, a local plane wave is created in a zone called the “quiet zone,” by way of one or several reflectors used to collimate the beam of a smaller source. Various designs exist, ranging from the basic one with a single offset reflector to triple reflector systems, according to the required cross-polarization and spillover levels and the size of the antennas under test. Diffraction at the edges of the reflectors is less critical than in the microwave range, but reflector surfaces requirements are more stringent because the root-mean-square (rms) surface error should be better than $1/100$ wavelength to obtain good precision on the plane wave phase. Corrugated or special multimode horns are used as sources.

Hologram CATRs are being developed. Reflectors are replaced by a hologram, with a surface accuracy requirement divided by 10. This technique is thus less expensive, but it is still very new and faces problems concerning the size of the required holograms as well as frequency bandwidth limitations (20% to 30%) and polarization difficulties.

In the near-field scanning technique, fields are measured close to the antenna under test, on either a planar, cylindrical, or spherical surface. This technique requires both amplitude and phase measurements, because the sampled fields are used to calculate the radiated far-field through a near-field to far-field transformation. In the millimeter-wave domain, this technique encounters problems of time consumption and precision phase measurement.

Figure 11. Quasioptical bench.

Other Antenna Performance Measurement. The “beam efficiency measurement” is performed by measuring the power radiated within the main beam of the antenna. It is especially important for radiometer antennas, which must have very low sidelobes. It requires both radiation pattern measurements, although not with wide-angle scanning, and absolute power measurements. The “phase center position measurement” is useful only for horns used as primary sources in reflector antennas. It is performed by positioning the center of phase patterns in different planes along the axis of the horn. It requires precise phase measurements and mechanical positioners.

Quasi-Optical Measurement

Power Measurement. Most of the power detectors used in the microwave measurement (Schottky diodes for instance) still work in the millimeter-wave frequency range. Moreover, bolometers and the calorimeters also operate in this range. These devices mounted in a waveguide structure can be associated with a horn to make up a beam detector. To increase the sensitivity, synchronous detection and heterodyne conversion may be used. Absolute calibration must be performed with photoacoustic detectors (used at Brewster angle and through amplitude modulation).

Quasi-Optical Device Characteristics Measurement. A basic quasi-optical bench allows us to measure the main of millimeter-wave characteristics of a DUT inserted in the optical

path: transmittance, loss and scattering by insertion, and reflection by comparison with a good reflector. Much attention must be paid to (1) the radial size of the DUT compared with the usable beam size, (2) the compensation for phase differences, and (3) the VSWR (which can be reduced by choosing an incidence angle other than zero).

For low losses, noise measurements provide a better accuracy. The equivalent noise temperature T_1 is increased to T_2 by the insertion of a DUT at the front of a low noise receiver. Giving the DUT physical temperature T_d , the loss factor L is obtained from

$$T_2 = T_d(L - 1) + LT_1(1 + \Gamma^2)$$

with $\Gamma^2 = [(VSWR - 1)/(VSWR + 1)]^2$

Noise Measurement. In addition to classic noise measurement using a noise source (diode, gas tube) associated in this case with a horn, the common noise measurement uses two absorbing targets with two different radiant temperatures. The target with the higher temperature T_h , the “hot load,” takes the place of the target with the lower temperature T_c , the “cold load,” in front of the DUT. The respective output powers are P_h and P_c . With ideal targets the equivalent noise temperature of the DUT is

$$T_x = (T_h \cdot P_c - T_c \cdot P_h)/(P_h - P_c)$$

Radiometer systems must be extremely stable over long periods and linear over the whole level range. The target size must be enough to cover the whole beam. Temperature and absorption coefficients must be homogeneous over the target surface. At millimeter wavelengths, $h\nu < kT$, the brightness temperature is very near the physical temperature. Measurement uncertainties come from variations of the effective emissivity of the target and from the mismatch with the receiver. In addition, as a result of the standing wave effect, the total noise entering the receiver becomes frequency-dependent.

The standard ferrite-loaded foam absorbers may be used as calibration targets in the lower frequency range, but for higher frequencies the reflected power unfortunately reaches -20 dB, depending on the polarization angle. For a single polarization and when the configuration is fixed, a specially developed ridged absorber or dielectric surface at the Brewster angle acts as a quasi-perfect absorber.

To achieve good precision ($<1\%$), a lot of specific targets have been developed from the principle of a conical hole with an angle of $<10^\circ$ to increase the number of reflections.

Other Quasi-Optical Measurements. The frequency measurement may use a down conversion by means of a millimeter mixer coupled with a local oscillator by a quasi-optical coupler (an interferometer or a simple dielectric plate). The local oscillator and the low frequency counter are phase/frequency locked on a reference ultra stable oscillator. On the other hand, wave-meters may use very-high- Q -factor cavities in quasi-optical techniques.

The measurement of the polarization of a signal usually takes advantage of the sensitivity of the detector for one electromagnetic field direction (detection diodes and rectangular waveguide mounts). To increase the accuracy or to use a nonpolarized detector, a polarized plate (grid) may be inserted (with an incident angle to decrease a possible VSWR effect). This method requires us to rotate the whole receiver or to insert a waveguide twist behind the horn (causing a calibration problem). The other solution is to use a quasi-optical polarization rotator on the optical path. This device uses three grids in transmission (32) or one grid and one reflector (33). In this way the mechanical rotation is limited to one light device, and the transition time may be very short (<10 ms). Circular polarization may be measured with a particular disposition of Martin-Puplett interferometer.

The knowledge of the insertion effects (loss and phase variations) allows us to compute the complex dielectric constant of a material. Other methods for material characteristics measurement use modifications of a cavity resonator's Q -factor.

Interferometry

The resolution of an antenna has a diffraction limit of $\approx \lambda/D$, and an interferometer increases the resolution according to the area covered by two or several connected antennas. More generally, an interferometer can be used to measure the Fourier components of a brightness distribution. Since Ryle and Hewish (34) have formulated the principle of aperture synthesis, many interferometers have been built or are in progress (mainly for radioastronomy). The aperture may be synthesized by multiplication, physically moving of elements, or by using the rotation of the earth. As baselines are increased, the major problem in millimeter-wave measurement is the maintenance of phase

stability of local oscillators; for very long baseline interferometry (VLBI), the local oscillators are independent and need very accurate frequency standards.

MECHANICAL VARIABLES

DISPLACEMENT MEASUREMENT

The measurement of displacement is an important aspect of many industrial, scientific, and engineering systems. The displacement is associated with the motion or the change in the position of an object. It is basically the vector representing a change in position of a body or from one stable point to another with respect to a reference point. In measurement systems, when the word *displacement* is used, the change in the relative position is considered to be very small—within few millimeters or less. Because displacement is a fundamental component of many instrumentation and measurements systems, many different devices have been developed to measure it ranging from a few nanometers to a few meters. A list of manufacturers is given in Table 1.

Displacement is closely associated with acceleration and velocity. Double integration of acceleration and single integration of velocity yield the displacement of an object. Therefore, some devices resembling acceleration and velocity sensors are modified for displacement measurements. Displacement sensors are manufactured in different dimensions and sizes, and they are based on many different physical principles (e.g., capacitance, magnetism, optics, piezoelectricity, resistivity). Here, the most frequently used displacement sensors will be explained.

CAPACITIVE DISPLACEMENT SENSORS

Capacitive displacement sensors enjoy wide application in industry. They satisfy the requirements of applications where high linearity and wide ranges from a few centimeters to a couple of nanometers are needed. Precision signal processing allows sensing of capacitance changes down to a few femtofarads.

The basic sensing element of a typical displacement sensor consists of two simple electrodes with capacitance C . The capacitance is a function of the distance d (meters) between the electrodes of a structure, the surface area A (square meters) of the electrodes, and the permittivity ϵ (8.85×10^{-12} F/m for air) of the dielectric between the electrodes; therefore,

$$C = f(d, A, \epsilon) \quad (1)$$

There are three basic methods for realizing a capacitive displacement sensor (i.e., by varying d , A , or ϵ , as discussed next).

Variable Plate-Distance Sensors

A variable-distance capacitive displacement sensor, made from two flat coplanar plates with a variable distance x apart, is illustrated in Fig. 1. Ignoring fringe effects, the capacitance of this arrangement may be expressed by

$$C(x) = \epsilon A/x = \epsilon_r \epsilon_0 A/x \quad (2)$$

where ϵ is the dielectric constant or permittivity, ϵ_r is the relative dielectric constant (in air and vacuum $\epsilon_r \approx 1$),

$\epsilon_0 = 8.854188 \times 10^{-12}$ F/m is the dielectric constant of vacuum, x is the distance of the plates in meters, and A is effective area of the plates in square meters.

The capacitance of this transducer is nonlinear with respect to distance x , which has hyperbolic transfer function characteristics. The sensitivity of capacitance to changes in plate separation may be found as

$$dC/dx = -\epsilon_r \epsilon_0 A/x^2 \quad (3)$$

Equation (3) indicates that the sensitivity increases as x decreases. Nevertheless, from these equations, it follows that the percent change in C is proportional to the percent change in x , which can be expressed as

$$dC/C = -dx/x \quad (4)$$

This type of sensor is often used for measuring small incremental displacements without making contact with the object.

Variable-Dielectric Displacement Sensors

The displacement may also be sensed by the relative movement of the dielectric material, attached to the object under investigation, between the plates. The corresponding equations will be

$$C = \epsilon_0 w [\epsilon_2 l - (\epsilon_2 - \epsilon_1)x] \quad (5)$$

where ϵ_1 is the relative permittivity of the dielectric material and ϵ_2 is the permittivity of the displacing material (e.g., liquid).

In this case, the output of the transducer is linear. This type of transducer is mostly used in the form of two concentric cylinders for measuring the level of nonconducting fluids in tanks.

Variable Plate-Area Displacement Sensors

The displacements may be sensed by varying the surface area of the electrodes of a flat plate capacitor, as illustrated in Fig. 2. In this case, the capacitance can be written as

$$C = \epsilon_r \epsilon_0 \frac{A - wx}{d} \quad (6)$$

Figure 1. A variable plate-distance capacitive displacement sensor. In response to a physical stimuli, one of the plates of the capacitor moves; this varies the distance between plates. The outputs of these sensors are nonlinear with respect to distance x , having an hyperbolic transfer function characteristics. Appropriate signal processing must be employed for linearization.

Figure 2. A variable-area capacitive displacement sensor. The sensor operates on the variation of the effective area between plates. The output is linear with displacement x . This type of sensor is normally implemented as a rotating capacitor for measuring angular displacement.

where w is the width and wx is the reduction in the area caused by the movement of the plate.

The transducer output is linear with displacement x . This type of sensor is normally implemented as a rotating capacitor for measuring angular displacement. The rotating capacitor structures are also used as an output transducer for measuring electric voltages.

Differential Capacitive Sensors

Some of the nonlinearity can be eliminated by using differential capacitive sensors. These sensors are basically three terminal capacitors, as shown in Fig. 3. Slight variations of these sensors find many applications including differential pressure measurements. In some versions, the center plate responds to physical variables while the other two plates are fixed. In the others, the center plate is fixed, and the outer plates are allowed to move. The output from the center plate is zero at the center position, and it increases as it moves left or right. The range is equal to twice the separation d . For a small displacement d , the change in capacitance will be

$$2\delta C = C_1 - C_2 = \frac{\epsilon_r \epsilon_0 l w}{(d - \delta d)} - \frac{\epsilon_r \epsilon_0 l w}{(d + \delta d)} = \frac{2\epsilon_r \epsilon_0 l w \delta d}{d^2 + \delta d^2} \quad (7)$$

Figure 3. A differential capacitive sensor is three terminal capacitors with one fixed center plate and two outer plates. The response to motion is linear. In some versions, the center plate moves in response to a physical variable with respect to the two outer plates; in others, the center plate is fixed, and the outer plates are allowed to move.

and

$$C_1 + C_2 = 2C = \frac{\epsilon_r \epsilon_0 l w}{d - \delta d} + \frac{\epsilon_r \epsilon_0 l w}{d + \delta d} = \frac{2\epsilon_r \epsilon_0 l w d}{d^2 + \delta d^2} \quad (8)$$

Giving approximately

$$\delta C / C = \delta d / d \quad (9)$$

This indicates that the response of the device is more linear than the response of the two parallel plate types. However, some nonlinearity is still observed in practice as a result of defects in the structure. Therefore, the outputs of these types of sensors may still need to be processed carefully by appropriate signal-processing techniques.

MAGNETIC DISPLACEMENT SENSORS

Magnetic displacement sensors are commonly used in industry, particularly in manufacturing. The majority of the magnetic displacement sensors are inductive types based on Faraday's Law of Induction. They can be classified as reluctance, transformative, tachogenerator, induction potentiometer, eddy current, and magnetometer types. They are designed to measure linear as well as rotary displacements.

Linear Variable-Reluctance Types

The variable-reluctance transducers are based on change in the reluctance of a magnetic flux path. These types of transducers find applications particularly in acceleration measurements. However, they can be configured for sensing displacements and velocities. They are constructed in many different forms as described later.

Single-Coil Linear Variable-Reluctance Sensors. A typical single-coil variable-reluctance displacement sensor is illustrated in Fig. 4. The sensor consists of three elements: a

Figure 4. A typical single-coil variable-reluctance displacement sensor. The sensor consists of three elements: a ferromagnetic core in the shape of a semicircular ring, a variable air gap, and a ferromagnetic plate. The reluctance of the coil is dependent on the air gap. The air gap is the single variable, and the reluctance increases nonlinearly with the increasing gap.

ferromagnetic core in the shape of a semicircular ring, a variable air gap, and a ferromagnetic plate. The total reluctance of the magnetic circuit is the sum of the individual reluctances:

$$\mathcal{R}_T = \mathcal{R}_C + \mathcal{R}_G + \mathcal{R}_A \quad (10)$$

where $\mathcal{R}_C$, $\mathcal{R}_G$, and $\mathcal{R}_A$ are the reluctances of the core, air gap, and armature, respectively.

Each one of these reluctances can be determined from its material properties and dimensions. In this particular case, $\mathcal{R}_T$ can be approximated as

$$\mathcal{R}_T = \frac{R}{\mu_C \mu_0 r^2} + \frac{2d}{\mu_0 \pi r^2} + \frac{R}{\mu_A \mu_0 r t} \quad (11)$$

In Eq. (11), the length of the flux path in the core is taken as πR , and the cross-sectional area is assumed to be uniform with a value of πr^2 . The total length of the flux path in air is $2d$, and it is assumed that there is no fringing or bending of the flux through the air gap, so that the cross-sectional area of the flux path in air will be close to the cross section of the core. The length of an average central flux path in the armature is $2R$. The calculation of an appropriate cross section of the armature is difficult, but it may be approximated to $2rt$, where t is the thickness of the armature.

Equation (11) may be rewritten by fixing all the parameters except the air gap, which is the independent variable. Hence,

$$\mathcal{R}_T = \mathcal{R}_0 + kd \quad (12)$$

where $\mathcal{R}_0 = R/(\mu_0 r^2)[1/(\mu_C r) + 1/(\mu_A t)]$ and $k = 2/(\mu_0 \pi r^2)$. Now, the inductance can be written as

$$L = \frac{n^2}{\mathcal{R}_0 + kd} = \frac{L_0}{1 + \alpha d} \quad (13)$$

where L_0 represents the inductance at zero air gap and

$$\alpha = k/\mathcal{R}_0$$

The values of L_0 and α can be determined mathematically; they depend on the core geometry, permeability, and the like, as explained previously. From Eq. (13), it can be seen that the relationship between L and α is nonlinear. Despite this nonlinearity, this type of single-coil sensor finds application in such areas as force measurements and telemetry. In force measurements, the resultant change in inductance can be made to be a measure of the magnitude of the applied force (say on a spring). A coil usually forms one of the components of an LC oscillator whose output frequency varies with the applied force. Hence, the coil modulates the frequency of the local oscillator.

Variable-Differential Reluctance Sensors. The problem of the nonlinearity may be overcome by modifying a single-coil system into a variable-differential reluctance sensor (also known as a push-pull sensor), as shown in Fig. 5. This sensor consists of an armature moving between two identical cores separated by a fixed distance $2d$. If the core is displaced by x , Eq. (13) can now be modified to consider the effect of the two coils, as

$$L_1 = \frac{L_{01}}{1 + \alpha(d - x)} \quad L_2 = \frac{L_{02}}{1 + \alpha(d + x)} \quad (14)$$

Figure 5. A variable-differential reluctance sensor consists of an armature moving between two identical cores separated by a fixed distance. The armature moves in the air gap in response to a mechanical input. This movement alters the reluctance of coils 1 and 2, thus altering their inductive properties. This arrangement overcomes the problem of nonlinearity inherent in single-coil sensors.

Although the relationship between L_1 and L_2 is still nonlinear, the sensor can be incorporated into an ac deflection bridge to give a linear output for small movements. The hysteresis errors of these transducers is almost entirely limited to the mechanical components. These sensors respond to static and dynamic displacements. They have continuous resolution and high outputs, but they may give an erratic performance in response to external magnetic fields. A typical sensor of this type has an input span of 1 cm, a coil inductance of 25 mH, and a coil resistance of 75 Ω . The resistance of the coil must be carefully considered when designing oscillator circuits. The maximum nonlinearity is 0.5%.

A typical commercially available variable differential sensor is shown in Fig. 6. The iron core is located half way between the two E-shaped frames. The flux generated by primary coils depends on the reluctance of the magnetic path, the main reluctance being the air gap. Any motion of the core increases the air gap on one side and decreases it on the other side. Consequently, reluctance changes in accordance with the principles already explained, thus inducing more voltage on one of the coils than the other. Motion in the other direction reverses the action with a 180° phase shift occurring at null. Depending on the requirements in signal processing, the output voltage can be modified by means of rectification, demodulation, and filtering. In these instruments, full-scale motion may be extremely small, on the order of few thousandths of a centimeter.

In general, variable-reluctance transducers have small ranges and are used in specialized applications such as pressure transducers. Magnetic forces imposed on the armature are quite large, and this can limit the application severely.

Linear Variable-Inductive Sensors

A typical linear-variable inductor consists of a movable iron core, which provides the mechanical input, and the two coils forming two legs of a bridge network. A typical example of such a transducer is the variable coupling transducer.

Variable-Coupling Sensors. Variable-coupling sensors consist of a former holding a center-tapped coil and a ferromagnetic

Figure 6. A typical commercial variable-differential sensor. The iron core is located half way between the two E frames. Motion of the core increases the air gap for one of the frames while decreasing for the other. This causes reluctances to change, thus inducing more voltage on one side than the other. Motion in the other direction reverses the action, with a 180° phase shift occurring at null.

plunger. The plunger and the two coils have the same length l . As the plunger moves, the inductances of the coils change. The two inductances are usually placed to form two arms of a bridge circuit with two equal balancing resistors. The bridge is excited with 5 V to 25 V ac at a frequency of 50 Hz to 5 kHz. At the selected excitation frequency, the total transducer impedance at null is set typically to the $100\ \Omega$ to $1000\ \Omega$ range. The resistors are chosen to have about the same value as the transducer impedances. The load for the bridge output must be at least ten times the resistance R value. When the plunger is in the reference position, each coil will have equal inductances of value L . As the plunger moves by δl , changes in inductances $+\delta L$ and $-\delta L$ create a voltage output from the bridge. By constructing the bridge carefully, the output voltage may be made a linear function of the displacement of the moving plunger within a rated range.

It is easy to construct transducers of this type, by simply winding a center-tapped coil on a suitable former. Variable inductance-transducers are commercially available in strokes from about 2 mm to 500 cm. The sensitivity ranges between 1% full scale to 0.02% in long-stroke special constructions. These devices are also known as linear displacement transducers (LDTs) and are available in various shape and sizes.

In addition to linear variable inductors, rotary types are available. Their cores are specially shaped for rotational motion applications. Their nonlinearity can vary between 0.5% and 1% full scale over a range of 90° rotation. Their sensitivity can be up to $100\text{ mV}/1^\circ$ of rotation.

Linear Variable-Differential Transformers

The linear variable-differential transformer (LVDT) is a passive inductive transducer finding extensive applications;

Figure 7. An LVDT is a passive inductive transducer consisting of a single primary winding positioned between two identical secondary windings wound on a tubular ferromagnetic former. As the core inside the former moves, the magnetic paths between primary and secondaries alter, thus producing secondary outputs proportional to the movement. The two secondaries are made to be as identical as possible by having equal sizes, shapes, and number of turns.

therefore, they deserve lengthy discussion here. An LVDT consists of a single primary winding positioned between two identical secondary windings wound on a tubular ferromagnetic former, as shown in Fig. 7. The primary winding is energized by a frequency of 50 Hz to 20 kHz ac. The two secondaries are made identical by having an equal number of turns. They are connected in series opposition so that the induced output voltages oppose each other.

The ferromagnetic core or plunger moves freely inside the former, thus altering the mutual inductance between the primary and secondaries. With the core in the center, or at the reference position, the induced electromagnetic fields (emfs) in the secondaries are equal; because they oppose each other, the output voltage is zero. When the core moves, say to the left, from the center, more magnetic flux links with the left-hand coil than the right-hand coil. The voltage induced in the left-hand coil is, therefore, larger than the induced emf on the right-hand coil. The magnitude of the output voltage is then larger than at the null position and is equal to the difference between the two secondary voltages. The net output voltage is in phase with the voltage of the left-hand coil. The output of the device is then an indication of displacement of the core. Similarly, movement in the opposite direction to the right from the center reverses this effect, and the output voltage is now in phase with the emf of the right-hand coil.

In many applications, the outputs are connected in opposing form, as shown in Fig. 8(a). The output voltages of the individual secondaries v_1 and v_2 at the null position are illustrated in Fig. 8(b). However, in opposing connection, any displacement in the core position x from the null point causes the amplitude of the voltage output v_o and the phase difference α to change. The output waveform v_o in relation to the core position is shown in Fig. 8(c). When the core is positioned in the middle, there is an equal coupling between the primary and the secondaries, thus giving a null point or reference point

Figure 8. The voltages induced in the secondaries of a linear variable-differential transformer (a) may be processed in a number of ways. The output voltages of individual secondaries v_1 and v_2 at the null position are illustrated in (b). In this case, the voltages of individual coils are equal and in phase with each other. Sometimes the outputs are connected opposing each other, and the output waveform v_o becomes a function of core position x and phase angle α as in (c). Note the phase shift of 180° as the core position changes above and below the null position.

of the sensor. As long as the core remains near the center of the coil arrangement, the output is very linear. The linear ranges of commercial differential transformers are clearly specified, and the devices are seldom used outside this linear range.

For mathematical analysis of the operation of LVDTs, Fig. 8(a) may be used. The voltages induced in the secondary coils are dependent on the mutual inductance between the primary and individual secondary coils. Assuming that there is no cross coupling between the secondaries, the induced voltages may be written as

$$v_1 = M_1 s i_p \quad \text{and} \quad v_2 = M_2 s i_p \quad (15)$$

where M_1 and M_2 are the mutual inductances between the primary and secondary coils for a fixed core position, s is the Laplace operator, and i_p is the primary current.

In the case of opposing connection, no load output voltage v_o without any secondary current may be written as

$$v_o = v_1 - v_2 = (M_1 - M_2) s i_p \quad (16)$$

writing

$$v_s = i_p (R + s L_p) \quad (17)$$

Substituting i_p in Eq. (16) gives the transfer function of the transducer as

$$\frac{v_o}{v_s} = \frac{(M_1 - M_2) s}{R + s L_p} \quad (18)$$

However, if there is a current resulting from output signal processing, then the equations may be modified as

$$v_o = R_m i_s \quad (19)$$

where

$$i_s = \frac{(M_1 - M_2) s i_p}{R_s + R_m + s L_s}$$

and

$$v_s = i_p (R + s L_p) - (M_1 - M_2) s i_s \quad (20)$$

Eliminating i_p and i_s from Eqs. (19) and (20) results in a transfer function

$$\frac{v_o}{v_s} = \frac{R_m(M_1 - M_2)s}{[(M_1 - M_2)^2 + L_s L_p]s^2 + [L_p(R + R_m) + R L_s]s + (R_s + R_m) + R} \quad (21)$$

This is a second-order system, which indicates that with the effect of the numerator, the phase of the system changes from $+90^\circ$ at low frequencies to -90° at high frequencies. In practical applications, the supply frequency is selected such that at the null position of the core the phase angle of the system is 0° .

The amplitudes of the output voltages of the secondary coils are dependent on the position of the core. These outputs may directly be processed from each individual secondary coil for slow movements of the core, if the direction of the movement of the core does not bear any importance. However, for fast movements of the core, the signals may be converted to dc, and the direction of the movement from the null position may be detected. There are many options to do this; however, a *phase-sensitive demodulator* and filter are the most popular methods.

Phase-sensitive demodulators are extensively used in differential-type inductive sensors. They basically convert the ac outputs to dc values and also indicate the direction of movement of the core from the null position. A typical phase-sensitive demodulation circuit may be constructed, based on the diodes as shown in Fig. 9(a). This arrangement is useful for very slow displacements, usually less than 1 or 2 Hz. In Fig. 9(a), bridge 1 acts as a rectification circuit for secondary 1, and bridge 2 acts as a rectifier for secondary 2. The net output voltage is the difference between the outputs of two bridges as in Fig. 9(b). The position of the core is given by the amplitude of the dc output, and the direction of the movement of the core can be determined from the polarity of the dc voltage. For rapid movements of the core, the output of the diode bridges is filtered. This output then passes only the frequencies of the movement of the core but filters all the other frequencies produced by the modulation process. For this purpose, a suitably designed simple *RC* filter may be sufficient.

There are phase-sensitive demodulator chips available, such as AD598 offered by Analog Devices, Inc., in the marketplace. These chips are highly versatile and flexible in order to satisfy particular application requirements. These chips offer many advantages over conventional phase-sensitive demodulation devices. For example, frequency of excitation may be adjusted to any value between 20 Hz and 20 kHz by connecting an external capacitor between two pins. The amplitude of the excitation voltage can be set up to 24 V. The internal filters may be set to the required values by external capacitors. Connections to analog-to-digital converters are made easy by converting the bipolar output to a unipolar scale.

The frequency response of LVDTs is primarily limited by the mechanical inertia characteristics of the device. In general, the frequency of the applied voltage should be at least ten times the desired frequency to be measured. Commercial LVDTs are available in a broad range of sizes, and they are extensively used for displacement measurements in a variety of applications. The displacement sensors are available to cover ranges from ± 0.25 mm to ± 7.5 cm. They are sensitive enough to

respond to displacements well below $0.5 \mu\text{m}$. They can have an operational temperature range from -265° to 600°C , also are available in radiation-resistant designs for operation in nuclear reactors. For a typical sensor in the range of ± 25 mm, the recommended supply voltage is 4 V to 6 V, with a nominal frequency of 5 kHz and a maximum nonlinearity of 1% full scale. Several commercial models that can produce a voltage output of 300 mV for a 1 mm displacement of the core are available.

One important advantage of the LVDT is that there is no physical contact between the core and the coil form; hence, there is no friction or wear. Nevertheless, there are radial and longitudinal magnetic forces on the core at all times. These magnetic forces may be regarded as magnetic springs that try to displace the core from its null position. This may be a critical factor in some applications.

One problem with LVDTs is that it may not be easy to make the two halves of the secondary identical; their inductance, resistance, and capacitance may be different, causing a large unwanted quadrature output in the balance position. Precision coil-winding equipment may be required to reduce this problem to an acceptable level.

Another problem is associated with null-position adjustments. The harmonics in the supply voltage and stray capacitances result in small null voltages. The null voltage may be reduced by center-tapped voltage source arrangements and proper grounding, which reduces the capacitive effects. In center-tapped supplies, a potentiometer may be used to obtain a minimum null reading.

The LVDTs find a variety of applications including controlling jet engines and measuring roll positions in the thickness of materials in hot-slab steel mills. Force and pressure measurements may also be made from LVDTs after some mechanical modifications.

Eddy Current Displacement Sensors

Inductive transducers based on eddy currents are mainly probe types, containing two coils. One of the coils, known as the active coil, is influenced by the presence of the conducting target. The second coil, known as the balance coil, completes the bridge circuit and provides temperature compensation. The magnetic flux from the active coil passes into the conductive target by means of the probe. When the probe is brought close the target, the flux from the probe links with the target, producing eddy currents within the target.

The eddy current density is greatest at the target surface and becomes negligibly small about three skin depths below the surface. The skin depth depends on the type of material used and the excitation frequency. Even though thinner targets can be used, a minimum of three skin depths may often be necessary to minimize temperature effects. As the target comes closer to the probe, the eddy currents become stronger, causing the impedance of the active coil to change, altering the balance of the bridge in relation to target position. This unbalance voltage of the bridge may be demodulated, filtered, and linearized to produce a dc output proportional to the target displacement. The bridge oscillation frequency may be as high as 1 MHz. High frequencies allow the use of thin targets and provide a good system frequency response.

Probes are commercially available with full-scale ranges from 0.25 mm to 30 mm with a nonlinearity of 0.5% and a maximum resolution of $0.1 \mu\text{m}$. Targets are usually supplied by the

Figure 9. A typical phase-sensitive demodulation circuit based on diode bridges as in (a). Bridge 1 acts as a rectification circuit for secondary 1, bridge 2 acts as a rectifier for secondary 2, and the net output voltage is the difference between the two bridges as in (b). The position of the core can be found from the amplitude of the dc output, and the direction of the movement of the core can be determined from the polarity of the voltage. For rapid movements of the core, the outputs of the diode bridges need to be filtered. For filters, a suitably designed simple RC filter may be sufficient.

user, and often for noncontact measurements of machine parts. For nonconductive targets, conductive materials of sufficient thickness must be attached to the surface by means of commercially available adhesives. Because the target material, shape, and the like influence the output, it is necessary to calibrate the system statistically for a specific target. The recommended measuring range of a given probe begins at a standoff distance equal to about 20% of the stated range of the probe. In some cases, a standoff distance of 10% is recommended and so is calibrated as the standard for the system. A distance greater than 10% of measuring range can be used as long as the calibrated measuring range is reduced by the same amount.

Flat targets must be the same diameter as the probe or larger. If the target diameter is smaller than the probe diameter, the output drops considerably, thus becoming unreliable. Curved-surface targets may behave similarly to flat surfaces if the diameter exceeds about three or four probe diameters. In this case, the target essentially becomes an infinite plane. This also allows some cross-axis movement, which is the movement parallel to the axis of rotation, without affecting the system output. Target diameter comparable in size to the sensor can result in detrimental effects from cross-axis movements.

For curved or irregularly shaped targets, the system needs to be calibrated using the exact target that may be seen in the operation. This tends to eliminate the errors caused by the curved surfaces. However, special multiprobe systems are available for orbital motions of rotating shafts. If the curved (shaft) target is about ten times greater than the sensor diameter, it acts as an infinite plane; hence, it does not need special calibration. Special care must be exercised to deal with electrical runout caused by such factors as inhomogeneities in hardness, and are particularly valid for ferrous materials.

ANGULAR DISPLACEMENT SENSORS

Angular displacement sensors generally involve rotational capacitive or magnetic devices. The most commonly used devices involve tachogenerators, microsyns, synchros, and induction potentiometers.

Tachogenerators

An example of an angular displacement sensor is the variable-reluctance tachogenerator shown in Fig. 10. These sensors are based on Faraday's Law of Electromagnetic Induction.

Figure 10. A variable-reluctance tachogenerator is a sensor based on Faraday's Law of Electromagnetic Induction. It consists of a ferromagnetic toothed wheel attached to the rotating shaft and a coil wound onto a permanent magnet extended by a soft iron pole piece. The wheel rotates in close proximity to the pole piece, thus causing the flux linked by the coil to change. The change in flux causes an output in the coil similar to a square waveform whose frequency depends on the speed of the rotation of the wheel and the number of teeth.

Basically, the induced emf in the sensor depends on the linear or angular velocity of the motion.

The variable-reluctance tachogenerator consists of a ferromagnetic toothed wheel attached to the rotating shaft and a coil wound onto a permanent magnet, extended by a soft iron pole piece. The wheel moves in close proximity to the pole piece, causing the flux linked by the coil to change, thus inducing an emf in the coil. The reluctance of the circuit depends on the width of the air gap between the rotating wheel and the pole piece. When the tooth is close to the pole piece, the reluctance is minimal, and it increases as the tooth moves away from the pole. If the wheel rotates with a velocity ω , the flux may mathematically be expressed as

$$\Psi(\theta) = A + B \cos m\theta \quad (22)$$

where A is the mean flux, B is the amplitude of the flux variation, and m is the number of teeth.

The induced emf is given by

$$E = \frac{-d\Psi(\theta)}{dt} = -\frac{d\Psi(\theta)}{d\theta} \times \frac{d\theta}{dt} \quad (23)$$

or

$$E = bm\omega \sin n\omega t \quad (24)$$

Both amplitude and frequency of the generated voltage at the coil are proportional to the angular velocity of the wheel. In principle, the angular velocity ω can be found from either the amplitude or the frequency of the signal. In practice, the amplitude measured may be influenced by loading effects and electrical interference. In signal processing, the frequency is the preferred option because it can be converted into digital signals easily.

Microsyn

Another commonly used example of a variable-reluctance transducer is the microsyn illustrated in Fig. 11. In this arrangement, the coils are connected in such a manner that, at the null position of the rotary element, the voltages induced in coils 1 and 3 are balanced by voltages induced in coils 2 and 4.

Figure 11. A microsyn is a variable-reluctance transducer, which consists of a ferromagnetic rotor and a stator carrying four coils. The stator coils are connected such that at the null position, the voltages induced in coils A and C are balanced by voltages induced in coils B and D. The motion of the rotor in one direction increases the reluctance of two opposite coils while decreasing the reluctance in others resulting in a net output voltage e_o . The movement in the opposite direction reverses this effect with a 180° phase shift.

The motion of the rotor in the clockwise direction increases the reluctance of coils 1 and 3 while decreasing the reluctance of coils 2 and 4, thus giving a net output voltage e_o . The movement in the counterclockwise direction causes a similar effect in coils 2 and 4 with a 180° phase shift. A direction-sensitive output can be obtained by using phase-sensitive demodulators, as explained in the LVDT section of this article.

Microsyn transducers are extensively used in applications involving gyroscopes. By using microsins, very small motions can be detected, giving output sensitivity as low as 0.01° of changes in angles. The output of the device can be made as high as $5 \text{ V/}1^\circ$ of rotation. The nonlinearity may vary from 0.5% to 1.0% of full scale. The main advantage of these transducers is that the rotor does not have windings and sliprings. The magnetic reaction torque is also negligible.

Synchros

The term *synchro* is associated with a family of electromechanical devices, which could be discussed under different headings. They are primarily used in angle measurements and are commonly applied in control engineering as parts of servomechanisms, machine tools, antennas, and the like.

The construction of synchros is similar to that of wound-rotor induction motors. The rotation of the motor changes the mutual inductance between the rotor coil and the three stator coils. The three voltage signals from these coils define the angular position of the rotor. Synchros are used in connection with a variety of devices, including control transformers, Scott T transformers, resolvers, phase-sensitive demodulators, and analog-to-digital (AD) converters.

In some cases, a control transformer is attached to the outputs of the stator coils such that the output of the transformer produces a resultant magnetomotive force (mmf) aligned in the same direction as that of the rotor of the synchro. In other words, the synchro rotor acts as a search coil in detecting the direction of the stator field of the control transformer. When the axis of this coil is aligned with the field, the maximum voltage is supplied to the transformer.

In other cases, ac signals from the synchros are first applied to a Scott T transformer, which produces ac voltages with amplitudes proportional to the sine and cosine of the synchro shaft angle. It is also possible to use phase-sensitive demodulation to convert the output signals to make them suitable for digital signal processing.

Induction Potentiometers

A version of the rotary-type linear inductor is the induction potentiometer. Two concentrated windings are wound on stator and rotor. The rotor winding is excited with alternating current, thus inducing voltage in the stator windings. The amplitude of the output voltage is dependent on the mutual inductance between the two coils, where the mutual inductance itself is dependent on the angle of rotation. For concentrated coil-type induction potentiometers, the variation of the amplitude is sinusoidal, so linearity is restricted to the region of the null position. A linear variation over an angle of $\pm 180^\circ$ may be obtained by carefully designed distributed coils.

Standard commercial induction pots operate in the 50 Hz to 400 Hz frequency range. They are small in size, from 1 cm to 6 cm, and their sensitivity can be in the order of $1 \text{ V}/1^\circ$ of rotation. Although the range of induction pots is limited to less than 60° of rotation, it is possible to measure displacement in angles from 0° to full rotation by suitable arrangements of a number of induction pots. As in the case of most inductive sensors, the output of the induction pots may need phase-sensitive demodulators and suitable filters. In many inductive pots, additional dummy coils are used to improve linearity and accuracy.

Rotary Variable-Differential Transformers

A variation of the linear variable-differential transformer is the rotary core differential transformer shown in Fig. 12. Here the primary winding is wound on the center leg of an E core, and the secondary windings are wound on the outer legs of the E core. The armature is rotated by an externally applied force about a pivot point above the center leg of the core. When the

Figure 12. A rotary-core differential transformer has an E-shaped core, carrying the primary winding on the center leg and the two secondaries on the outer legs. The armature is rotated by an externally applied force about a pivot point above the center leg of the core. When the armature is displaced from its reference or balance position, the reluctance of the magnetic circuit through one secondary coil is decreased; simultaneously the reluctance through the other coil is increased. The induced emfs in the secondary windings are different in magnitude and phase as a result of the applied displacement.

armature is displaced from its reference or balance position, the reluctance of the magnetic circuit through one secondary coil is decreased; simultaneously the reluctance through the other coil is increased. The induced emfs in the secondary windings, which are equal in the reference position of the armature, are now different in magnitude and phase as a result of the displacement. The induced emfs in the secondary coils are made to oppose each other, and the transformer operates in the same manner as an LVDT. The rotating variable transformers may be sensitive to vibrations. If a dc output is required, a demodulator network may be used as in the case of LVDTs.

In most rotary linear-variable differential transformers, the rotor mass is very small, usually less than 5 g. The nonlinearity in the output ranges between $\pm 1\%$ and $\pm 3\%$, depending on the angle of rotation. The motion in the radial direction produces small output signals that can effect the overall sensitivity. But this transverse sensitivity is kept less than 1% of the longitudinal sensitivity.

LINEAR SENSORS

In this section, a number of displacement sensors, based on different principles such as resistance or piezoelectric principles, are discussed.

Resistive Displacement Sensors

In these displacement sensors, the sliding or rotational arm of a potentiometer is connected to the moving object while the main body of the potentiometer is kept in a fixed position, as illustrated in Fig. 13(a,b). Essentially, these are passive sensors requiring a stable external power source. By careful design of the potentiometers, a resolution of less than $20 \mu\text{m}$ may be obtained. They are also manufactured from conductive plastic materials, which covers a displacement span from few millimetres to 250 mm. Typical resistances are in the range of 500Ω to $100 \text{ k}\Omega$. In ideal operations, the relation between position and output voltage is linear. If the output devices draw excessive currents, the output and input relation becomes nonlinear as shown in Fig. 13(c).

A commonly used resistive displacement sensor is manufactured as a hybrid track potentiometer by depositing a conductive plastic coating on a precision wire-wound resistance track. This enables the best use of wire-wound and film technology. Although a linearity exist between the voltage and displacement, this linearity may be disturbed by the presence of load currents in the output. In many cases, the resistance of the load used with the potentiometer must be several times greater than the potentiometer resistance to avoid severe nonlinearity effects.

Strain Gage Sensors

Strain gage displacement sensors are based on resistance properties of electrical conductors. If a conductor is stretched or compressed, its resistance alters because of dimensional changes and changes in the fundamental property of material called *piezoresistance*. This indicates that the resistivity ρ of the conductor depends on the mechanical strain applied onto it. The dependence is expressed as the gage factor

$$\frac{dR/R}{dL/L} = 1 + 2\nu + \frac{d\rho/\rho}{dL/L} \quad (25)$$

Figure 13. Resistive displacement sensors. The object under investigation is connected to the sliding arm of the potentiometer. They can measure linear motion or rotary motion as shown in (a) and (b), respectively. A loading effect occurs if the output devices have low impedance (c).

where l indicates the resistance change due to length, 2ν indicates resistance change due to area, and $(d\rho/\rho)/(dL/L)$ indicates the resistance change due to piezoresistivity.

In displacement measurements, the resistance strain gages can be selected from different types, such as unbonded metal-wire gages, bonded metal-wire gages, bonded metal-foil gages, vacuum deposited thin-metal-film gages, bonded semiconductor gages, and diffused semiconductor gages. But, generally, bonded and unbonded metal-wire gages find wider applications. Occasionally bonded semiconductor gages, known as piezoresistive transducers, are used, but they suffer from high-temperature sensitivities, nonlinearity, and some mounting difficulties.

Unbonded strain-gage displacement sensors use the strain wires as spring elements and as the motion transducer, using arrangements similar to those in Fig. 14. They are useful for general-purpose motion and vibration measurements from low- to medium-frequency displacements. They are often manufactured in the form of piezoelectric ceramic cartridges giving inexpensive but highly reliable displacement measurements.

Piezoresistive Displacement Sensors

Piezoresistive displacement sensors are essentially semiconductor strain gages with large gage factors. High gage factors are obtained because the material resistivity depends primarily on the stress, not on dimensions only. Most piezoresistive sensors use two or four active gages arranged in a Wheatstone bridge. Extra precision resistors are used (as part of the circuit) in series with the input to control the sensitivity, balancing and offsetting temperature effects. The mechanical construction of a piezoresistive displacement sensors is similar to the installation in Fig. 14.

Figure 14. Bonding of piezoelectric and piezoresistive elements onto an inertial system. As the inertial member is displaced, deformation of the tension and compression gages causes the resistance to change. The change in resistance is picked up and processed further.

In some applications, overload stops are necessary to protect the gauges from high-amplitude inputs. These instrument is also useful for acquiring vibration information at low frequencies (e.g., below 1 Hz).

OPTICAL AND LASER DISPLACEMENT SENSORS

Optical methods are commonly used in displacement sensing particularly where high precision and small displacements are involved. There are many different techniques available, some of which are optical fibers, laser methods, encoders, and interferometric types. Here, some common methods will be described.

Optical Fibers

Optical fibers are suitable to measure linear and angular displacements in a noncontacting manner. Figure 15(a,b) illustrates two typical arrangements in which the intensity of the radiation incident on the detector is dependent on the relative displacement of the optical fibers. In Fig. 15(a) one of the fibers is fixed and the other is allowed to move with respect to displacement. The maximum intensity is detected when the fibers are at closest proximity and axially aligned. As the distance x between fibers increases, the light entering the second fiber decreases. Hence, the output of the detector can be related to displacement. In this arrangement, the displacement must be strictly in one direction, in a straight line of x or in y directions only. Some of the problems of using a two-fiber arrangement can be eliminated by using multiple fibers as exemplified in Fig. 16(a). In this case, the emitting fiber is fixed, and the distance between the emitting fiber and the receiving fibers is kept constant. As the fibers move in the y and x directions, the intensity of light received by each fiber varies. These variations are related to the displacement of the object. A slight modification of this arrangement can lead to reflection-type arrangements in which case the emitting and receiving fibers are bunched together, as shown in Fig. 16(b). As the reflecting surface is displaced, the detected intensity of light is varied.

Figure 15. Examples of optical fiber displacement sensor. The intensity of the radiation incident on the detector is dependent on the relative displacement of the optical fibers. The maximum intensity of light is detected when the fibers are at closest proximity and axially aligned. Arrangement in (a) detects displacement in the x direction and that in (b) detects in the y direction.

Another common optical fiber application uses microbending principles, as illustrated in Fig. 17. As the displacement between the fixed and the displaced plates varies, the changes in the fiber dimensions between the two plates alters such fiber

Figure 16. Multiple fiber displacement sensors. In some types, emitting fibers are fixed, and the distance between the emitting fiber and the receiving fibers is kept constant allowing vertical movements of the detectors. As the fibers move in the y and z directions, the intensity of light received by each fiber varies. In other types, the emitting and receiving fibers are bunched together, and the reflections from the moving surface are detected.

Figure 17. Microbend optical fiber displacement sensor. The displacement between the fixed plate and the displaced plate varies the fiber characteristics between the two plates, altering the attenuation and absorption. These changes are detected suitably as a measure of the displacement.

characteristics as attenuation and absorption. These changes are detected suitably as a measure of the displacement.

In all fiber optic displacement sensors, the variations in intensity and amplitudes are detected. For accurate operations, the source intensity must be stable.

Interferometric Sensors

There are many different types of interferometric sensors including optical fiber, laser, holographic, and monochromatic light types. In these sensors, Michelson, Sagnac, or Fizeau effects of interference of two or more light beams is used by suitable optical arrangements. The most commonly used optical arrangements are beam splitters, polarizing prisms, and diffraction gratings.

As two light beams interfere, interactions of light cause a series of bright and dark lines. If, for example, two interfering lights with wavelengths $1.5 \mu\text{m}$ are interfered. By suitable arrangements as in Fig. 18, the spacing of bright and dark lines will be $0.75 \mu\text{m}$. In many cases, the dark and bright points are counted in relation to the displacement of an object located within the interference. The laser interferometric sensors operate on precise wavelength monochromatic light and are the most accurate in these family of sensors. An accuracy better than 1 nm can be obtained. Many different designs based on different displacement mechanisms are available. Some of these include fringe counting interferometers, frequency modulation interferometers, heterodyne interferometers, phase-locked

Figure 18. Interferometric displacement sensor. Interference of two light beams causes a series of bright and dark lines. In many cases, the dark and bright points are sensed by photodetectors in relation to the displacement of an object located within the interference area.

Figure 19. Encoder displacement sensors. These are digital sensors used for both angular and linear measurements. As the wheel rotates, light from the source is transmitted and stopped, giving a digital signal in the photodetectors. The output of the detector is counted and processed to measure the angular displacement of the wheel.

interferometers, laser Doppler and laser feedback interferometers, and fiber interferometers.

Encoders and Digital Displacement Sensors

Digital optical displacement sensors are used for both angular and linear measurements. An example of these sensors is shown in Fig. 19. As the wheel rotates, light from the source is transmitted and blocked, producing digital signal in the photodetectors. The output of the detector is counted and processed to give the angular displacement of the wheel. In another version, it is possible to use regularly positioned reflectors on the surface of the wheel rather than punching holes. In this case, light from the source is alternatively reflected or absorbed. Reflective-type encoders can be arranged to give natural binary-coded or Gray-coded digital signals. Some of these encoders are manufactured to give resolution better than $1\ \mu\text{m}$. In many cases, semiconductor laser light sources, which can give over 1 million samples per revolution, are used.

VELOCIMETERS

Velocimeters are instruments used to measure the speed of a moving object or medium. Velocity is a vector quantity; that is, it has both magnitude (commonly referred to as speed) and direction. Many devices classified as velocimeters only measure

the magnitude of the motion or its speed; the direction of the motion is known a priori or must be assumed. Speed is an important quantity in many situations. We may want to know the speed of an automobile, the rate of expansion of the universe, or the flow profile in a blood vessel in the heart. Because velocity and volume flow rates are directly related, some of the techniques described in this article might also be classified as flow meters. One specific category of flow meters is anemometers—devices for measuring the speed of gases, usually air.

A transducer is a device used to convert a physical measurand or variable, such as speed, into a signal in an alternate energy form. For our purposes, this is usually an electrical signal, but it could be a mechanical deflection in a direct reading gauge, for example. The electrical parameter that varies with the measurand can be voltage, current, frequency, or phase. The electrical signal may be directly generated, as in electromagnetic induction, or it may arise from modulation, as in the change of resistance in hot-wire anemometry.

For a linear or translational frame of reference, the following definitions and relationships exist. Displacement, x , is the change in position. Velocity, v , is the rate of change of position. Acceleration, a , is the rate of change of velocity. These can be expressed mathematically by the following differential equations:

$$v(t) = \frac{d}{dt} x(t) \quad \text{and}$$

$$a(t) = \frac{d}{dt} v(t)$$

A similar set of relations exists in an angular or rotational frame of reference.

$$\omega(t) = \frac{d}{dt} \theta(t) \quad \text{and}$$

$$\alpha(t) = \frac{d}{dt} \omega(t)$$

where θ is the angular displacement, ω is the angular velocity, and α is the angular acceleration. From this, we can see that if we can measure displacement or acceleration then we can calculate velocity. However, the signal processing may introduce additional sources of error. In particular, differentiation will tend to enhance any high-frequency noise present in the displacement signal. On the other hand, an offset error or low-frequency drift in the zero level of the acceleration signal will cause errors in the integration process. The use of digital computers has greatly facilitated signal processing and has reduced the sources of errors that can corrupt the velocity signal. However, both high-frequency noise and offset or drift can occur in the analog electronics required for most transducers prior to the signal being digitized.

PHYSICAL PRINCIPLES OF DIRECT VELOCITY MEASUREMENT

As mentioned previously, several physical phenomena can be made to depend directly on the speed of a moving object or fluid. These include electromagnetic induction, the Hall effect, and several variations of the Doppler effect.

Electromagnetic Induction

Electromagnetic induction and the Hall effect (see the next subsection) have the same physical basis—namely, that an electric charge moving through a magnetic field undergoes a lateral force known as the Lorentz force. Michael Faraday first described the phenomenon of electromagnetic induction that has become familiar to electrical engineers through the mathematical relationship referred to as Faraday's law of induction. That is, a voltage will be induced across the windings of a coil that is proportional to the rate of change of flux linkages, λ , in the coil. The polarity of the voltage will be such that if a current can flow it will tend to oppose the change in flux; hence, the minus sign in Eq. (1):

$$e = -\frac{d}{dt}(\lambda) \quad (1)$$

and

$$\lambda = n\phi$$

where n is the number of turns linked with the flux and ϕ is the magnetic flux. If the number of turns linked with the flux is fixed, then a more familiar form of Faraday's law results:

$$e = N \frac{d}{dt} \phi(t) \quad (2)$$

The flux, ϕ , can be represented more usefully as

$$\phi = BA$$

where B is the flux density and A is the cross-sectional area of the coil exposed to the magnetic field. Velocity transducers based on electromagnetic induction have a coil that moves with respect to a magnetic field such that the rate of change of flux linkages is proportional to the velocity. Two possibilities, a moving coil or a moving core, are shown in Fig. 1.

Figure 1. Electromagnetic induction of an electrical potential difference by changing the number of turns linked with the flux. (a) Moving coil and a stationary magnet, (b) two coils connected in series opposition with a moving magnet in the lumen of the coil.

Figure 2. Electromagnetic induction of an electrical potential difference by changing the area of a coil exposed to a magnetic field; l is the width of the coil, and x is the length of the coil in the magnetic field.

If a single rectangular loop under motion is only partially within the magnetic field (Fig. 2), then Eq. (2) can be restated as

$$e = \frac{d}{dt} BA(t)$$

since $N = 1$.

The area exposed to the magnetic field is the lx , where l is fixed and x changes due to being linked to the system being measured. Then

$$\begin{aligned} e &= \frac{d}{dt} Blx(t) \\ \Rightarrow e &= Bl \frac{dx(t)}{dt} \\ \Rightarrow e &= Blv \end{aligned}$$

where the velocity, v , is the time derivative of position, x . Strictly speaking, the voltage induced is due to the vector product of the magnetic field and the velocity of the conductor:

$$e = \mathbf{v} \times \mathbf{Bl}$$

The operator $\times$ indicates the vector or cross product.

Hall Effect

Hall effect transducers are based on the same separation of charge due to the Lorentz force, as in electromagnetic induction. However, in Hall effect transducers, a current is made to flow through a stationary conductor that is exposed to a dc magnetic field (see Fig. 3):

$$\mathbf{F} = q_0 \mathbf{v} \times \mathbf{B}$$

where $\mathbf{F}$ is the force vector, q_0 is the charge, $\mathbf{v}$ is the velocity vector of the charge, and $\mathbf{B}$ is the magnetic flux density vector. The magnitude of the force is therefore

$$|\mathbf{F}| = F = q_0 v B \sin \theta$$

where θ is the angle between the velocity and the magnetic field. Since the electric charges are free to move laterally, the

Figure 3. Hall effect principle: An external voltage source is connected across the top and bottom terminals, which causes an electric current to flow. In the presence of a magnetic field (B), the moving charges are displaced laterally due to the Lorentz force. This sets up an induced electrical potential difference (the transverse Hall potential) orthogonal to the current direction and the direction of the magnetic field.

Lorentz force will act to deflect the charges. Then an electrical potential difference will develop perpendicular to the flow path. This potential is referred to as the transverse Hall potential, V_H .

$$V_H \propto iB \sin \theta$$

This principle can also be used in flow meters for ionized solutions in which the flow of ions becomes the current. In this case, the ion concentration and temperature of the solution will also affect the Hall potential as well as the velocity of the fluid.

Doppler Effect

The Doppler effect is most commonly observed when a sound source is in motion relative to a receiver. Thus, the engine of a racecar is perceived to have a higher pitch as it approaches a spectator than after it passes the spectator. This can be extended to any source of propagating waves—ultrasound, microwave, and light:

$$f_0 + f_d = f_0 \frac{c}{c + v_s \cos \theta}$$

where f_0 is the frequency of the transmitter, f_d is the frequency shift, v_s is the velocity of the source with respect to the receiver (positive away from the receiver), θ is the angle between the trajectory of the source and the path of propagation between the source and the receiver, and c is the speed of the propagating wave. This formulation assumes a frame of reference relative to the receiver. This is the basis for the “red shift” observed in the photoemissions from stars, which has allowed astronomers to estimate the rate of expansion of the visible universe. In many applications involving Doppler frequency shift, the transmitter and receiver are both stationary, but an intermediary object, referred to as the target, is moving with respect to both. Then two shifts occur: the target with respect to the source and the receiver with respect to the target. If the transmitter and receiver are located in close proximity to each other, then the Doppler

shift becomes

$$f_0 + f_d = f_0 \frac{(c + v \cos \theta)}{(c - v \cos \theta)}$$

If $v \ll c$, then this becomes

$$f_d \cong \frac{2 f_0 v \cos \theta}{c}$$

Sonic and microwave Doppler velocimeters are usually based on this principle. The object to be measured must have a different impedance than the surrounding medium so that a reflection occurs. For microwave Doppler velocimeters (such as “radar guns”), this is not usually a problem. However, for Doppler flow meters, particles or bubbles must be suspended in the flowing medium in order for a reflected signal to occur. This formulation is applicable if the source is a continuous wave. Pulsed ultrasound flow meters are often referred to as Doppler flow meters. Strictly speaking, however, their principle of operation is time of flight for two successive pulses (1).

Transit Time

The motion of the medium through which the wave propagates can also be used to measure velocity. This does not require any reflective objects in the medium as is required in the Doppler flow method. The length of time taken for a signal to propagate from a transmitter to a receiver depends on the velocity of the medium through which the signal flows. For a more complete development, the reader is referred to Lynnworth (2):

$$T = \frac{D}{c + v_c \cos \theta}$$

where T is the transit time, D is the distance between the source and the receiver, c is the speed of wave propagation, v_c is the average velocity of the medium along the propagation path, and θ is the angle between the flow vector and the propagation path (see Fig. 4). Note that v_c is taken as positive when the transmitted wave is in the downstream direction. Note also that v_c is not the average velocity across the cross section of the flow. The propagation speed also depends on the density and adiabatic compressibility of the medium. These parameters

Figure 4. Schematic representation of the measurement of velocity by the transit time of a pulse of sound energy. The fluid is shown flowing in a pipe. The transmitter and receiver are on opposite sides of the pipe at an angle θ to the flow. The transmitter and receiver are separated by a distance L along the pipe and a distance D along the path of the propagated sound.

vary with temperature. Usually the transit time is measured in both the upstream and downstream directions, and the time difference is taken. The time difference varies directly with velocity (3).

$$\Delta T = \frac{2Dv_c \cos \theta}{c^2 - v_c^2 \cos^2 \theta}$$

For $c \gg v_c$,

$$\Delta T \cong \frac{2Dv_c \cos \theta}{c^2} \quad (3)$$

The distance, L , is the separation of the transmitter and receiver along the flow path (Fig. 4). This parameter may be easier to measure than the actual path length. Equation (3) becomes

$$\Delta T \cong \frac{2Lv_c}{c^2}$$

since

$$D = \frac{L}{\cos \theta}$$

For ultrasonic velocity measurement, the velocity of the fluid is typically less than 1% of the speed of sound. Therefore, the speed of sound must be known to within 0.01% for the velocity to be calculated to within 1%. The speed of sound is dependent on the bulk modulus and the temperature of the conducting medium. Therefore, where either of these variables is not carefully controlled, large errors in the calculated velocities will result from measuring the difference in transit times.

However, further calculation can be used to remove the speed of wave propagation. The sum of the upstream and downstream transit times is

$$\sum T \cong \frac{2D}{c}$$

Then dividing the time difference by the square of the sum of the transit times gives

$$\frac{\Delta T}{(\sum T)^2} \cong \frac{v_c \cos \theta}{2D}$$

Now the angle between the flow and wave propagation must be known. Subnanosecond time resolution is required for 1% accuracy for typical measurement situations (2).

An alternative approach is to have the pulse repetition rate inversely proportional to the transit time. Then the difference in frequency between the upstream and downstream pulse trains is

$$\Delta f = \frac{2v_c \cos \theta}{D}$$

or

$$\Delta f = \frac{2v_c}{L}$$

In this formulation, the propagation speed of the wave does not affect the pulse repetition frequency, and only the axial

separation of the transmitter and receivers needs to be known. However, for ultrasonic velocity measurement, Δf is expected to be small, which can result in considerable error in the calculated velocity.

The time shift can also be considered as a phase shift with respect to the source oscillator:

$$\begin{aligned} \Delta \phi &= 2\pi f_o \Delta T \\ \Rightarrow \Delta \phi &= \frac{4\pi f_o D v_c \cos \theta}{c^2} \end{aligned}$$

where $\Delta \phi$ is the phase shift, f_o is the oscillator frequency, and all other variables are as defined previously. Phase shifts can be measured optically through interference effects. With the proper choice of materials in the optical path, changes in ambient conditions have a negligible effect on the speed of light, and laser light sources provide a stable frequency (or wavelength). For acoustic velocimeters, variations in the speed of sound introduce errors in calculated velocities, as was the case for transit time. However, phase difference is easier to measure than small time differences. The disadvantage of phase measurement is the ambiguity that results from the periodicity of the phase shift. This restricts the flow range that can be measured. The maximum carrier frequency, f_o , is calculated by setting the preceding equation to π and solving for frequency given the maximum value of velocity to be measured, the separation distance and angle of the two transducers, and the minimum expected speed of sound over the operating temperature range. A standard crystal frequency below this value may then be selected.

Errors due to changes in the speed of sound with temperature can be eliminated by using two frequencies (4). The phase difference is then obtained between the two upstream signals, and a second phase difference is obtained between the two downstream signals:

$$\Delta \phi_1 = \frac{2\pi f_1 D}{c + v_c \cos \theta}$$

and

$$\Delta \phi_2 = \frac{2\pi f_2 D}{c + v_c \cos \theta}$$

where f_1 and f_2 are the two signal frequencies and all other variables are as previously defined. Then

$$\Delta \phi_u = \frac{2\pi(f_2 - f_1)D}{c - |v_c| \cos \theta} \quad (4)$$

and

$$\Delta \phi_d = \frac{2\pi(f_2 - f_1)D}{c + |v_c| \cos \theta} \quad (5)$$

where u and d indicate the upstream and downstream phase shifts, respectively. One of the frequencies, say f_1 , is still used to calculate the upstream-downstream phase shift.

$$\Delta \phi_1 = \frac{4\pi f_1 D v_c \cos \theta}{(c - |v_c| \cos \theta)(c + |v_c| \cos \theta)} \quad (6)$$

Equations (4) and (5) are rearranged and substituted into Eq. (6), and the resulting equation is rearranged to give

$$v_c \cos \theta = \frac{\pi(f_2 - f_1)^2 D \Delta \phi_1}{f_1 \Delta \phi_u \Delta \phi_d}$$

In this way, the calculation of flow velocity does not depend on the speed of wave propagation. As mentioned previously, stable oscillators are readily available, and phase differences can be measured relatively easily. A second calculation of the flow velocity can also be made using the second frequency upstream-downstream phase shift. Then the average of these two values can be taken, which provides some reduction in the error. The frequency, f_1 , is calculated as for the single-frequency method. The maximum difference between the two frequencies is found by taking the difference of the upstream and downstream phase shifts [Eqs. (4) and (5)] and setting the difference equal to π . In this case, the minimum expected speed of sound is used for the upstream phase shift, and the maximum expected speed of sound is used for the downstream phase shift. The second frequency, f_2 , is then chosen as a standard crystal frequency above that of f_1 but less than the calculated difference.

PHYSICAL PRINCIPLES OF INDIRECT MEASUREMENTS

As mentioned previously, velocity can be determined from successive measurements of position. Many displacement transducers are based on variable resistance, capacitance, inductance, or reluctance. Differentiation of an electrical signal that is modulated by the change of one of these parameters is a straightforward process. Only those displacement techniques developed specifically for use with velocimeters and anemometers will be discussed here. Time is a parameter that can be measured with good accuracy and resolution. Therefore, it is not surprising that measurement of time is the basis for two of these indirect approaches—namely, the time to travel a known distance and the time of flight of two successive pulses of a signal. A related technique is to measure the displacement before and after a known time interval. A third principle is that thermal convection is dependent on mass flow rate, from which velocity can be derived. This is the basis of hot-wire and hot-film anemometry.

Time-Based Techniques

One of the most obvious ways of measuring the average speed of an object is to measure the time it takes to travel a known distance. The transducer for detecting the presence of the object as it passes the start and end points is the major consideration in developing a velocimeter based on this technique. Usually, it is preferable to have a nonintrusive method for detecting the object. Photoelectric timers use a light source (visible or infrared) aligned with a photodetector across the path of the object. These transducers can be readily adapted to a number of applications, including industrial processes and sports activities. Contact switches are another rugged transducer that can be made in a number of form factors and for different environments, such as measuring the speed of automobiles. Because timers and counters can be made with high accuracy and resolution relative to the speed of most large objects, the largest sources of error in such systems are the transduction pro-

Figure 5. Surface texture correlation. The output of the second photoreceiver is ideally identical to that of the first photoreceiver, but delayed by an amount t_d that is proportional to the separation distance of the two photoreceivers and the speed of the material.

cess and measuring the separation distance of the two position detectors.

Surface texture correlation is a more sophisticated method of determining the time required to travel a known distance. In this technique, two light sources, usually laser beams, illuminate a portion of the surface of a moving object, such as steel or aluminum in a rolling mill or paper, wire, or cable as they are being metered onto rolls. The two beams are a fixed and known distance apart; they are aligned so that the same part of the material passes underneath both beams (Fig. 5). Two photoreceptors provide an analog signal of the light reflected from the two illuminated spots. Differences in surface texture or reflectance will cause variations in these signals. After the signals are digitized and buffered, crosscorrelation is performed on the two signal sequences to find the time lag required to create the largest match between the two signals. Theoretically, if the spots illuminated the same strip of material that passes under both, then the second signal will be a delayed version of the first. In practice, of course, the match is not identical due to differences in photoreceptor response and the presence of noise. High-speed, digital signal processing microprocessors have made this technique feasible for not only monitoring velocity but also, through digital integration, determining the total length of material. Accuracy of better than 0.1% is obtainable. This technique has the advantage of being a noncontact process in which the standoff distance may be more than 0.5 m. Unlike Doppler and transit time techniques, the method is not sensitive to the angle of the beams relative to the material motion, as long as the distance between the two beams on the material surface remains constant.

For time-of-flight measurements, a transmitter emits a pulsed wave that propagates at a known speed. The pulse is reflected off the object of interest (target), and the reflected pulse is received by a detector mounted immediately adjacent to the transmitter. (In the case of ultrasonic time of flight, the transducer can be both the transmitter and the receiver.) The time taken to travel from the transmitter to the detector is proportional to twice the distance from the transmitter to the target. Then successive time measurements allow the calculation of

the change in position, and the velocity can be calculated given the interval between pulses:

$$v \cos \theta = \frac{c \Delta t}{2PRI}$$

where v is the velocity, θ is the angle between the path of the target and the path of the propagating pulse, c is the speed of propagation of the pulse, Δt is the difference in the time of flight of two successive pulses, and PRI is the pulse repetition interval. This is the technique used in optical radar guns, or lidar.

In pulsed Doppler ultrasound, the reflected pulse can be demodulated by being mixed with a phase-shifted version of the original pulse (1). The phase shift of the original pulse controls the sample depth at which the velocity will be measured. After demodulation and filtering, the phase of the resulting low-frequency signal is proportional to the velocity of a single target:

$$\phi = \frac{4\pi K v \cos \theta}{c}$$

where ϕ is the phase and K is a multiple of PRI . Rather than using demodulation, direct sampling of the high-frequency return signal is also possible at a fixed time with respect to the time of pulse emission. If the pulse repetition rate is sufficiently high with respect to the velocity of the target and if a large number of pulse echoes are sampled, then the frequency of the sampled return signal will be proportional to the velocity of the target:

$$f_p = \frac{2f_0 v \cos \theta}{c}$$

where f_p is the frequency of the sampled return signal and f_0 is the frequency of the ultrasonic wave in the pulse. If the pulse is reflected off multiple objects, as is the case for red blood cells, then the signal processing becomes more complicated, and a frequency spectrum results.

Displacement-Based Techniques

A wide variety of displacement transducers have been manufactured based on changes in resistance, capacitance, reluctance, or inductance. Any of these could be used for velocimeters by differentiating the displacement signal with respect to time. Such transducers will not be discussed here. However, shaft encoders are used in an important category of velocimeters—namely, vane anemometers—as well as being used more generally for any shaft angular velocity measurement. A shaft encoder is one of the few transducers that directly outputs a signal in digital form. Shaft (or linear) encoders come in two types: incremental and absolute. Incremental encoders can be further subdivided into single channel and two channel. The latter have two tracks of encoding bits offset by 90° of the mechanical pitch. Two digital signals are thus generated in quadrature. This allows bidirectional information to be obtained, as well as quadrupling the angular resolution of the encoder. Shaft encoders make use of proximity detectors to determine incremental changes in shaft rotation. This can be done by optical transmission through a disc with alternating opaque and transparent windows, with ferromagnetic gears and a variable reluctance or magnetoresistive transducer that “counts” the gear teeth (5),

or with a conductive gear and an eddy-current device. A variation of this technique is to use a reflective target mounted on the shaft of a rotating machine. A photodetector then emits a pulse for each rotation, and the pulses are counted for a fixed duration of time.

Vane anemometers always rotate in the same direction and the absolute angular position is not required; therefore, single-channel incremental shaft encoders are well suited to this application. The angular velocity, ω , can be determined by counting the output pulses for a fixed interval of time. Then the sensitivity of the anemometer is determined by the number of pulses per revolution, N , and the counting interval, T . The range of the anemometer is determined by the size of the counter.

$$\omega = \frac{\text{count}}{NT}$$

Long stroke length (>1 m) linear displacement transducers are difficult to manufacture. Converting the linear displacement to angular displacement is often used for such measurements. This technique is used with cable extension-type displacement transducers. In these transducers, a light, stainless steel line is wound on a reel with a spring return. The shaft of the reel may be connected via a gear train to a potentiometer for an analog output or a two-channel incremental shaft encoder for a digital output (6). These devices are often the transducer of choice for measurements requiring long stroke length (up to 19 m) (7). Some models are available that have a dc tachometer built into the transducer, so that the output is directly proportional to velocity. Typical sensitivities are 30 to 130 mV·m⁻¹·min.

A change in displacement can also be measured from successive images of a moving object or fluid field. This is the basis for high-speed cinematography or video recording and for particle velocimeters. High-speed cinematography requires manual digitization of limb or body centroid positions and joint positions on a frame-by-frame basis. Prior to the development of video recordings, there were no effective means of doing this automatically. Video cameras with high frame rates can replace photographic film to capture the images. This lends itself to digitization of the image and subsequent automatic or human-assisted determination of the position of anatomical landmarks. The advantage of cinematography for biomechanical studies is that the positions of individual limbs as well as the whole body can be determined. Thus, forces acting around joints can be calculated from the velocities. However, it is very difficult to acquire images for motions in three dimensions; thus errors are introduced since the velocity vectors are assumed to always lie in the plane of the two-dimensional image. Some systems [e.g., SelSpot II (Selective Electronics, Partille, Sweden)] with markers placed on the body have been developed in an attempt to overcome this limitation.

Particle image velocimeters take successive images of particles in a fluid field. Then two-dimensional correlation is used to find the displacement of greatest match of particle position between the two images. Any motion out of the plane of the image can introduce substantial error in subsequent velocity calculations (8). Various techniques have been used to acquire the two images. The time interval between exposures is usually less than 100 μs in order to get reliable estimates of high-speed

irregular flow profiles. Mechanical shutters and mechanical film advancing are too slow for such short interexposure timing. Pulsed lasers are frequently used as a stroboscopic light source to create two images at short time intervals. The image may be a double exposure on a single sheet of film or charge coupled device (CCD) camera. In this case, autocorrelation is used to find the position of the second largest peak, which represents the location of the shifted particles. To determine a complicated flow profile over a large image area, the correlation must be done in subregions of the image. The peaks of interest represent the average shift in particle position within that region.

Autocorrelation results in two such peaks, as there is 180° directional ambiguity in the correlation process. Crosscorrelation of two independent images does not have this ambiguity. However, this requires two independent images, which is a technically challenging proposition. Two exposures at different optical wavelengths can be used to create two separable images, or high-speed liquid crystal shutters can be used to create two images on different halves of a single photographic negative (9).

Acceleration-Based Techniques

In a manner analogous to displacement-based velocimeters, it is possible to create a velocity proportional signal by integrating the output of any accelerometer. In the field of vibration measurement on rotating machines, displacement, velocity, or acceleration may be the preferred parameter to measure. The lowest vibration frequency of interest is usually determined by the angular velocity of the rotating machine. For machines rotating at less than 500 rpm, displacement is usually the preferred measurement because of the frequency response of seismic vibration velocimeters (see the section title in "Linear Electromagnetic Induction Velocimeters") is limited to >5 Hz. For vibration frequencies above approximately 1 kHz, acceleration is usually the preferred measurand. In the midrange (5 Hz to 1 kHz), velocity used to be the preferred measurand using seismic velocimeters. With the development of piezoelectric accelerometers, the practical lower limit for acceleration measurement is now as low as for electromagnetic seismic velocimeters. However, because of the historical use of seismic velocimeters in the midfrequency range, some manufacturers [e.g., (10) and (11)] build velocity sensors based on piezoelectric accelerometers that have an integrator built into the transducer package.

Thermal Convection

Hot-wire anemometry is based on convective heat transfer from a (usually) cylindrical heated wire to a flowing medium. That is, the rate of heat transfer will depend on the fluid's mass flow rate, which is, of course, dependent on the velocity of the fluid. The probes can also be made by depositing a thin film of resistive material on a substrate. This allows shapes other than cylinders to be readily manufactured. These are referred to as hot-film probes. Hot-wire probes can be operated in either a constant temperature mode or a constant current mode. The latter is usually used for measuring temperature rather than mass flow rate. The reader is referred to H. H. Bruun (10) for a full development of the behavior of hot-wire probes.

For a finite length of hot wire,

$$d\dot{Q}_e = d\dot{Q}_{fc} + d\dot{Q}_c + d\dot{Q}_r + d\dot{Q}_s$$

where $\dot{Q}_e$ is the electrical heat generation rate, $\dot{Q}_{fc}$ is the forced convective heat transfer rate, $\dot{Q}_c$ is the convective heat transfer rate from the heated wire to the prongs supporting it, $\dot{Q}_r$ is the radiation heat transfer rate, and $\dot{Q}_s$ is the heat storage rate. This assumes that the forced convection rate is much greater than the natural convection rate. For hot-film probes, which have a thin layer of conductive material on a substrate, an additional term must be added for the heat loss to the substrate as this greatly affects its frequency response. The convective loss to the supporting prongs can represent a substantial proportion (~15%) of the total heat loss. For a finite length wire, the preceding relationship can be expressed in terms of the fluid velocity as

$$\frac{I^2 R_w}{R_w - R_a} = A + BU^n$$

where I is the current through the wire, R_w is the resistance of the wire at its operating temperature T_w , R_a is the resistance of the wire at the temperature of the fluid T_a , U is the velocity of the fluid, and A , B , and n are constants. A and B depend on the temperature coefficient of the wire; the density, the viscosity, and the specific heat of the fluid; and the diameter and the length of the wire. A , B , and n must be determined through calibration of a specific probe design. The voltage across the hot-wire element is

$$\frac{E_w^2}{R_w} = (A + BU^n)\alpha_0 R_0 (T_w - T_d) \quad (7)$$

where α_0 is the average temperature coefficient of the wire and R_0 is its resistance at 0°C.

In the constant temperature mode, the probe is connected in a feedback circuit to maintain a constant temperature difference ($T_w - T_a$) as shown in Fig. 6. The voltage across the probe, E , is then used as a measure of the fluid velocity. From Eq. (7), it can be seen that the voltage across the wire, and hence across the probe, depends on both the velocity of the fluid and the

Figure 6. Constant temperature circuit for a hot-wire anemometer. R_3 may be a sensing element for ambient temperature rather than for balancing the bridge. The differential amplifier has gain G .

temperature difference. However, the sensitivity to changes in velocity is greater than the sensitivity to small changes in the ambient temperature (12). Furthermore, the sensitivity to velocity increases with temperature difference and the sensitivity to ambient temperature decreases. Therefore, constant temperature, hot-wire anemometers (HWA) are operated at the largest temperature difference that the wire can sustain. The exponential nature of the voltage-velocity relationship, while being highly nonlinear, means that the relative sensitivity stays approximately constant over a wide measurement range. Hence, HWA systems can be designed to operate at low air velocities as well as supersonic air velocities. The sensitivity will change in the presence of dust, smoke, oil vapor, and other contaminants.

PRACTICAL CONSIDERATIONS

Within the limitations of the transducer, direct measurement of a variable is preferable to indirect measurement. However, the measurement situation may impose constraints that require such indirect measurements. For example, a low-frequency velocity signal may result in unacceptable signal resolution for a direct velocity transducer, and a displacement transducer followed by differentiation may be preferred. However, high-frequency noise introduced on the displacement signal may result in high apparent velocities after differentiation. Care must be taken in filtering the displacement signal to reduce the noise bandwidth without removing signal information. Similarly, at high frequencies, accelerometers may be the transducers of choice followed by integration. Here offset errors can result in a drift in the calculated velocity. Digitization of the signal prior to integration will remove the drift associated with analog integrators. However, offset voltages can occur in the analog amplification of the signal and in the analog to digital conversion. The mechanical resonance of the transducer and the apparatus on which it is mounted must also be known in order to avoid errors whenever step or impulse forces are present or when measuring high-frequency velocities such as occur in vibration.

As in any measurement situation, loading effects must also be taken into consideration. Mechanical loading occurs when the transducer adds inertia to the system, through frictional losses, or when aerodynamic drag is increased. In flow measurement, the transduction process may introduce a pressure drop similar to a voltage drop when measuring electric current. This pressure drop must be kept sufficiently small such that the reduction in velocity is within an acceptable error limit for the measurement. Flow disturbances upstream of the transducer can cause measurement errors, but the transducer may also introduce flow disturbances that affect the process under measurement. This is particularly true when the velocity profile in a boundary layer is being investigated. Particles present in the fluid may cause abrasion of the transducer, or the transducer may cause accumulation of the particles, which then results in an excess pressure loss.

LINEAR ELECTROMAGNETIC INDUCTION VELOCIMETERS

Electromagnetic transducers (and sensors based on variable inductance and variable reluctance) tend to be mechanically robust and relatively immune to contamination from humidity, dirt, and grease. This type of transducer generates electrical energy from the motion of the system under measurement.

Therefore, mechanical loading effects and energy available must be taken into consideration when choosing a suitable transducer.

The coil and magnetic field can be arranged such that linear motion of the coil with respect to the field induces a voltage across the coil. One way of doing this is to have the coil in motion, as illustrated in Fig. 1(a). As long as the coil is not completely over the magnet, the number of flux linkages will change with position, and hence a voltage will be generated. Since the mass of the coil is usually less than the mass of the magnet, this arrangement has a higher mechanical resonant frequency than a moving core transducer. A moving core transducer is typically arranged as shown in Fig. 1(b), with two coils wound and connected in series opposing fashion. In this case, the coil is substantially longer than the magnet. As the flux linkages increase in one coil, they will decrease in the other, but with the series opposing connection, the sensitivity will be doubled.

Two sources of error affect the output of an electromagnetic velocimeter (13). The linear range (or stroke length) of the transducer is that distance where the core is fully within the two coils. As the core moves through the coils at a constant velocity, some variation in the output amplitude will occur. This is referred to as the linearity error. However, the transfer function of the transducer—that is, output voltage versus velocity input—will also have some nonlinearity—the characteristic linearity error. Decalibration can occur due to exposure to high temperature or mechanical shock as these affect the magnetization of the permanent magnet core. The stroke length may be 10 mm to 600 mm, and the sensitivity can be as high as $20 \text{ mV} \cdot \text{mm}^{-1} \cdot \text{s}$ (14).

A specialized version of this type of velocimeter is the seismic vibration transducer (15). In this device, the coils are attached directly to the case of the transducer, and the permanent magnet core is suspended within the coils by two springs. The core and springs form a second-order system with a high-pass frequency response. The components are chosen to provide a low resonant frequency ($<1 \text{ Hz}$) with a critically damped or slightly underdamped frequency response. Above resonance, the core will stay fixed in space with the case (and coils) moving with the vibrating structure to which it is attached. The magnitude of the induced voltage will be constant with respect to vibration frequency for frequencies above approximately three times the resonant frequency of the system. The voltage magnitude will be directly proportional to the velocity of the case. The electrical load impedance of any circuitry connected to the coil must be at least 10 times the coil resistance. A load impedance less than this will affect both the frequency response and the sensitivity of the transducer. The practical upper frequency limit for such devices is approximately 2 kHz (16).

ELECTROMAGNETIC FLOW METERS

As mentioned previously, electromagnetic flow meters are effectively Hall effect devices. In this case, the electric current is in the form of ions in a liquid. Both insertion-type and in-line type meters are commercially available; these are often referred to as magnetic flow meters in commercial literature. For an in-line device, the flow meter is a section of plastic or ceramic-lined pipe that is installed in the fluid path. Two electrodes of an inert metal (e.g., stainless steel or platinum) are

mounted diametrically opposite each other and flush to the inner surface of the plastic liner. Outside the plastic liner, coils are formed to create as uniform a magnetic field as possible mutually orthogonal to the flow direction and the electrodes. If the internal diameter of the flow meter is matched to the inlet and outlet pipe, then the pressure drop across the meter will only be that of a similar length of straight pipe. The coils may be excited with a dc current, a sinusoidal current, or a square-wave ac current. A dc magnetic field has the advantage of not inducing a voltage directly in the lead wires of the electrodes. However, polarization of the electrodes occurs due to creation of a space charge layer as positive ions tend to build up along one wall and negative ions along the other.

An alternating magnetic field can be used to reduce this polarization. A sinusoidal magnetic field is easy to generate, and a continuous reading of voltage and hence flow can be made by rectifying and filtering the resulting signal. However, it is difficult to minimize the voltage that will be directly induced in the lead wires by the electromagnet, since the lead wires and solution will form a single-loop coil. This induced voltage artifact is at 90° electrically to the flow-induced voltage. Thus, a phase-sensitive detector can be used to attenuate the interference signal. The alternating field has the advantage of eliminating the reduced signal amplitude due to polarization. An additional error is introduced if a resistive coating builds up on the electrode surface. This creates a phase shift in the flow-induced signal. The phase-sensitive detector may then reject the flow signal if the phase shift is too large.

Square-wave, ac excitation (sometimes referred to as dc pulsed excitation) can also be used to overcome the polarization error that arises in a steady dc magnetic field. In this case, a large transient voltage will be induced when the magnetic field changes polarity, but once the transient decays, a voltage proportional to the flow will remain. This signal can then be sampled and rectified to determine the flow velocity. Since phase-sensitive detection is not required, nonconductive coating of the electrodes does not introduce an error. Gating of the signal is required to avoid saturating the input amplifier with the transient voltage. The measured signal will be equivalent to that for a dc type, but the alternating polarity substantially reduces the polarization effect.

Electromagnetic flow meters measure the average velocity of the fluid. Therefore, they must be placed in the stream at a point where the flow profile is fully developed. A rule of thumb is that there should be 10 pipe diameters of straight pipe upstream of the flow meter and 5 pipe diameters of straight pipe downstream of the flow meter. The pipe must be full of the fluid being measured. The fluid conductivity must be greater than approximately 0.5 $\mu\text{S}/\text{mm}$. The dynamic range (or turn-down ratio) is typically 100:1 but may be as high as 3000:1 (17). Insertion-type flow meters are capable of accuracy of $\pm 2\%$, and in-line-type flow meters are capable of $\pm 1\%$.

TACHOMETERS

Tachometers are rotary or angular velocity transducers. Although angular velocity may be of interest itself, tachometers also find use in measuring linear velocity. Long stroke length (>0.25 m) velocity transducers are usually impractical or uneconomic, but a wheel or gear can usually be set up to convert the linear motion to rotary motion.

Generating tachometers are based on the same principles as electric power generators, and as such can be either ac or dc generators. A dc tachometer comprises a permanent magnet to establish a constant magnet flux through a rotor that has multiple coils each separately connected to a commutator. The advantage of a dc tachometer is that its output is rectified by the commutation of the rotor windings. The polarity of the output voltage depends on the direction of rotation. The output is linear with respect to angular velocity, although there will be some ripple (6% to 8%) (18) in the signal due to the commutation process. The ripple frequency is directly proportional to the angular velocity and the number of poles on the commutator. The brushes require some maintenance and eventual replacement over time. The sensitivity of dc tachometers is typically 2.5 to 10 V/1000 rev/min (19).

Generating ac tachometers, on the other hand, do not require commutators and brushes, as the permanent magnet is the rotor and the voltage is taken from the stator winding. This output is sinusoidal with a frequency proportional to the angular velocity of the rotor. The amplitude of the generated voltage is also proportional to the angular velocity; however, the direction of rotation cannot be determined from the output signal. By using the frequency of the output rather than the amplitude, errors due to temperature variation and loading effects can be minimized. Squaring of the output also lends itself to digital processing of the signal.

More commonly, ac tachometers are not of the generating type, but they are based on variable mutual induction between two stator windings. The rotor may be a squirrel cage, and the two windings are at 90° to each other. One winding is excited sinusoidally at frequency ω_s . Then the output will be of the form

$$e = k\omega_s\omega_r \sin \omega_s t$$

where ω_r is the angular speed of the rotor. Although the mains distribution frequency is often used for the excitation field, in electrically noisy environments an alternative frequency can be chosen so that a tuned filter can be used to eliminate mains interference. Ac tachometers typically have sensitivities similar to those of dc tachometers. Compensating thermistors with a negative temperature coefficient may be used to reduce temperature effects on winding resistance.

Digital tachometers use proximity detectors that give a pulse output as a sensed object passes the transducer. Tachometers with a pulse output may use any of the following: electromagnetic transduction, Hall effect, eddy current, variable reluctance, optical reflectance, or shaft encoder. An electromagnetic induction tachometer has a coil wound around a permanent magnet placed next to a toothed ferromagnetic rotor (i.e., a steel gear or fan) or key way in a rotor. The reluctance of the magnetic path will be different for a gear tooth passing close to the coil compared to when a gap in the gear is near the coil. This change in reluctance will create a change in magnetic flux and hence will generate a voltage pulse across the coil. A variable reluctance proximity detector is similar in physical layout; however, the coil is energized with a constant current. The voltage across the coil changes as the reluctance of the magnetic path changes. A Hall effect transducer can be placed between a stationary permanent magnet and the rotating gear teeth. Again, the change in reluctance will cause a voltage pulse to occur. However, in this case, the magnitude of the pulse will not be

affected by the angular velocity as occurs for the electromagnetic induction and variable reluctance types. Eddy current proximity transducers can also be used. In this case, a coil in close proximity to an electrically conducting rotor such as a gear or fan is excited at radio frequency (RF) frequencies. The resulting ac magnetic field will create eddy currents in the rotor teeth (or blades) when they pass close to the coil. The induced currents change the self-inductance of the coil and, therefore, will change the voltage across the coil. Reflective digital tachometers usually require a special reflective target be mounted on the rotating component. A light emitting diode (LED) or other light source is aimed at the target, and a photodetector emits a pulse each time the target rotates into its field of view. Angular velocities up to 1,000,000 rpm can be measured with this type of tachometer (20). Optical shaft encoders are also used in pulse-type tachometers. Here a LED/phototransistor pair is aligned with a rotating mask revolving between them. The mask has alternately opaque and transparent sections evenly spaced around its perimeter. Except for the shaft encoder, the digital tachometers do not require mechanical contact with the rotating component and have a minimal mechanical loading effect.

Two signal processing schemes can be used with pulse-type tachometers once the output has been squared. As a direct replacement for analog output tachometers, the output can be fed to a frequency to voltage converter (5). In this case, the pulses must be of constant duration independent of the rotational velocity. A completely digital technique can also be employed. The velocity is determined by counting the output pulses over a fixed duration of time. Very low angular velocities can be measured with better resolution by counting the number of "clock ticks" of a high-frequency clock that occur between successive pulses of the tachometer output.

VELOCITY MEASUREMENT USING ULTRASOUND

Flow Meters

Industrial ultrasonic flow meters may use either the Doppler shift technique or the time of flight. The former has the potential to provide information about the velocity profile across the flow pattern; the latter has the advantage of being usable in "clean" liquids and gases. Doppler shift techniques require reflective targets. Frequently, the targets are bubbles or particles that are either inherently present or are introduced into the fluid. It is also possible to use turbulent swirls within the fluid as the reflectors (21,22). Because of the need for reflective targets, Doppler techniques are not usable in gases.

Ultrasonic flow-meter transducers are mounted in one of three ways: clamped on the outside of the pipe, inserted through an opening in the side of the pipe, or installed in-line via a spool piece. Clamp-on transducers can be mounted on most existing pipe—steel, iron, hard PVC, or glass. Some transducers may also work with concrete lined pipes (23). The alignment of clamp-on transducers must take into account the diffraction of the wave at the two wall-fluid interfaces. The signal will also be substantially reduced in amplitude because of the reflections that occur at these interfaces due to the large acoustic impedance mismatch between the pipe wall and the fluid. For this reason, clamp-on transducers are most frequently used with liquids rather than gases. Clamp-on transducers may be

used where the fluid is corrosive, abrasive, or at high temperature, since the transducer does not come into direct contact with the fluid.

The measurement of flow velocity requires that a laminar flow profile be developed upstream of the flow transducer. This may require as much as 10 pipe diameters of pipe upstream of the transducer and 5 pipe diameters of pipe downstream of the transducer. [However, where vortices are the reflective targets, the flow meter must be located 1 to 3 pipe diameters below a 90° elbow (21).] Doppler ultrasound flow transducers require particles (or vortices) to be present. These may be present by the nature of the fluid, or they may be seeded into the flow. The size and concentration of the particles required will depend on the frequency of the ultrasonic signal. For example, particles must be at least 25 $\mu\text{L/L}$ and 30 μm for 1 MHz ultrasound. Lower frequencies require higher concentrations and larger particles. However, high concentrations of particles can result in reduced signal to noise ratio due to excessive scattering of the signal.

Water in rivers, lakes, and ocean has enough naturally occurring particles to allow Doppler velocity measurements. Several approaches have been developed to measure water currents. Small sample volumes can be used to measure boundary layer velocities, or multiple transmitter/receivers can be used to monitor the current at several depths simultaneously. A third technique is to use range gating of the returned signal from a single transducer to scan the depth of the channel being measured. In this case, a pulse of ultrasonic energy is emitted, and the return signal is monitored for only a short time. The time between pulse emission and gating of the return signal is varied to sample at different depths. The transmitted frequency may be as low as 300 kHz for depths of 100 m or more. Range gating has also been applied to medical ultrasound systems and for flow in pipes and tanks (24).

Flow meters and anemometers based on acoustic or ultrasonic transit time techniques are finding increased use industrially (25). One example is a wind speed system that uses three pairs of transmitter/receivers that are oriented 120° with respect to each other (26). This combination allows the velocity—that is, both magnitude and direction—to be calculated, assuming that the flow is in the plane of the transceiver pairs. Ultrasonic anemometers can measure down to zero velocity, whereas cup anemometers have a threshold speed of about 2 $\text{km}\cdot\text{h}^{-1}$. Where improved accuracy is needed, such as in custody transfer of natural gas, several transmitter/receiver pairs may be used across different chords of the pipe to improve the estimate of the average flow velocity. Four beam paths may be sufficient if the flow profile is not turbulent, or two crossed sets of four paths may be used where some turbulence occurs (27).

Medical Ultrasound Systems

Ultrasound is used extensively in medicine, not only for flow measurement but also flow visualization and imaging more generally. The reader is referred to Jensen (1) for a more complete mathematical development of the techniques described here. A shorter explanation is also available in an article by Routh (28). Medical ultrasound systems use transmitted frequencies in the range of 2 MHz to 10 MHz. Higher frequencies give better spatial resolution but have less penetration due to increased attenuation. In velocity measurement, the most common application is blood flow, but moving structures such as heart valves are also of clinical interest. Flow velocity varies

from $0.01 \text{ m}\cdot\text{s}^{-1}$ to $10 \text{ m}\cdot\text{s}^{-1}$. Amplifiers for the returned ultrasonic signal have a gain function that increases with time after pulse emission. This compensates for the attenuation that occurs as the signal passes through more tissue.

The ultrasound signal is emitted by a one-dimensional array of elements whose drive signals are controlled electronically to steer and focus the signal at the desired position in the tissue or blood vessel. These transducer arrays are either linear or convex. The size and shape of the array depends on the intended site of use: transcutaneous, transesophageal, transvaginal, or transrectal. With the speed of sound in tissue (approximately $1540 \text{ m}\cdot\text{s}^{-1}$), 3500 traces can be scanned each second at a penetration depth of 200 mm. Most ultrasound systems use pulsed rather than continuous wave signals. Pulsed wave systems have the advantage of allowing a two-dimensional image to be obtained with the velocity image overlain on it. The operator can then indicate, by means of a cursor on the display, the approximate direction of flow so that the actual velocity can be calculated. The display may be color enhanced with flow toward the transducer being red and flow away from the transducer blue. Pulsed wave signals are usually referred to as pulsed Doppler; however, Jensen (1) provides a strong mathematical derivation to show that the velocity information is actually contained in the time shift of successive pulses rather than the Doppler frequency shift. The classical approach to signal processing has been to use coherent demodulation of the returned echo with the transmitter oscillator followed by low-pass filtering. The mean frequency of the demodulated signal is determined by autocorrelation. An alternate approach is to sample directly the return signal and to crosscorrelate successive pulses. This method has become feasible with development of analog to digital converters capable of sampling at the frequencies used for ultrasound imaging.

A more recent development in medical flow imaging is power or energy flow imaging, sometimes referred to as power Doppler imaging. In this case, an estimate is made of the power in the return signal. The power is not dependent on the angle of incidence of the ultrasound beam and the moving target. However, the result is only an image of where flow is occurring without any ability to estimate the velocity of the flow. Clinically, the advantage to power imaging is that smaller arteries can be resolved. This allows a better understanding of tissue perfusion. Another improvement currently undergoing investigation is three-dimensional ultrasonic velocimetry [for example, see (29)]. Two approaches for this have been identified: to use multiple receivers whose beam axes are not co-planar and to use crosscorrelation of two successive images (similar to particle image velocimetry below).

MICROWAVE VELOCIMETRY

Perhaps the most notorious velocimeter is the microwave Doppler velocimeter or radar gun—used primarily for traffic speed enforcement. The target must be electrically conductive to behave as a reflector. A continuous wave microwave signal, at about 10 GHz, is generated by a Gunn diode and varactor in a resonant cavity and is emitted from a horn antenna. The return signal is received by the same antenna, where it is led by means of a waveguide to a Schottky mixer diode, where it is mixed with a portion of the oscillator output (30). The output of the mixer is the low-frequency, Doppler shift signal. The

frequency, and hence the velocity of the target, can be obtained from this signal, for example, by using a zero crossing detector (31). More complex Doppler radar systems are used in aircraft navigation systems to determine aircraft velocity (32). These are particularly useful in helicopter navigation and control because the helicopter may have long periods of low velocity when hovering. During these periods, drift in an inertial guidance system based on gyroscopes may affect the accuracy of position calculations.

The global positioning satellite (GPS) system and its Russian counterpart (GLONASS) are being used increasingly for navigation purposes. Collectively these are referred to as the global navigation satellite system (GNSS). The standard civilian GPS coded information channel (C/A on the L1 carrier frequency) has a resolution of less than 100 m 95% of the time (33). For short time intervals, this level of repeatability leads to highly erroneous velocity estimates based on successive positions and the elapsed time. However, it is possible to use the carrier signal rather than the coded information to improve both position and velocity calculations. Carrier phase tracking (33,34) takes advantage of the 1000-fold improvement in spatial resolution by using the wavelength of the carrier (approximately 190 mm) to obtain position information. Surveying instruments are available (34,35) that provide 10 mm resolution. They do not suffer from the dithering of the coded information channel referred to as selective availability. The most recent instruments do not require a base station at a known location to provide this level of accuracy. Thus, successive estimates of position can provide velocity information. Since GNS receivers must have highly stable clocks, time information is inherently readily available.

A third use of electromagnetic waves in velocimetry is measuring high-latitude ionospheric convection, which are currents of ionized particles that flow due to the interaction of the solar wind with the earth's magnetic field (36). The velocity of the ionized particles flowing in these field aligned currents can be measured using the Doppler shift that arises when an electromagnetic beam is reflected off the particles. The radar frequencies are in the range of 8 MHz to 20 MHz with corresponding wavelengths of approximately 10 m. Therefore, the reflective target cannot be individual charged particles, but irregularities in the electron density that have a size of approximately one-half of the wavelength. Particle drift velocity is on the order of $300 \text{ m}\cdot\text{s}^{-1}$ to $400 \text{ m}\cdot\text{s}^{-1}$ and may exceed $1000 \text{ m}\cdot\text{s}^{-1}$. With two radars separated by several thousand kilometers, it is possible to calculate the magnitude and direction of the currents in the plane of the radar beam.

OPTICAL VELOCIMETRY

Particle Image Velocimetry

Particle image velocimetry (PIV) is used for imaging complex flow profiles (8). Because of the cost and complexity of the apparatus, this technique is used primarily in research applications. Areas of application include combustion flows, unsteady aerodynamic flow around rotors, turbulent water flow, flows in internal combustion engines, and natural convection.

A laser beam is passed through a cylindrical lens to create a sheet of light that illuminates the fluid field. The thickness of the laser sheet can be controlled by interposing a spherical

lens after the cylindrical lens. The flow must be in the plane of the illuminating sheet, and the fluid must be transparent to the wavelength of the illuminating source. The fluid must have naturally occurring particles, or it must be seeded with particles appropriate to the fluid and the desired frequency response. Particles can range from $0.2\ \mu\text{m}$ to $40\ \mu\text{m}$, depending on the particle dynamics of the flow. Particular care must be taken in determining the particle size required to image swirling flows. Light from the particles is imaged onto a camera, and two successive images are taken. If irregularities in the flow pattern are smaller than the area being imaged, then subsequent processing is done on overlapping subsets of the total image. The light source is usually a pulsed laser with short duration (10 ns) pulses. In a dual laser system, the time between pulses may be adjusted from 200 ns to 0.5 s (37). The time between pulses must be known, of course, for the speed to be calculated. If both pulses are captured on the same image, then there will be an ambiguity as to the direction of flow. The image may be captured on a photographic transparency or a CCD video camera. The former has the advantage of high resolution; the latter has the advantage of representing the image electronically so that it can be readily converted into a digital representation.

The displacement information contained in the double exposure image can be extracted in a number of ways. If the image is on a transparency, this can be illuminated by a laser beam. The particle image pairs will cause Young's fringes to be formed from which the image displacement can be inferred. A transparency can be made of the Young's fringes. When this is, in turn, illuminated by a laser source, the autocorrelation function is created. The two first-order side peaks represent the displacement distance between the two images. Alternatively, the Young's fringes can be digitized via a CCD camera, and a digital autocorrelation can be calculated. If a CCD camera is to be used, then the original two PIV images can be captured directly on a single frame, and digital autocorrelation can be performed. If the velocity is sufficiently slow, successive images may be on the even and odd fields of a frame. However, this reduces the spatial resolution. Where separate images have been obtained, crosscorrelation or maximum quadrature difference can be used to determine the displacement (38).

A variety of techniques has been used to separate the two images to avoid the directional ambiguity. A rotating mirror can be used before the camera to move the second image by more than the largest expected displacement. This value can then be subtracted from that calculated by one of the aforementioned methods. This is particularly useful where turbulence prevents a priori knowledge of the direction of flow. In a dual laser system, the two beams can be given different optical polarization, and a birefringent crystal, such as calcite, can be used to shift one beam. Wirth and Baritaud (9) describe a method of using a ferroelectric liquid crystal retarder on the imaging path (rather than the illuminating path). Their technique resulted in one image with only the first laser pulse and a second image with the usual double image. A CCD camera that has storage cells associated with each pixel element of the camera is capable of acquiring two full frames of information at short time intervals (39). In this case, the image information is transferred in parallel from the light-sensitive elements to the storage cells prior to the second laser pulse. This technology has allowed on-line calculation of velocity vectors for flow velocities up to supersonic speeds. Such high-speed image calculations are usually performed by dedicated computers configured to maximize the

throughput of parallel calculations. Grant (8) provides a review of developments in the field, which are under development at the time of this writing.

Laser Doppler Anemometry

Laser Doppler anemometry (LDA) is also known as laser Doppler velocimetry, laser anemometry, or optical anemometry because its main application is in complex aerodynamic flow fields. The reader is referred to Durst, Melling, and Whitelaw (40) for a more complete explanation of the physics of laser Doppler anemometry. As with particle image velocimetry, no flow disturbance occurs; particles must be present; and there must be optical access to the flow. The Doppler frequency shift is detected as a phase shift by creating an interference pattern between the Doppler-shifted beam and a reference beam. The interference fringes will have a beat frequency because of the Doppler shift. The beat frequency is proportional to the flow velocity perpendicular to the source of illumination, unlike Doppler ultrasound, which measures the component parallel to the insonation beam. The beat frequency can then be detected with a photomultiplier tube or other photodetector. The technique has the advantages of high accuracy, wide dynamic range (a few microns per second to Mach 8) (37), and fast response time.

Three modes of operation are possible: dual beam (or fringe or differential Doppler), reference beam, and two scattered beam. The dual beam technique uses a beam splitter to create two beams from a single laser. By means of appropriate optical elements, including optical fibers, the two beams are focused on the same volume region of the flow but from different angles. A light-collecting lens and mask are used to image the interference fringes from a single particle onto a photodetector. The optical axis of the collecting side is symmetrical with respect to the two illuminating beams. This approach has a large solid angle but requires relatively few particles in the flow. The reference beam technique has a smaller solid angle and can be used in particle-rich flows. Both the reference beam and the scattering beam illuminate the flow region, as before. However, in this case, the optical axis of the collecting system is coincident with the axis of the reference beam. The two-scattered-beam configuration has a single beam illuminating the flow volume, but there are two collecting axes. The scattered light along these axes is then combined to create the desired interference fringes. The collected light can be backscattered rather than forward scattered, which means that optical access is required from only one side of the flow field. This last approach has the further advantage of being readily adapted to measure two- or three-dimensional flow components by having two or three mutually orthogonal collecting systems.

As with other Doppler shift techniques, LDA will have directional ambiguity. Where this is problematic, such as with turbulent flow, a rotating diffraction grating on one of the two illuminating beams can be used to create a frequency preshift. Alternately, the two beams can have their wavelengths shifted in opposite direction by being passed through a Bragg cell (41).

This technique has also been applied to the study of perfusion of soft tissues in medicine (42). In this application, a laser beam is scanned across the surface of the tissue by means of a rotating mirror. The reflected light is then processed in a manner similar to the aforementioned techniques. This is one of the

few methods that can image the low blood flow in peripheral vasculature. However, only relative flow measurements can be made, not absolute measurements.

Time-of-Flight Optical Velocimeters

If the radar gun is the most notorious velocimeter, then the lidar (or ladar) is quickly gaining a similar status for the same reason. This is the optical replacement for the radar gun in traffic speed enforcement. Lidar (light or laser distance and ranging) is based on the time of flight of a short pulse of laser light emitted and received by a single unit. Since the speed of light is constant with respect to temperature and atmospheric conditions, the time taken will be directly proportional to the distance. In fact, commercial units (43,44) include the ability to measure range as well as speed. Successive measurements can then be used to calculate the speed of the target. Because of the short duration of the laser pulses, up to 60 pulses may be used in a single speed measurement, which takes 0.3 s to perform. The infrared laser diodes have a beam divergence of 3 mrad (that is, 3 m in 1000 m) so individual vehicles can be targeted as reflectors. A geometric correction must be made if the target is not moving in line with the laser beam path.

Optical Gyroscopes

Gyroscopes measure rotational velocity usually for navigation purposes or stabilization of a platform. The propagation velocity of electromagnetic waves is not affected by motion of the medium through which they are passing, as was the case for acoustic waves. That is, electromagnetic waves, and photons particularly, can be thought of as moving in an inertial frame of reference. However, suppose that three mirrors are mounted on a platform that may be rotated as shown in Fig. 7. A photon traversing the path in the clockwise direction will experience a longer path length than one traversing in the opposite direction if the whole apparatus rotates clockwise. This is known as the Sagnac effect (45). Two types of optical gyroscopes have been

developed based on the Sagnac effect: ring laser gyroscopes and fiber optic gyroscopes.

In a ring laser, the rotating ring is filled with the lasing medium. The output is two independent beams—one in each direction. The two beams will be at different frequencies (that is, wavelengths) since there must be an integer number of wavelengths in the resonant path (46). The two path lengths will be different by the amount

$$\Delta p = \frac{2\Omega A}{c}$$

where p is the path length, Δp is the difference in path length, Ω is the rotational velocity, A is the projected area of the ring, and c is the speed of light. This leads to a difference in time it takes for light to travel around the ring:

$$\Delta t = \frac{2\Delta p}{c}$$

The wavelength shift can be measured through interference fringes created by mixing the two output beams. Ring lasers are used in research applications such as measuring the rotation of the earth.

Fiber optic gyroscopes (FOG) have counterpropagating light that is injected into opposite ends of a coil of single-mode optical fiber. The light source may be a laser or a superluminescent light emitting diode. The latter has the advantage of reducing one source of phase error—namely, the Kerr effect (47). If the optical fiber undergoes rotation in the plane of the coil, then the two beams will have had a different time of flight, as mentioned previously. This leads to a phase shift that can be detected through interference fringes. Multiple turns of the coil increase the phase shift and hence the sensitivity of the gyroscope:

$$\Delta\phi = \frac{8\pi\Omega NA}{\lambda c}$$

where $\Delta\phi$ is the phase shift, Ω is the angular velocity, N is the number of turns, A is the area, λ is the wavelength, and c is the speed of light. Note that in both the FOG and the ring laser, it is the area of the closed path that is important, not the path length. A detector placed at the output of the interfering beams has an amplitude that is dependent on the phase shift (48):

$$P_D = \frac{P_{in}(1 + \cos \Delta\phi)}{2 \text{ Loss}}$$

The maximum sensitivity will occur when the beams are 90° optically with respect to each other. A phase modulator is, therefore, usually placed in the path of one of the incoming beams. The phase modulator has the additional advantage of causing the interferometer to oscillate $\pm 90^\circ$. Thus, the otherwise dc signal becomes an ac signal at the frequency of the phase modulator. A tuned filter is then used on the output of the detector to reduce 1/f noise.

FOGs are manufactured to cover a wide range of performance requirements. Inertial navigation quality FOGs have maximum sensing rates of up to 400° per second and stability of 0.0001° per hour. At the low end of the performance scale, the maximum rate is 100° per second and the bias stability is

Figure 7. A Sagnac interferometer consists of a light source, a closed optical path, and a means of detecting the fringes that are generated as the platform rotates.

100° per hour. A typical FOG might have 1000 m of optical fiber on an 84 mm diameter spool (49).

Hot-Wire Anemometry

Hot-wire anemometry (HWA) is based on the physical principle that heat dissipation from a heated object is dependent on the mass flow of the medium in which the object is immersed. The heat dissipation is dependent not only on velocity but also on temperature, pressure, specific heat, and density of the medium. In most cases, HWA is used for air velocity measurements, in which case the relative humidity of the air affects its density and specific heat. For environmental air speed monitoring, such as in building ventilation systems, the atmospheric pressure and relative humidity must be known, or assumed, to calculate velocity from the mass flow rate. Since the technique is based on a differential temperature measurement, many instruments built for environmental monitoring also include the capability of measuring the ambient air temperature (20). Measurement of atmospheric pressure may also be included (50). Air speed from 0 to 60 m·s⁻¹ can be measured by such instruments. In instruments designed for mass flow measurements rather than velocity measurements, multiple sensors may be included on a single mount to obtain a better estimate of the flow profile (50).

HWA is also used to measure complex flow fields involving high air speeds and/or turbulence. Although HWA inherently alters the flow field, it is often used instead of laser Doppler anemometry or particle image velocimetry because of its lower cost and no requirement for optical access to the flow field or an optically clear fluid. In turbulent flow, the frequency response is an important figure of merit as well as the maximum velocity. Because of their small size, hot-film probes can be designed with a frequency response up to 300 kHz. Cone- or wedge-shaped hot-film probes are preferred over cylindrical probes due to greater strength (50). The film material is usually platinum and the substrate material is quartz. If the probes are coated, they can be used in conductive liquids, although this will increase the response time of the probe.

ACCELERATION MEASUREMENT

When we use the term *acceleration*, we usually implicitly mean *instantaneous acceleration*. However, when acceleration is measured, we actually obtain an estimate of *average acceleration* within some time window. The average acceleration a_a during a certain time interval Δt is equal to the change in velocity Δv per unit time during that interval. The instantaneous acceleration

(or just acceleration) a is the limiting value of the average acceleration, when the observation interval approaches zero (1). This can be expressed mathematically as

$$a = \lim_{\Delta t \rightarrow 0} a_a = \lim_{\Delta t \rightarrow 0} \frac{\Delta v}{\Delta t} \quad (1)$$

Acceleration measurements are frequently needed for automatic control, protective supervision, and condition monitoring in applications like vertical and horizontal transportation, robotics, aerospace navigation, and technical diagnostics (2,3). Acceleration belongs to the important chain of kinematic quantities: position, velocity, acceleration, and jerk. They all have a linear connection to their neighbor quantities; for example, acceleration is obtained by differentiating the corresponding velocity or integrating the jerk. Therefore, in principle, all the kinematic quantities could be derived from a single quantity. In practice, however, only integration is widely used to process these kinematic quantities, since integration always provides advantageous noise attenuation. Differentiation, on the other hand, is noise amplifying by its nature. Therefore it is seldom utilized in practical applications when the input signal contains noise or other disturbances.

This possible noise results from various measuring and processing errors, as well as external disturbances like electromagnetic interferences (EMI). The measuring errors are caused by sensor nonidealities and by cumulative effects of the entire measuring instrumentation (4). Quantization, finite-precision computations, sampling, and approximative algorithms are typical sources of processing errors. External disturbances may enter a measuring system due to inadequate grounding, shielding, isolation, or poor cabling.

REFERENCE AXES AND DIFFERENT TYPES OF MOTION

Measurement of acceleration, as well as all kinematic quantities, are made with respect to some system of reference axes. The basic frame of reference used in mechanics is known as the *primary inertial system* (or astronomical frame of reference). It consists of an imaginary set of rectangular axes that neither translate nor rotate in space. Measurements made with respect to this primary inertial system are said to be *absolute*. In most earth-bound engineering applications, measurements made relative to the earth can also be considered absolute (at least the introduced error is negligible).

There are many engineering problems for which the analysis of motion is simplified by measuring kinematic quantities with respect to a moving coordinate system. These measurements, when combined with the observed motion of the moving coordinate system, permit the determination of the absolute motion. This approach is known as a *relative motion analysis* (2).

Direct and Indirect Measuring Techniques

There exist two classes of acceleration measurement techniques: *direct* measurements by special sensors or accelerometers and *indirect* measurements where velocity is differentiated using some differentiator circuitry or a computational algorithm (2). The applicability of these techniques depends on whether one is measuring rectilinear, angular, or curvilinear motion or equilibrium-centered vibration, which is a special class of acceleration.

Direct measuring using an accelerometer is usually preferred when the motion is either rectilinear or curvilinear. Techniques used to measure linear unidirectional acceleration include spring mass, stretched wire, pendulum, piezoelectric, strain gauge, and force balance (3). Vibration measurements are based almost solely on direct techniques because there usually exists no actual velocity signal that can be differentiated successfully. Angular acceleration, on the other hand, is usually measured indirectly because the rotation range of existing angular accelerometers is severely limited due to their mechanical structures (5). Angular velocity, a necessary basis for indirect measurement of angular acceleration, can easily be measured by ac or dc tachogenerators or pulse encoders with some post-processing electronics (6–8). Besides, rectilinear motion is often first converted mechanically into angular motion, and the corresponding angular acceleration is then measured using some indirect technique.

Differentiators needed in indirect measuring have two important requirements: They must provide simultaneously *adequate noise attenuation* and *appropriate delay characteristics*. The delay properties are particularly critical in real-time control and protective supervision applications. Even a small delay in an acceleration signal that is used for feedback control can reduce the control performance drastically. Besides, a considerably delayed acceleration curve is not a sufficient basis for time-critical actions.

RECTILINEAR, ANGULAR, AND CURVILINEAR ACCELERATION

Before we go into specific measuring techniques, we need to formulate the different types of acceleration in the corresponding coordinate systems. The applicable measuring techniques are closely connected to these formulations.

Rectilinear Acceleration

Rectilinear motion is illustrated in Fig. 1. This kind of motion occurs, for example, in vertical and horizontal transportation as well as in various positioning servo applications. The average velocity v_a during a time interval Δt is the displacement Δs divided by the time interval. The instantaneous velocity (or just velocity) v can be defined in a similar way as the instantaneous acceleration of Eq. (1):

$$v = \lim_{\Delta t \rightarrow 0} v_a = \lim_{\Delta t \rightarrow 0} \frac{\Delta s}{\Delta t} = \frac{ds}{dt} \quad (2)$$

Figure 1. Rectilinear motion of a particle. Its original position is $s(P)$, and the new position is $s + \Delta s(P')$. *Instrumentation for Engineering Measurements*, J. W. Dally, W. F. Riley, and K. G. McConnell, Copyright © 1984, by John Wiley & Sons, Inc. Reproduced by permission of John Wiley & Sons, Inc.

Rectilinear acceleration can now be written as the time derivative of velocity or the double time derivative of the corresponding distance

$$a = \lim_{\Delta t \rightarrow 0} \frac{\Delta v}{\Delta t} = \frac{dv}{dt} = \frac{d(ds/dt)}{dt} = \frac{d^2s}{dt^2} \quad (3)$$

Equation (3) is used frequently in indirect acceleration measurement. However, the double differentiation is seldom implemented in practice due to the noise amplification problem discussed earlier. Instead, the time derivative of measured velocity is somehow approximated. By combining Eqs. (2) and (3), we obtain another important formula to be potentially used in indirect acceleration measurement:

$$a = v \frac{dv}{ds} \quad (4)$$

Depending on the applied velocity measuring technique, it is sometimes more natural to compute the displacement derivative instead of the time derivative.

The roughness of motion is widely described by jerk. This roughness is directly related to ride comfort in vertical and horizontal transportation systems. Acceleration difference Δa at the beginning and end of a diminishing time interval Δt can be used to derive the instantaneous jerk k as

$$k = \lim_{\Delta t \rightarrow 0} \frac{\Delta a}{\Delta t} = \frac{da}{dt} \quad (5)$$

All the kinematic quantities can be either positive or negative. Throughout the preceding equations, the sign of a kinematic quantity follows the base convention of defining the rectilinear displacement Δs positive or negative.

Angular Acceleration

Angular motion is illustrated in Fig. 2. Here the counterclockwise direction is defined to be positive, and the signs of the other motion quantities are selected correspondingly. This type of motion exists, for example, in electric machines and industrial robots. Therefore the measurement of angular motion quantities is of great practical importance. In angular motion the

Figure 2. Angular motion of a rotating line. Its original angle is θ , and the new angle is $\theta + \Delta\theta$. *Instrumentation for Engineering Measurements*, J. W. Dally, W. F. Riley, and K. G. McConnell, Copyright © 1984, by John Wiley & Sons, Inc. Reproduced by permission of John Wiley & Sons, Inc.

observed displacement is an angle $\Delta\theta$ instead of a linear distance. Thus the SI unit of angular acceleration is rad/s^2 instead of m/s^2 .

The average angular acceleration α_a during a defined time interval Δt is equal to the change in angular velocity $\Delta\omega$ per unit time during that interval. Now the instantaneous angular acceleration (or just angular acceleration) α can be expressed as

$$\alpha = \lim_{\Delta t \rightarrow 0} \alpha_a = \lim_{\Delta t \rightarrow 0} \frac{\Delta\omega}{\Delta t} = \frac{d\omega}{dt} \quad (6)$$

The equation of angular velocity is analogous to the rectilinear velocity of Eq. (2) and can be written as a time derivative of the angular displacement

$$\omega = \lim_{\Delta t \rightarrow 0} \omega_a = \lim_{\Delta t \rightarrow 0} \frac{\Delta\theta}{\Delta t} = \frac{d\theta}{dt} \quad (7)$$

By combining Eqs. (6) and (7), we obtain another useful formula for indirect measurement of angular acceleration:

$$\alpha = \omega \frac{d\omega}{d\theta} \quad (8)$$

Angular jerk is a seldom used quantity, but it can be computed indirectly using an equation analogous to Eq. (5).

Curvilinear Acceleration

When a particle is moving along a curved path, the motion is curvilinear. Curvilinear motion can be two-dimensional, plane curvilinear or three-dimensional, space curvilinear. Next we discuss the curvilinear acceleration, referring to Figs. 3 and 4.

Plane Curvilinear Acceleration. Plane curvilinear motion equations are very similar to those of rectilinear motion. Now we only need a two-dimensional vector instead of a scalar to

Figure 3. Plane curvilinear motion of a particle. Its original position is A, and the new position is B. The moving path is denoted by s , and Δs is the traveled distance. Now the particle can be located by a position vector $\mathbf{r}$ (and $\mathbf{r} + \Delta\mathbf{r}$). *Instrumentation for Engineering Measurements*, J. W. Dally, W. F. Riley, and K. G. McConnell, Copyright © 1984, by John Wiley & Sons, Inc. Reproduced by permission of John Wiley & Sons, Inc.

Figure 4. Space curvilinear motion of a particle along the path s . The position is determined by rectangular coordinates (x, y, z) . The position vector $\mathbf{R}$ can be expressed as $x\mathbf{i} + y\mathbf{j} + z\mathbf{k}$. *Instrumentation for Engineering Measurements*, J. W. Dally, W. F. Riley, and K. G. McConnell, Copyright © 1984, by John Wiley & Sons, Inc. Reproduced by permission of John Wiley & Sons, Inc.

define the position $\mathbf{r} = x\mathbf{i} + y\mathbf{j}$ of a particle. All the other kinematic quantities are correspondingly of vector value. Figure 3 illustrates such a motion type. The instantaneous velocity $\mathbf{v}$ can be expressed as the limiting value of the average velocity $\mathbf{v}_a$ when the observation interval Δt approaches zero:

$$\mathbf{v} = \lim_{\Delta t \rightarrow 0} \mathbf{v}_a = \lim_{\Delta t \rightarrow 0} \frac{\Delta\mathbf{r}}{\Delta t} = \frac{d\mathbf{r}}{dt} = \frac{dx}{dt}\mathbf{i} + \frac{dy}{dt}\mathbf{j} \quad (9)$$

The vector displacement $\Delta\mathbf{r}$ is called *linear displacement*, while the scalar displacement Δs is the traveled distance. The magnitude of the instantaneous velocity is called the *speed* of the particle. Next we define the instantaneous acceleration $\mathbf{a}$ using the limiting value of average acceleration $\mathbf{a}_a$ as the observation interval approaches zero:

$$\mathbf{a} = \lim_{\Delta t \rightarrow 0} \mathbf{a}_a = \lim_{\Delta t \rightarrow 0} \frac{\Delta\mathbf{v}}{\Delta t} = \frac{d\mathbf{v}}{dt} = \frac{d^2x}{dt^2}\mathbf{i} + \frac{d^2y}{dt^2}\mathbf{j} \quad (10)$$

Different coordinate systems (rectangular, normal, tangential, and polar) are commonly used to describe plane curvilinear motion. A detailed discussion of these is given by Dally et al. (2).

Space Curvilinear Acceleration. Rectilinear acceleration of Eq. (3) is a special case of plane curvilinear acceleration of Eq. (10). Further, plane curvilinear acceleration is a special case of space curvilinear acceleration (see Fig. 4). The most general form of motion, space curvilinear motion occurs in a three-dimensional space. We use the rectangular coordinates in defining the kinematic quantities.

The spatial position $\mathbf{R}$ can be expressed as

$$\mathbf{R} = x\mathbf{i} + y\mathbf{j} + z\mathbf{k} \quad (11)$$

The corresponding spatial velocity $\mathbf{v}$ is a time derivative of the spatial position

$$\mathbf{v} = \frac{d\mathbf{R}}{dt} = \frac{dx}{dt}\mathbf{i} + \frac{dy}{dt}\mathbf{j} + \frac{dz}{dt}\mathbf{k} \quad (12)$$

Finally, we can write the spatial acceleration $\mathbf{a}$ as a time derivative of the spatial velocity

$$\mathbf{a} = \frac{d\mathbf{v}}{dt} = \frac{d^2x}{dt^2}\mathbf{i} + \frac{d^2y}{dt^2}\mathbf{j} + \frac{d^2z}{dt^2}\mathbf{k} \quad (13)$$

Cylindrical and spherical coordinates are considered in Dally et al. (2). The choice of coordinates (rectangular, cylindrical, or spherical) for a particular application, involving space curvilinear motion, depends on the nature of the motion and the choice of measurement techniques.

VIBRATORY ACCELERATION

Vibratory acceleration is a distinct form of planar or spatial acceleration. It can be one-, two-, or three-dimensional. The principal characteristic of vibratory motion is that it occurs around some equilibrium position. Therefore the longer-term time average of the vibratory displacement is zero.

Vibratory motion occurs, for example, in all kinds of machines, as well as in almost all natural and artificial structures. The considerable interest in vibration analysis has three main motivations: (1) persistent vibration causes long-term wearing and possible breakdown of vibrating structures, (2) even slight vibration can degrade the performance of vibrating machines, and (3) medium-frequency vibration can also cause disturbing audible noise. For monitoring the condition of machines and installations, diagnostic procedures based on frequency-domain vibration analysis are in everyday use. Piezoelectric accelerometers have become widely used in machine vibration acquisition. Small dimensions and rigid design allow their utilization in various fields of technology. In contrast to displacement pickup and velocity pickup, these acceleration sensors can be applied into a wider range of frequencies (9).

A simple vibration can be modeled as a periodically repeated motion about the position of equilibrium (2). Figure 5 illustrates a rotating line representation of a simple type of vibratory motion that occurs commonly in various physical systems. This two-dimensional vibration can be separated into vertical (y -axis) and horizontal (x -axis) vibration components. The $x(y)$ position of the vibrating particle $P(Q)$ can be expressed as a function of time as

$$\begin{cases} x_P = A_0 \cos \omega t \\ y_Q = A_0 \sin \omega t \end{cases} \quad (14)$$

By differentiating the separate xy -position components of Eq. (14), we obtain the corresponding horizontal and vertical velocities of the vibratory motion:

$$\begin{cases} v_P = \frac{dx_P}{dt} = -A_0\omega \sin \omega t \\ v_Q = \frac{dy_Q}{dt} = A_0\omega \cos \omega t \end{cases} \quad (15)$$

Figure 5. Rotating line representation of a simple type of vibratory motion. A_0 is the amplitude of vibration, T is the vibration period, and ω is the angular velocity of the rotating line OR . *Instrumentation for Engineering Measurements*, J. W. Dally, W. F. Riley, and K. G. McConnell, Copyright © 1984, by John Wiley & Sons, Inc. Reproduced by permission of John Wiley & Sons, Inc.

Finally, after differentiating the vibratory velocity components, we can write the vibratory acceleration components as

$$\begin{cases} a_P = \frac{dv_P}{dt} = -A_0\omega^2 \cos \omega t \\ a_Q = \frac{dv_Q}{dt} = -A_0\omega^2 \sin \omega t \end{cases} \quad (16)$$

Given the basic trigonometric equivalencies of Eq. (17), we can easily see that the vibratory velocities, Eq. (15), can be calculated straightforwardly by multiplying the corresponding displacement, Eq. (14), by ω and increasing the angle by $\pi/2$ radians:

$$\begin{cases} \sin \omega t = -\cos \left(\omega t + \frac{\pi}{2} \right) \\ \cos \omega t = \sin \left(\omega t + \frac{\pi}{2} \right) \end{cases} \quad (17)$$

Similarly, given the equivalencies of Eq. (18), we obtain the vibratory accelerations, Eq. (16), by multiplying the displacements, Eq. (14), by ω^2 and increasing the angle by π radians:

$$\begin{cases} \cos \omega t = -\cos(\omega t + \pi) \\ \sin \omega t = -\sin(\omega t + \pi) \end{cases} \quad (18)$$

Now we can write the vibratory acceleration as a simple function of the vibratory position:

$$\begin{cases} a_P = -\omega^2 x_P \\ a_Q = -\omega^2 y_Q \end{cases} \quad (19)$$

Any motion for which the acceleration is proportional to the displacement from a fixed point on the path of motion and always directed toward that point is defined as *simple harmonic motion* (2). Periodic motion that is not simple harmonic motion can be modeled as a sum of several simple harmonic

motions with different displacement amplitudes and harmonically related angular frequencies. This natural generalization is discussed further by Dally et al. (2).

ACCELERATION MEASUREMENT TECHNIQUES

After defining the different types of motion, we are ready to go into the details of the available measurement techniques. The main emphasis of our discussion is in the indirect measuring methods of acceleration. The direct methods, based on commercially available linear or angular accelerometers, are usually straightforward instrumentation applications where low absolute or differential voltages or currents are measured from a specific acceleration sensor. For a comprehensive presentation of accelerometers see Accelerometers.

Indirect Acceleration Measurement

Indirect acceleration measuring techniques are based on analog or digital postprocessing of position or velocity signals. These are typically measured by pulse encoders or tachogenerators. Therefore some kind of differentiator needs to be constructed to provide the acceleration signal. As discussed earlier, this complete differentiator is not trivial because the differentiation operator is noise amplifying by nature. To loosen the noise attenuation requirements of the final differentiator that produces the acceleration signal, the measuring noise problem must be tackled already in all the functional blocks of the preceding measuring chain. High-performance velocity measuring techniques are presented, for example, by Brown et al. (9), Pasanen et al. (8), and Laopoulos and Papageorgiou (10). The articles contain velocity measuring techniques that can be parametrized to provide low output noise. The applied sensors are pulse encoders. Thus the proposed methods can be used to measure both angular and rectilinear velocities, which can then be postprocessed by a differentiator.

In principle, it is easy to attenuate any noise when the primary signal and the disturbing noise are clearly separated in the frequency domain. However, the filtering task becomes considerably more difficult if there also are strict delay constraints for the filtering process. Simple nonrecursive and recursive smoothing techniques to enhance the quality of the differentiator output were suggested by Jaritz and Spong (11). The z -domain transfer functions of their smoothers are given as

$$S_n(z) = \frac{1}{N} \sum_{i=0}^{N-1} z^{-i} \quad (20)$$

$$S_r(z) = \frac{1/N}{1 - \sum_{i=1}^{N-1} z^{-i}/N} \quad (21)$$

These smoothers still suffer from a notable tracking error or lag. This forces the designer to use a small value of N that, on the other hand, leads to poor noise attenuation capabilities.

Ultimately we would prefer a delayless lowpass filter because any additional delay degrades the overall performance when the filtered acceleration signal is used for feedback control or time-critical supervision. Unfortunately, there exists no general-purpose lowpass filter that does not delay the frequencies on its passband. At present we can choose between two

approaches to solve this difficult problem: predictive filtering or state observing. In the first case, an application-specific, predictive lowpass filter is cascaded with a differentiator, and in the second, a linear (or nonlinear) stochastic model to represent acceleration is developed and used as an acceleration estimator. Under greatly time-varying conditions, the predictive filter as well as the stochastic estimator should be adaptive to maximize the noise attenuation capabilities and to minimize the harmful lag of the primary acceleration curve.

Predictive Postfiltering. Predictive filters (8) as well as state observers (12) are usually implemented in the discrete time domain either because they have their theoretical origins in digital signal processing or because an analog implementation would be unfeasible due to the mathematical operations required. This assumption is valid throughout the following discussion. Predictive (or phase-advancing) lowpass filtering is possible if we can place easing constraints for the incoming signal characteristics. These constraints may be explicit either in the time domain or in the frequency domain. There are many practical applications where the kinematic quantities can be approximated with sufficient accuracy by piecewise low-degree polynomials, as illustrated in the experimental sections of Refs. 12, 8, and 5. This is due to the mechanical inertia that necessarily smoothens the movements of masses. Typical rectilinear position curves, such as those related to vertical and horizontal transportation, can be approximated piecewise by third- and fourth-degree polynomials, velocity curves by second- and third-degree polynomials, acceleration curves by first- and second-degree polynomials, and jerk curves by zeroth- and first-degree polynomials. For instance, a third-degree polynomial model can be expressed as

$$f(k) = \beta_0 + \beta_1 k + \beta_2 k^2 + \beta_3 k^3 \quad (22)$$

where k is the discrete time index, and $\beta_i, i = 0, 1, 2, 3$, are the signal-dependent curve-fitting parameters. A thorough discussion of polynomial modeling is given by Williams (13).

By using the polynomial signal model, we can easily design predictive filters that provide the desired forward prediction behavior with the mandatory lowpass characteristics (14). One-step-ahead prediction is typically adequate to compensate for the delay caused by the differentiation algorithm as well as the data acquisition and processing delays. Thus we are performing on-line curve fitting. For this we only need to select an appropriate polynomial degree; the signal-dependent parameters of the polynomial model are handled implicitly.

The difference equation of a general n -step-ahead predictive filter can be expressed as

$$\hat{u}(k+n) = \sum_{i=1}^N \chi_i \hat{u}(k+n-i) + \sum_{j=0}^M \delta_j u(k-j) \quad (23)$$

where the coefficients χ_i and δ_j are real-valued constants, $\hat{u}(k+n)$ is the n -step-ahead output of the predictive filter, and $u(k)$ is the corresponding input sample. The prediction step n is an application-specific parameter, and it depends on the cumulative measuring and processing delays of the entire instrumentation system. An important consequence of the polynomial model is naturally that the result of predictive filtering is less satisfactory for other signal classes, like vibratory

acceleration. This is due to a narrow prediction bandwidth (a frequency range where the group/phase delay of the filter is negative) that is a principal restricting characteristic of polynomial predictive filters. There exist several finite impulse response (FIR) and infinite impulse response (IIR) polynomial predictors as reviewed by Ovaska (15).

Recursive linear smoothed Newton (RLSN) predictors form a class of computationally efficient IIR predictors (14), which are particularly attractive for postprocessing of the noisy output of a differentiator. Their applicability is an immediate consequence of the simple design process and efficient noise attenuation capabilities. The z -domain transfer functions of the first- and second-degree [$H_1(z)$ and $H_2(z)$, respectively], one-step-ahead RLSN polynomial predictors are given as

$$H_1(z) = \frac{[c + (1/N)] - (z^{-N}/N)}{1 - (1 - c)z^{-1}} \quad (24)$$

$$H_2(z) = \frac{[2c + (1/N)] + [c^2 - 2c - (1/N)]z^{-1} - (z^{-N}/N) + (z^{-(N+1)}/N)}{1 - (2 - 2c)z^{-1} + (1 - 2c + c^2)z^{-2}} \quad (25)$$

The only adjustable parameters, c and N , control primarily the stopband attenuation and the passband gain peak, respectively. In acceleration measurement applications, typical values for these parameters are $c = 0.01$ – 0.05 and $N = 16$ – 64 .

Hence we can postfilter the noisy output of the simple backward-difference differentiator of Eq. (26) by a polynomial predictive filter without harmfully delaying the low-degree polynomial component. This polynomial component approximates our desired acceleration signal. The delay introduced by the difference operation of Eq. (26) is half a sampling period.

$$a(k) = \frac{v(k) - v(k-1)}{T_s} \quad (26)$$

In Eq. (26), $a(k)$ is the average acceleration, $v(k)$ the instantaneous velocity, and T_s the constant sampling period. The accuracy of Eq. (26) can be improved by decreasing the sampling period as suggested in the original definition, Eq. (3), of this time derivative. In practical applications the selection of the sampling period is based on the bandwidth requirements of the closed acceleration control loop, the latency requirements of some supervision action such as emergency shutdown, and the computational capacity of the implementation environment. Figure 6 depicts the indirect acceleration measuring scheme based on differentiation and predictive postfiltering. Three alternative implementation techniques are presented: fully analog, analog-digital, and fully digital. Analog polynomial predictors needed in the fully analog alternative were introduced in Ref. 16.

Linear State Observing. Instead of differentiation and (predictive) postfiltering, an optimized Kalman filter-based state observer can be used for estimating acceleration. An angular acceleration estimator is proposed by Bélanger (12), but the same principle can be used in estimating rectilinear acceleration. First, a stochastic state-space model is developed to rep-

Figure 6. Alternative implementations of indirect acceleration measurement using a cascade of a differentiator and a polynomial predictive postfilter. The prediction step is τ with the analog predictive filter and one sampling period with the digital ones.

resent the rotation angle $\theta(t)$:

$$\begin{cases} \frac{d\mathbf{x}}{dt} = \mathbf{A}\mathbf{x}(t) + \Gamma w(t) \\ y(t) = \theta(t) = \mathbf{C}\mathbf{x}(t) + e(t) \end{cases} \quad (27)$$

where $\mathbf{x}(t)$ is the state vector containing the angle, angular velocity, and angular acceleration; $w(t)$ is zero mean, white Gaussian noise with covariance q . When the modeled motion is not characterized by such a stochastic process but is merely deterministic, the parameter q may be considered as a pure filter parameter to be adjusted empirically. Further $\mathbf{A}$ is a (3×3) matrix, Γ is a (3×1) vector, and $\mathbf{C}$ is a (1×3) vector. The scalar output $y(t)$ is the actual angle measurement, $\theta(t)$, and $e(t)$ is the additive quantization error. The versatile Kalman filter (11,17) provides an optimal (minimum variance) solution to this observing problem (12). Before the model of Eq. (27) can be implemented by some digital processor, it must be discretized using one of the available continuous-time to discrete-time transformations (18).

For estimating the angular acceleration, Bélanger (12) postulates the fixed numerical model:

$$\left\{ \begin{array}{l} \frac{d\mathbf{x}(t)}{dt} = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix} \mathbf{x}(t) + \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} w(t) \\ y(t) = \begin{bmatrix} 1 & 0 & 0 \end{bmatrix} \mathbf{x}(t) + e(t) \end{array} \right. \quad (28)$$

The application discussed in that article is a single robot joint under proportional-derivative (PD) control with all the evaluated estimates corresponding to one-step-ahead prediction. Although only a marginal improvement of the angle

estimates is reported over those provided directly by the pulse encoder, the velocity estimate standard deviations are improved by a factor of 2 to 4 over the standard deviations of the plain backward-difference differentiation. In the estimate of the angular acceleration, there is an order of magnitude improvement. Hence even the fixed Kalman filter approach offers clear benefits by remarkably improving the accuracy of acceleration measurements. On the other hand, the computational complexity of the Kalman filter may be a limiting factor when the estimator must be adapted on-line with a high sampling rate. Nevertheless, such an adaptive approach offers satisfactory accuracy even under unknown and time-varying conditions.

An advantageous characteristic of such a linear state observer is that it provides estimates of all the state variables *simultaneously*. Therefore no explicit cascade processing structure is needed as in the case of differentiation and predictive postfiltering. When direct measurements of the velocity signal are available, the number of states, namely the dimension of the state vector $\mathbf{x}(t)$, is reduced from three to two. This simplifies the implementation of the optimized Kalman filter.

Conclusions of the Indirect Methods. As a conclusion, we can state that backward-difference differentiation cascaded with a polynomial predictive filter provides a computationally efficient indirect method for acceleration measurement. However, the method is applicable solely when the acceleration curve can be approximated piecewise by a low-degree polynomial. Practical degrees of the polynomial model are less than three or four because the available polynomial predictive filters for higher degree polynomials can offer only marginal noise attenuation capabilities (14).

Linear state observing is an attractive method when no such assumption on the polynomial nature of the acceleration curve can be made. By using an adaptive Kalman filter, estimators for time-varying acceleration behavior can be developed if only the required computational complexity can be supported by the available implementation hardware. Also, nonlinear state observers can be developed to handle the possible nonlinearities of the underlying dynamic system, as shown in the case of velocity estimation by Jaritz and Spong (11).

Direct Acceleration Measuring

Direct acceleration measuring is based on sensors that transform either linear or angular acceleration into an electrical variable: charge, voltage, or current. Acceleration measurement without a fixed reference requires the use of a seismic transducer (2). Those transducers detect relative motion between a fixed mounting base and a moving seismic mass. The seismic mass tends, due to inertia, to resist any changes in the movement. Acceleration sensors require an extremely small mass, which is connected to the frame through a stiff spring. This makes it possible to provide a wide operating bandwidth.

The currently available accelerometers usually need an external high-sensitivity preamplifier with a high-input impedance to amplify the weak primary signal (proportional to acceleration) to a suitable level for the following signal processing or data acquisition electronics. In recent designs, however, the critical preamplifier is often incorporated into the transducer housing. This is an obvious advantage because an application engineer can concentrate on higher-level

instrumentation electronics instead of highly sensor-dependent solutions. Now a high-level voltage output with moderate or high signal-to-noise ratio (SNR) is obtainable. On the other hand, some design flexibility is always lost with such integrated components.

Linear and Vibratory Acceleration. Compact piezoelectric accelerometers are widely applied to the measuring of linear acceleration due to their wide operating bandwidth, usually from a few Hz to several kHz. This wide bandwidth is particularly useful in precise inertial navigation and the measurement of vibratory acceleration. In inertial navigation the spatial acceleration of Eq. (13) is measured with three accelerometers, one accelerometer for each of the three dimensions (x, y, z). Vibratory acceleration may also have more than one dimension, but all these spatial dimensions are usually represented by individual linear components.

Piezoelectric accelerometers are charge-generating devices, and after the necessary charge-to-voltage conversion and preamplification, they can produce typical output voltages of 10 mV/g to 30 mV/g (where g is the acceleration of gravity, 9.8 m/s^2) with accuracies of a few percent (2,3). Hence the electrical measuring task is necessarily more demanding with low acceleration levels than it is with moderate or high accelerations. The operating range of such sensors is typically from zero to a few hundred or thousand g : s. Manufacturers of piezoelectric accelerometers include, e.g., the following companies (in alphabetic order): Endevco Corporation, PCB Piezotronics, Kistler, and Murata. For a comprehensive presentation of various types of accelerometers see Accelerometers.

We can model a piezoelectric accelerometer as a charge generator, which is connected in parallel with an internal capacitor C_T . The terminals of this capacitor are the actual output pins of the transducer. Therefore we can measure the voltage difference over these pins. When we connect a measuring cable to the terminals of the piezoelectric accelerometer, the cable and possible connectors introduce an additional capacitance C_C , which is summed to the internal capacitance. Further the input capacitance of the preamplifier C_I is an additional component of the total capacitance $C_\Sigma = C_T + C_C + C_I$. An ac-coupled voltage follower or an instrumentation amplifier is preferred to amplify the low voltage that is observed over the total input capacitance. Figure 7 illustrates the voltage follower-based measuring circuitry. Typical values of the total capacitance C_Σ range from 300 pF to 10 nF, and the value of the ac-coupling capacitor C_A is usually about 100 nF (2).

Figure 7. Voltage follower-based acceleration measuring scheme using a piezoelectric transducer.

Figure 8. Charge-to-voltage converter-based acceleration measuring scheme using a piezoelectric transducer.

Unfortunately, the voltage sensitivity of such a straightforward measuring system is inversely proportional to the total capacitance C_{Σ} (2). This may cause accuracy problems because, in an industrial operating environment, the cable capacitance C_C can change remarkably due to varying environmental conditions, such as humidity and dirt. Besides, the variation of C_C causes changes in the transfer function of the dynamical system formed by the sensor, cable, and preamplifier. These changes necessarily affect both the magnitude and phase (or delay) responses of the acceleration sensor.

Thus there is a natural demand toward integrated sensor modules, where the critical wiring would be of minimal length and the entire circuitry could even be hermetically sealed. Also the critical component values would be trimmed by the manufacturer during fabrication of the accelerometer module to provide constant voltage sensitivity and dynamical characteristics.

Charge amplifiers are widely used to preamplify the output of a piezoelectric acceleration transducer. They make use of an operational amplifier having a high open loop gain. A complete charge amplifier consists of two cascaded sections: a charge-to-voltage (C/V) converter and a trimmed voltage amplifier. Figure 8 illustrates a basic inverting C/V-converter, which is formed by using a capacitive feedback C_F . The voltage gain of this circuit is proportional to C_F/C_T . Here the possibly varying cable capacitance C_C appears between the summing point and circuit common. Because the voltage at the summing point is zero, C_C does not affect the provided voltage gain. However, the cable capacitance naturally affects the noise gain of the C/V-converter, which is proportional to $(C_T + C_C)/C_F$. Morrison (19) gives a short practical presentation of the implementation aspects of charge amplifiers. His discussion concentrates on the noise characteristics and the required component tolerances of charge-to-voltage converters. Hence the voltage sensitivity is subject solely to negligible variations due to changes in environmental conditions. On the other hand, a complete charge amplifier (C/V-converter cascaded with a standardization amplifier) is more complex than a simple voltage follower. Charge amplifiers can handle frequencies down to about 1 Hz (3-dB point). A detailed presentation and analysis of charge amplifier-based measurement circuits is given by Dally et al. (2).

Angular Acceleration. Although the angular acceleration can be measured indirectly using either a rotating angle sensor or a velocity sensor, the cumbersome noise-amplification problem associated with differentiators has motivated the efforts to develop transducers for direct sensing of angular acceleration.

Direct measuring of linear acceleration is in wide everyday use, but the angular acceleration sensors, particularly those with unlimited rotation angle, can still be considered as emerging devices. Therefore the measuring techniques to be discussed below are not yet used widely in practical applications.

Godler et al. (5) proposed a rotary acceleration transducer that senses the angular acceleration independently of the rotation velocity and has an unlimited rotation angle. This *mechanic-opto-electronic* sensor is intended for motor control and vibration control in robotics applications. It has an obvious advantage when compared with indirect measuring techniques: The bandwidth of the output filter can be made wider than that of the (predictive) postfilter attenuating the noise of the differentiator. This is due to the more advantageous shape of the introduced noise spectrum. Therefore the new sensor offers a wider acceleration bandwidth that could directly improve the performance of an acceleration control loop. Considering the structural details and laboratory experiments presented in Ref. 5, it can be concluded that the mechanic-opto-electronic angular acceleration sensor can provide comparable accuracy with the indirect time derivative methods when the base velocity ω of Eq. (6) is measured, for example, by a low-ripple dc tachogenerator. The sensor can provide a buffered voltage output, and hence its usage is very simple. No demanding preamplifiers are needed as with the piezoelectric accelerometers. Unfortunately, only evaluation prototypes were available when Ref. 5 was published in 1995.

Furukawa et al. (20) proposed a *piezoresistive* angular acceleration sensor for robotics applications. This sensor is manufactured by micromachining a small wafer of silicon. The micro acceleration sensor manufactured by integrated circuits (IC) technology has the advantage that the necessary measuring electronics can be integrated in the same chip design as the sensor itself. Therefore a compact, low-noise, and possibly even an intelligent accelerometer unit could be developed. The final accelerometer is so small that it can be mounted at most required places and will not disturb the primary motion of a robot arm. From the instrumentation point of view, the electronics required simply measures the change of sensor resistance, which is proportional to the angular acceleration. This could be accomplished using the Wheatstone bridge (21). In contrast to the proposed sensor of Godler et al. (5), this sensor operates solely within 0° to 360° angles. This accelerometer was still in the prototype phase when Ref. 20 was published.

Conclusions of the Direct Methods. Direct methods to measure linear acceleration are widely used because of the availability of accurate, compact, and low-cost accelerometers. They are far more accurate than indirect methods for wide acceleration bandwidths. However, in cases where a narrow bandwidth is adequate, either a direct or an indirect method can be applied with comparable results. The selection of an appropriate technique depends on the presence of distance or velocity sensors; if no other sensor type is needed in the specific application, it is natural to use only an accelerometer.

Angular acceleration sensors are not yet widely available as commercial products. The demand for such transducers will rise steadily as the performance requirements of various motion control applications increase. The basic components are presented in Refs. 5 and 20. Therefore, the field of direct angular acceleration measurement will become an important area of future research and development activities.

ACCELERATION MEASUREMENT ERRORS

Acceleration measurement errors are due to three primary sources: sensors, acquisition electronics, and signal processing algorithms. For an economical and robust measurement system, the total measurement error should preferably be evenly distributed into different parts of the entire instrumentation chain.

Errors of the Direct Acceleration Measurement

In direct acceleration measurement, the primary error sources are usually the acceleration sensor and the immediate acquisition electronics. This combined error is typically less than 2% to 5% with piezoelectric accelerometers when the measurement electronics design is based on the application notes of the corresponding sensor manufacturer. Within this moderately accurate range the errors related to sampling and analog-to-digital (A/D) conversion are easily controlled by careful selection of multiplexers, sample-and-hold (S&H) circuits, and A/D-converters. Garrett gives a thorough presentation of the different error types of computerized instrumentation systems in Ref. 4. Those error components are not acceleration measurement-specific but exist in all computerized data acquisition systems.

Errors of the Indirect Acceleration Measurement

In indirect acceleration measurement the approximative differentiation is the main source of noiselike error. On the other hand, when a state observer is used instead of differentiation and postfiltering, the accuracy and bandwidth of the state-space model of Eq. (27) become especially important. Pulse encoders and tachogenerators provide the base quantities, linear or angular displacement and velocity, for indirect acceleration measurement. The measurement error of such a base sensor is typically no more than 1%. However, there is a complicated dependence between the error of the base sensor and the final acceleration error, particularly when the velocity estimate is first calculated from encoder pulse information. This is due to the usual nonlinearity of velocity estimation algorithms (8,10).

To quantify the noise problem of the backward-difference differentiator, Eq. (26), we consider a simple numerical example. Let us assume that we are measuring linear motion with constant velocity of 1.00 m/s, and our dc tachogenerator has a 1% ripple in its output voltage. The output is sampled with a constant 1-ms sampling period T_s . Let $v(k) = 0.995$ m/s and $v(k-1) = 1.005$ m/s be two consecutive measurements of the linear velocity containing sensor-originated ripple. Now the simple estimate of the instantaneous acceleration $a(k) = -10$ m/s². Although the base velocity with the 1% ripple could be considered adequate for many velocity control applications, even this small error makes the direct utilization of the differentiator output impossible. Therefore postfiltering is needed to reduce the acceleration ripple down to an acceptable level. In off-line data acquisition a conventional analog or digital low-pass filter can be used to achieve a suitable SNR. However, in real-time applications a predictive filter can offer indisputable benefits as discussed earlier.

To get insight into the required bandwidth of the low-pass postfilter, let us consider the simple case where the constant velocity signal v_c is deteriorated by an additive sinusoid

ripple $A \sin 2\pi ft$. The available measurement signal $v_r(t)$ can be expressed as

$$v_r(t) = v_c + A \sin 2\pi ft \quad (29)$$

This signal is sampled using a sampling period of T_s . When we apply the differentiator of Eq. (26), the maximum erroneous acceleration a_m has the value

$$a_m = \frac{2A}{T_s} \sin \pi f T_s \quad (30)$$

If the amplitude A of the sinusoid ripple is 0.005 m/s, and the sampling period is the same as in the example above, we can calculate the maximum acceleration value a_m for different sinusoid frequencies. With $f = 500$ Hz, $a_m = 10.00$ m/s²; with $f = 50$ Hz, $a_m = 1.56$ m/s²; with $f = 5$ Hz, $a_m = 0.16$ m/s²; and with $f = 0.5$ Hz, $a_m = 0.02$ m/s². This shows clearly the trade-off between the bandwidth and the corresponding erroneous acceleration level.

Hence a very narrow-band lowpass filter is needed to keep the disturbing acceleration ripple moderate or low. This is an obvious motivation for the usage of polynomial predictive filters in real-time applications because they can provide an adequate prediction bandwidth even when a narrowband magnitude response is required.

Quantization of the velocity signal during the sampling process is also a potential source of remarkable acceleration error because the quantization noise is amplified similarly as the sensor-originated ripple by the differentiator. There are two basic alternatives to alleviate this problem: Either perform the differentiation in the analog domain or use high-resolution quantization. In practice, however, the analog alternative is less attractive due to the large dynamic range required. If an analog differentiator is employed, a scaling amplifier with a programmable gain is suggested to be placed in front of the A/D-converter. Besides the sensor ripple and quantization noise, the coefficient word length and precision of arithmetic operations have effects on the noise level which is observed in the output of the composite differentiator. All these are very critical in real-time applications because of the greatly limited filtering freedom.

Since there are many potential sources of significant acceleration error in indirect acceleration measurement, the total error (or signal-to-error ratio, SER) is largely dependent on implementation. Thus a careful error analysis is important when any indirect technique is used. Typically even in well-designed systems the true maximum errors are between 5% and 10% depending on the required acceleration bandwidth and the allowed delay. In some applications this error is mainly due to the overshoot of a postfilter output under transient conditions. Such error percentages are obtainable in vertical and horizontal transportation as well as in robotics applications.

SPECIFIC ACCELERATION MEASUREMENT METHODS AND APPLICATIONS

Our presentation has, for the present, concentrated on the main principles of the available acceleration measurement methods. The characteristics and implementation considerations were presented mostly for the pure "main-line" techniques: direct

measuring using accelerometers, as well as indirect measuring based on either differentiating and (predictive) postfiltering, or state-observing. Besides these straightforward and multipurpose methods, there exist a vast number of application-specific and application-tailored techniques that can provide an excellent base for future development and engineering activities.

Selective Review of the Advanced Literature

A collection of diverse acceleration measurement methods will be reviewed briefly here. The assortment consists solely of indirect measuring techniques, particularly techniques for indirect measuring of angular acceleration. Our emphasis is set intentionally on the angular acceleration measurement. Since there exist only a few commercial (and economical) angular accelerometers with unlimited rotation range, the indirect techniques are naturally of utmost importance.

Hoffmann de Visme (22) introduced a purely digital method for obtaining acceleration information of rotating shafts in 1968. His method is based on a rotating pulse encoder, and it gives good sensitivity and accuracy when a high pulse rate N (pulses per revolution) is available and a long measuring interval T can be tolerated. The estimated angular acceleration α (rad/s²) is given by

$$\alpha = \frac{2\pi(n_1 - n_2)}{NT^2} \quad (31)$$

where n_1 and n_2 pulses are counted in two successive intervals of duration T . This method suits well both for hardware and software implementations.

Dunworth (6) proposed a sophisticated digital instrument for the measurement of angular acceleration, in which a rotating pulse encoder is used. This method comprises a digital frequency register controlling a variable-rate pulse generator that tracks the incoming pulse rate in a closed-frequency control loop. The rate at which the pulse generator frequency needs to be corrected (incremented or decremented) corresponds to the present acceleration if the control loop is just locked on the input pulse rate. Acceleration resolution of 1% is easily achievable. Although Dunworth's instrument shares the possibly troublesome long measuring interval of Ref. 22, it still provides an interesting measuring procedure that is particularly well suited for application-specific integrated circuit (ASIC) implementation.

Smith et al. (23) reported on a direct software implementation of Eq. (31) in 1973. A pulse encoder with 10,800 pulses per revolution was used. They utilized the angular acceleration estimate for computing the electromagnetic torque of an electric motor. When the inertia of the rotating loaded component is known and assumed to stay constant, the torque can be calculated as the product of acceleration and inertia. The presented experimental results are in close agreement with the corresponding theoretically computed quantities, the maximum errors being no more than 5% to 10%.

Hancke and Viljoen (7) presented an acceleration measurement technique for a condition-monitoring application of a turbo generator where only one pulse per shaft revolution is available. This naturally causes serious constraints for the obtainable performance, namely for resolution and measuring interval. The time interval between two consecutive pulses is measured using a counter that is clocked by a high-frequency square wave. An interesting characteristic of the developed

method is that it can estimate the angular acceleration between pulse instants satisfactorily by extrapolation of the past two acceleration samples. This extrapolation is based on a ramp assumption, namely a first-degree polynomial model. Here the applicability of the first-degree polynomial model is justified by the obvious fact that the inertia of the rotating components is so high that the angular velocity cannot vary greatly between any two pulses. If the angular acceleration estimates corresponding to the latest two pulse instants are $\alpha(k-1)$ and $\alpha(k)$, the next acceleration sample, $\alpha(k+1)$, can be extrapolated as

$$\alpha(k+1) = \alpha(k) + [\alpha(k) - \alpha(k-1)] \quad (32)$$

Now linear interpolation can simply be used to compute the acceleration estimates at arbitrary instants between the discrete time indices k and $k+1$.

Kadhim et al. (24) presented a straightforward method for the measurement of steady-state and transient acceleration of a rotating motor shaft. They suggested the use of a slight modification of Eq. (31); three total pulse counts (c_1, c_2, c_3) are used instead of the two pulse count differences (n_1, n_2):

$$\alpha = \frac{2\pi(c_3 - 2c_2 + c_1)}{NT^2} \quad (33)$$

Also here the increase of the measuring interval T improves the accuracy of average acceleration. However, it increases as well the harmful delay between the instant when a measurement becomes available and the moment at which it applies. Kadhim et al. have suggested that for off-line applications, low-degree polynomial curve-fitting techniques can improve the signal-to-error ratio. Also on-line curve-fitting techniques are readily available for such a purpose, as discussed above in "Predictive Postfiltering."

Laopoulos and Papageorgiou (10) proposed an angular acceleration measurement instrument based on a 24-bit signal processor in 1996. They computed the difference of the pulse encoder's output frequency ΔF for two consecutive pulse cycles with the measuring interval of ΔT . Hence the angular acceleration is directly proportional to $\Delta F / \Delta T$. In this division both the frequency difference and the measuring interval should have a high resolution to keep the amplified quantization noise low. To provide this necessity, a 24-bit binary counter was applied to count the period of an encoder pulse cycle using a 20 MHz clock. The angular acceleration is calculated from

$$\alpha = \frac{2\pi \Delta F}{N \Delta T} \quad (34)$$

Notice the varying length of the measuring interval ΔT which depends on the availability rate of fresh encoder pulses. With this method the accuracy of the (nonuniformly sampled) acceleration estimate is determined largely by the random jitter corrupting the nominal encoder pulse length. A high-performance, uniformly sampled acceleration measurement method can be constructed by combining the predictive synchronization and restoration method of Pasanen et al. (8) with the accurate acceleration measurement procedure of Ref. 10.

All the methods discussed above are based on the noise-amplifying difference function: either a pulse count difference or a frequency difference. Schmidt and Lorenz (25) use another possible indirect approach; they propose a computationally

efficient acceleration observer for a dc servo drive. Their acceleration observer uses two measured input quantities: the shaft angle and the actual current of the dc motor. The entire state-observer contains a velocity observer block that provides the estimate of the angular velocity for the following acceleration observer. It should be noted that this state-observer is intimately connected to the overall controller structure. A sampling period of 1.25 ms was successfully applied, and all the computations were performed using high-precision floating-point arithmetic. The observer-generated acceleration feedback was shown to improve the control performance remarkably.

Evaluative Discussion of the Specific Methods

The development of indirect measuring instruments of angular acceleration began in the late 1960s. Then there were two important advancements that made the classic work of Hoffmann de Visme (22) and Dunworth (6) possible: the emerging availability of rotating encoders with high-pulse rates and the rapid development of solid-state digital electronics and integrated circuits. The early instrumentation techniques were strongly technology driven without a strict connection to any specific application.

At the beginning of the 1970s no outstanding innovations occurred in the field while available methods continued to evolve, such as that of Smith et al. (23) which was implemented in a general-purpose minicomputer. Nevertheless, with the development of high-resolution optical encoders came an increase in the number of successful industry applications, and acceleration feedback provided opportunities to increase functional performance.

In the late 1970s and during all of the 1980s, the availability of microprocessors and microcontrollers turned the instrumentation engineers' interests almost entirely from pure hardware implementations to software implementation of acceleration measurement procedures. During that productive period the entire control and instrumentation industry began to introduce novel microprocessor-based products, pushing the need for acceleration feedback mostly to the background.

Finally, at the very beginning of the 1990s, it became evident that the performance of motion control systems in the well-established robotics and servo industry could be improved economically by using additional acceleration feedback. Acceleration feedback is advantageous because it allows higher overall stiffness without requiring higher bandwidths of the velocity and position control loops in servo applications. Essentially, as is pointed out by Schmidt and Lorenz (25), the acceleration feedback acts like an "active inertia." Along with this application-pull factor in the resurgence of interest in acceleration feedback, there were the traditional technology-push cases. The recent development of implementation techniques (signal processors and application-specific integrated circuits), signal-processing algorithms, and estimation methods has opened a new era of growth for indirect techniques in acceleration measurement. Therefore it is foreseeable that both the availability of high-performance methods (10,12,25), and their successful applications are going to increase steadily.

CONCLUSION

A comprehensive variety of direct and indirect techniques exist for acceleration measurement. Application-tailored measurement techniques currently predominate in real-time systems,

and computerized instrumentation, in general, is becoming widespread. However, mixed analog-digital processing offers some benefits over pure digital signal processing in cases where the primary measurement quantity is available as an analog voltage or current.

The field of linear and vibratory acceleration measurement is stable and well developed. A complete assortment of instruments for vibration measurement is available, for example, from Bruel and Kjaer Instruments. The main focus of future development is in the intelligent postprocessing of accelerometer data and the automatic interpretation of measurement results. The performance and capabilities of integrated accelerometer modules will continue to increase as low-cost accelerometers and more novel applications are introduced such as is presently being seen in the field of technical diagnostics.

The whole field of angular acceleration measurement is expanding as both direct and indirect techniques are evolving to new applications. There exist two principal challenges for the research and development community: to develop economical and accurate angular accelerometers for unlimited rotation range and to create wideband indirect techniques with a low signal-to-error ratio. It is likely that the entire technology profile of acceleration measurement will advance in the early twenty-first century.

DENSITY MEASUREMENT

Density of a substance is defined as the mass per unit volume ($\rho = m/V$) under fixed conditions. The term is applicable to solids, liquids, and gases. The density depends on temperature and pressure. This dependence is much greater in gases. Although there are many different units, usually the values of density are given in terms of grams per cubic centimeter.

Specific gravity (SG) is an abstract number expressing the ratio of the density of one substance to the density of another reference substance, both obtained at the same temperature and pressure. For solids and liquids, water is taken as the reference substance, whereas air is the reference for gases. The specific gravities of solids, liquids, and gases under reference

conditions may be expressed by

$$\text{Liquid (or solid) SG} = \frac{\text{density of liquid (or solid)}}{\text{density of water}}$$

$$\text{Gas SG} = \frac{\text{density of gas}}{\text{density of air}}$$

Care must be taken to define standard conditions under which the densities or specific gravities are measured, so as not to introduce errors due to variations in measurement conditions. Commonly accepted sets of conditions are Normal Temperature and Pressure (NTP) and Standard Temperature and Pressure (STP). NTP is usually used for solids at the temperature 0°C and a pressure of 760 mm mercury. The STP is used for solids and fluids at a temperature of 15.6°C and a pressure of 1 atm (or 101.325 kPa).

Density measurements are a significant part of instrumentation systems. In many processes, the density is taken as the controlling parameter for the rest of the process; therefore, accurate measurements are necessary. Density measurements are made for at least two important reasons: (1) to determine the mass and volume of products, and (2) to assess the quality of products. In many industrial applications, density measurement ascertains the value of the product. A list of manufacturers offering different types of density meters is provided in Table 1.

In many modern applications, densities are obtained by sampling techniques. However, there are two basic approaches: static density measurements and dynamic (on-line) density measurements. Within each concept, there are many different methods available, depending on physical principles and process characteristics. In many cases, application itself and process conditions determine the best suitable method to be employed. Generally, static methods are well developed, lower in cost, and more accurate. Dynamic samples are expensive, highly automated, and use microprocessor-based signal processing devices. Nevertheless, today, many static methods are also computerized, offering easy to use, flexible, and self calibrating features.

There is no single, universally applicable density measurement technique available. Different methods must be employed for solids, liquids, and gases. Here, some of these measurement techniques and the devices involved are introduced in the relevant sections of solid, liquid, and gas density measurements. Further detailed discussions are given for specific types of instruments.

DENSITY AND DENSITY MEASUREMENT OF SOLIDS

Theoretically, the density of solids may vary both with operating pressure and temperature. However, in many applications, the effect of pressure may be neglected in solids and incompressible fluids. In some cases, the effect of temperature can also be neglected if the operational temperature is not significantly higher from the temperature at which density measurements are made, or a high degree of accuracy is not required.

The volumetric effect of temperature on the density of liquids or solids may be expressed as

$$V = V_0(1 + \beta \Delta t) \quad (1)$$

where β is the coefficient of expansion of solid or liquid which is consistent with the temperature units used.

As the mass is same before and after temperature rise, the change in density is inversely proportional to the change in volume and can be expressed as

$$\rho/\rho_0 = V/V_0 \quad (2)$$

If the solid sample has a regular shape and uniform, the determination of its density is a simple task. Once the volume and mass of the solid are known, the density may be found by using the basic ratio: density = mass/volume (kg/m^3). In order to avoid errors, the weights and volumes must be determined by using accurate instruments.

However, in many applications, solids have different constituents and are made up from the mixture of different materials. The volumetric ratios of constituents may also change. A common method of determining the density of irregular and nonuniform samples is the hydrostatic weighting. In some cases, dynamic methods are employed, such as radioactive absorptions and ultrasonic methods.

Powdered solids occlude air between or inside individual particles, giving rise to apparent, bulk, tap, effective, and true densities. The apparent density includes the air lodged in the cavities or pores, and the density is determined without filling up the pores. The numerical value of the density depends on

the amount of compacting employed (tap density) which can be achieved by moderate mechanical means and also embedded foreign particles (effective density). For true density, it is necessary to dislodge the air by means of suitable liquids or gases. Special pycnometers are developed for this purpose.

DENSITY AND DENSITY MEASUREMENT OF LIQUIDS

Overall density of fluid is the ratio of total mass to total volume. Point density is the ratio of molecular mass in a volume element centered at a point to the element's volume, the volume being much smaller than the total volume. As in the case of solids, the densities of liquids are affected by temperature and pressure. Most liquids are incompressible; therefore, pressure effects may be neglected. Nevertheless, in determination liquid densities, the effects of temperatures must carefully be monitored as indicated in equations (1) and (2).

The measurements of densities of fluids are much more complex than solids; therefore, there are many different techniques developed. Hydrometers, pycnometers, hydrostatic weighing, flotation methods, drop methods, radioactive methods, optical methods, and so on are typical examples of measuring liquid densities.

Difficulties in the measurement of densities of fluids is due to complexities in processes, variations of fluid densities within the process, and the diverse characteristics of the process and fluids themselves. Some of these methods are custom designed and applicable to special cases only. Others are very similar in principles and technology, and can be used for many different type of fluids. At the present, apart from conventional methods, many novel and unusual techniques are reported to be undergoing extensive development and research stages. For example, densitometers based on electromagnetic principles may be given as a part of intelligent instrumentation systems.

Depending on the application, fluid densities can be measured both in *static* or *dynamic* forms. In general, static density measurements of fluids are well developed, precise, and have greater resolution than most dynamic techniques. Pycnometers and buoyancy are examples of static techniques that can be adapted to cover small density ranges with a high resolution and precision. Nowadays, many manufacturers are offering dynamic instruments previously known to be static. Also, many static density measurement devices are computerized, coming with appropriate supporting hardware and software. In general, static type measurements are employed in laboratory conditions, and dynamic methods are employed for real time measurements where properties of fluids vary from time to time.

DENSITY AND DENSITY MEASUREMENT OF GASES

The density of a gas will vary significantly with absolute pressure. Increasing the pressure of a gas at a constant temperature causes the gas to be compressed to a smaller volume of the same mass, thus increasing the density. Boyle's Law states that for ideal gases or a mixture of ideal gases at a constant temperature, the volume, V , is inversely proportional to the absolute pressure; that is

$$V = \text{Constant}/P \quad (3)$$

The following formula may be written for comparing the volumes of an ideal gas at a constant temperature but at different pressures, P :

$$V/V_0 = P_0/P \quad (4)$$

Charles' Law states that the density of gas will vary significantly with absolute temperature, T . Increasing the temperature of a gas at constant pressure causes the gas molecules to increase their activities and motions in relation to each other, whereby increasing the volume and decreasing the density of gas for the same mass. Charles' Law may be stated in the following form:

$$V/V_0 = T/T_0 \quad (5)$$

Charles' and Boyle's Laws can be combined to yield the Ideal Gas Law as

$$PV = nRT \quad (6)$$

where R is the universal gas constant in consistent units, and n is the number of moles.

The Ideal Gas Law can also be expressed in the following form:

$$V/V_0 = TP_0/T_0P \quad (7)$$

During gas density measurements, when variations in pressure and temperature are small, the temperature and pressure act almost independently of each other; thus, estimates of reasonable accuracy can be obtained by adding percentage temperature and pressure deviations from a given set of conditions.

Often, density measurements of Non-Ideal Gases are required which do not act as ideal gases at certain conditions, such as at high pressures, low temperatures, or under saturation. Their non-ideal behavior may be accounted for by modifying the Ideal Gas Law with a Z factor, as

$$V/V_0 = TP_0Z/T_0PZ_0 \quad (8)$$

The Z factor is numerically dependent on operating conditions and can be read from generalized compressibility charts, as shown in Fig. 1, with a reasonable degree of accuracy.

Due to the above reasons, extra care and further considerations are necessary in gas density measurements. For example, perfect gases contain equal numbers of molecules under same conditions and equal volumes. Therefore, molecular weights may be a better option in density measurements. Flask methods, gas balance methods, optical methods, x-ray methods are typical techniques employed for gas density measurements.

MAGNETIC AND VIBRATIONAL METHODS

Magnetic Method

This method is used for both liquids and gases. It allows the determination of effects of pressures and temperatures down to cryoscopic range. Basically, the device contains a small ferromagnetic cylinder, encased in a glass jacket. The jacket and ferromagnetic material combination constitutes a buoy

Figure 1. Generalized gas compressibility chart. In many applications, densities of Nonideal Gases are required. Nonideal gases do not act as ideal gases at certain conditions, such as at high pressures, low temperatures, or under saturation. Their behavior may be accounted for by modifying the Idea Gas Law with a Z factor. The Z factor is numerically dependent to different operating conditions and can be read from generalized compressibility charts such as this one.

or float. The cylinder is held at a precise height within the medium by means of solenoid which is controlled by a servo system integrated with a height sensor. The total magnetic force on the buoy is the product of the induced magnetic moment by the solenoid and the field gradient in vertical direction. The total magnetic force at a particular distance in vertical direction in the solution compensates the difference in the opposing forces of gravity (downwards) and buoyancy (upwards) exerted by the medium, through the Archimedes' principle. The magnetic force is directly proportional to the square of the current in the solenoid. If the buoyant force is sufficient to make the ferromagnetic assembly float on the liquids of interest, the force generated by the solenoid must be downward to add to the force of gravity for equilibrium.

By the use of precision resistors and accurate differential voltmeters, the measurements simply consist of reading and recording voltages. Calibrated curves obtained from standard solutions of known densities must be used for a given buoy, to be referred to solutions under test. Buoys cover a limited range of density; hence, many buoys must be provided to cover large density ranges. The complete measurement of a sample requires about 5 minutes for insertion, temperature, and buoy stabilization. The sensitivity of the devices is in the region of ± 0.01 mV with a tight temperature control. Their uses can also be extended into applications such as the specific gravity measurements under low pressures and density measurements of hazardous fluids.

In some instruments, a smaller buoy is used containing tiny permanent magnets. By this way, the sample volume and errors from adhering bubbles are reduced, and the current in the solenoid is linearized as a function of density. This provides a greater precision in calibrations. In other instruments, a rotating magnetic field is superimposed on a standard device via remotely situated field coils in such a way that controlled rotation of the immersed buoy can be accomplished. Since the rate of rotation is proportional to the viscosity of the medium, the density and viscosity are determined simultaneously.

Vibrational Methods

Devices based on vibrations are used for liquid and gas density measurements. They make use of the changes in natural

frequency of vibration of a body containing fluid in it or surrounded by it. The natural frequency of the vibrating body is directly proportional to the stiffness and inversely proportional to the combined masses of the body and the fluid. It also depends on the shape size and elasticity of materials, induced stresses, and the total mass and mass distribution of the body. Basically, the vibrations may be equated to the motion of a mass attached to a mechanical spring. Hence, expression for the frequency may be written as

$$\text{Resonant frequency} = \sqrt{(K/(M + k\rho))} \quad (9)$$

where K is the system stiffness, M is the transducer mass, k is the system constant, and ρ is the fluid density.

A factor common to all types of vibrating element densitometers is the problem of setting the element in vibration and maintaining its natural resonance. There are two drives available for this purpose, these being the magnetic drives and the piezoelectric drives.

Magnetic Drives. Magnetic drives of the vibrating element and the pick up sensors of vibrations are usually achieved using small coil assemblies. Signals picked up by the sensors are amplified and fed back for maintaining the disturbing forces on the vibrating body.

In order to achieve steady drives and minimize external effects, vibrating elements may be made from nonmagnetic materials. In this case, small magnetic armatures are attached to maintain vibrations.

The main advantage of the magnetic drive and pick up system is that they are noncontact methods. They use conventional copper windings, are simple to construct, and are reliable within the temperatures of -200 to $+200^\circ\text{C}$.

Piezoelectric Drives. The piezoelectric drives are mechanically fixed on the vibrating element by adhesives. Therefore, attention must be paid for the careful placement of the mount in order to reduce the strain experienced by the piezo elements, due to thermal and pressure stresses while the instrument is in service. A wide range of piezoelectric materials are available to meet the requirements. These materials demonstrate good temperature characteristics as in magnetic drive types. They have high impedances, thus making the signal conditioning circuitry relatively easy and cost effective.

A number of different types of densitometers are developed which utilize properties of vibrating bodies in liquids and gases. The three main commercial types are introduced here. In all cases, vibrations are maintained either through magnetic drives or piezoelectric drives. In recent years, the coriolis effect is used for density measurements yielding a new type of density meters.

In general, vibrating element meters have advantages and disadvantages. The advantages are:

1. They are suitable for both liquid and gas density measurements under static and dynamic conditions, with reasonable accuracy.
2. Real-time measurements may easily be interfaced to computers since they operate on frequencies and are inherently digital.
3. They are relatively robust and easy to install.

4. Programmable and computerized versions are available. Programmable versions make all the corrections automatically. They provide the output of process density, density at reference conditions, relative density, specific gravity, concentration, solid contents, etc.

The main disadvantage is that they do not relate directly to primary measurements; therefore, they have to be calibrated. They also have problems of measuring densities of multi-phase fluids.

Vibrating Tube Densitometers

These devices are suitable in highly viscous liquids or slurry applications. The mode of operation of vibration tube meters is based on the transverse vibration of single or twin tubes as shown in Fig. 2. The tube and the driving mechanisms are constrained to vibrate on a single plane. As the liquid moves inside the tube, the density of the entire mass of liquid is measured. The tube length is approximately 20 times greater than the tube diameter.

One major design problem with the vibrating tube method is the conflict to limit the vibrating element to a finite length, and also the accuracy of fixing the nodes. Special attention must be paid to avoid any exchange of vibrational energy outside the sensory tube. The single tube has the disadvantage of presenting obstructing to the flow, thus having some pressure losses. The twin tubes, on the other hand, offer very small blockage, and they can easily be inspected and cleaned. Their compact sizes are another distinct advantage. In some densitometers, the twin tubes are designed to achieve a good dynamic balance with the two tubes vibrating in anti-phase. Their nodes are fixed at the ends, demonstrating maximum sensitivity to installation defects, clamping, and mass loadings.

The main design problems of the vibrating tube sensors are in minimizing the influence of end padding and overcoming the effects of pressure and temperature. Bellows are used at either ends of the sensor tubes to isolate the sensors from external vibrations. Bellows also minimize the end loadings due to differential expansions and installation stresses.

The fluid runs through the tubes; therefore, it does not need pressure balances. Nevertheless, in some applications, the pressure stresses the tubes, resulting in stiffness changes.

Figure 2. Vibrating tube densitometer. A tube containing fluids is vibrated at resonant frequency by electromagnetic or piezoelectric vibrators. The tube and the driving mechanisms are constrained to vibrate on a single plane. The resonant frequency is a function of the density of the fluid moving inside the tube. The tube is isolated from the fixtures by carefully designed bellows. These devices are not suitable in highly viscous liquids or slurry applications. The tube length is approximately 20 times greater than tube diameter.

Some manufacturers modify the tubes to minimize the pressure effects. In these cases, corrections are necessary only when high accuracy is needed. The changes in the Young's modulus with temperature may be reduced to almost zero by using Ni-span-C materials whenever corrosive properties of fluids permit. Usually, manufacturers provide pressure and temperature correction coefficients for their products.

It is customary to calibrate each vibration element densitometer against other methods as a transfer of standards. Often, the buoyancy method is used for calibration purposes. The temperature and pressure coefficients are normally found by exercising the transducer over a range of temperatures and pressures on some liquid of well known properties. Prior to calibration, the vibration tube densitometers are subjected through a programmed burn-in cycle for stabilization against temperatures and pressures.

Vibrating Cylinder Densitometers

A thin walled cylinder, with a 3 to 1 ratio of length versus diameter, is fixed with stiff ends. The thickness of the wall of the cylinder varies from 25 to 300 μm , depending on the density range and type of fluid used. The cylinder can be excited to vibrate in a hoop mode by magnetic drives mounted either in or outside the cylinder.

For good magnetic properties, the cylinder is made from corrosion-resistant magnetic materials. Steel such as FV520 is used for the purpose. Such materials have good corrosion resistance characteristics. Unfortunately, due to their poor thermoelectric properties, they need extensive temperature corrections. Often, nickel iron alloys such as Ni-span-C are used to avoid temperature effects. Especially since once correctly treated, the Ni-span-C alloy has near zero Young's modulus properties. Since the cylinder is completely immersed in the fluid, there are no pressure coefficients.

The change in the resonant frequency is determined by the local mass loading of the fluid in contact with the cylinder. The curve of frequency against density is nonlinear and has a parabolic shape, thus requiring linearization to obtain practical outputs. The resonant frequency range varies from 2 to 5 kHz depending on the density range of the instrument. The cylinders need precision manufacturing and, thus, are very expensive to construct. Each meter needs to be calibrated individually for different temperatures and densities to suit specific applications. In the case of gas density applications, gasses with well known properties such as pure argon or nitrogen are used for calibrations. In this case, the meters are subjected to gas environment with controlled temperature, and pressure and calibration curves are achieved by repetitions to suit requirements of individual customers for their particular applications. In the case of liquids, the meters are calibrated with liquids of known density, or they are calibrated against another standard such as pycnometer or buoyancy type densitometers.

Vibration cylinder type densitometers have zero pressure coefficients and they are ideal for liquidised gas products or refined liquids. Due to relatively small clearances between cylinder and housing, they require regular cleaning. They are not suitable with liquids or slurries with high viscous properties.

Tuning Fork Densitometers

These densitometers make use of the natural frequency of a

Figure 3. Tuning fork densitometer. Twin forks are inserted into the liquid or gas media whose density needs to be measured. Since the natural frequency of the forks is a function of the density of the media, small changes in the natural frequencies must be monitored accurately. Calibration is necessary in each application.

low mass tuning forks, shown in Fig. 3. In some cases, the liquid or gas is taken into a small chamber in which the electromechanically driven forks are situated. In the other cases, the fork is inserted directly into the liquid. Calibration is necessary in each application.

Coriolis Densitometers

Another type of vibrational density meter is based on the coriolis principle. The device is similar in vibrating tube methods with slight variations in physical design. They are comprised of sensors and a signal processing transmitters. Each sensor consists of one or two flow tubes enclosed in a sensor housing. The sensor tubes are fixed at one end and free at the other end, shown in Fig. 4. The sensor operates by applying Newton's Second Law of motion ($F = ma$).

Inside the housing, the tubes are vibrated at their natural frequencies using drive coils and a feedback circuit. This resonant frequency of the assembly is a function of the geometry of the element, materials of construction, and mass of the tube assembly. The tube mass is comprised of two parts: the mass of the tube itself and the mass of the fluid inside the tube. The mass of the tube is fixed for a given sensor. The mass of fluid in the tube is equal to the fluid density multiplied by the volume. Since the tube volume is constant, the frequency of oscillation can be directly related to the fluid density. There-

Figure 4. Coriolis densitometer. Each sensor consists of one or two flow tubes enclosed in a sensor housing. Inside the housing, the tubes are vibrated at their natural frequencies using drive coils and a feedback circuitry. This resonant frequency of the assembly is a function of the geometry of the element, material of construction, and mass of the tube assembly. Vibration of the tube is detected and related to the mass and flow rate of the fluid. They are manufactured in various shapes and sizes.

fore, for a given geometry of a tube and the material of the construction, the density of the fluid can be determined by measuring the resonant frequency of vibration. Temperature sensors are used for overcoming the effects of changes in the modulus of elasticity of the tube. The fluid density is calculated using a linear relationship between the density and the vibrations of the tube and calibration constants.

Special peripherals, based on microprocessors, are offered by manufacturer for a variety of measurements. However, all density peripherals use the natural frequency of the sensor coupled with the sensor temperature to calculate the on-line density of the process fluid. Optional communication, interfacing facilities, and appropriate software are also offered. These devices come in different shapes and sizes.

WEIGHT/WEIGHING SYSTEM/MASS MEASUREMENT METHODS

Pycnometric Densitometers

Pycnometers are static devices used for measuring densities of liquids and gases. They are manufactured as fixed volume vessels which can be filled with sample fluids. The density of the fluid is measured by weighing the sample with the vessel. The simplest version consists of a glass vessel in the shape of a bottle with a long stopper containing a capillary hole as shown in Fig. 5. The volume and variation of volume with temperature has been accurately determined. The capillary is used to determine the exact volume of the liquid, thus giving high resolution when filling the pycnometer. If the weight of the empty pycnometer is W_1 and the weight of the pycnometer, when containing a volume V of liquid at temperature t , is W_2 , the density of liquid ρ_1 may be calculated directly from

$$\rho_1 V = W_2 - W_1 \quad (10)$$

Figure 5. Pycnometer. A fixed volume container is filled with liquid and weighed accurately. The capillary is used to determine the exact volume of the liquid, thus giving high resolution when filling the pycnometer. For accuracy and good precision in results, the bottle must be cleaned after each measurement, the temperature must be kept constant, and precision balances must be used. It is necessary to apply accurate buoyancy and thermal expansion corrections.

For accuracy and good precision in results, ultimate care must be exercised during measurements. That is, the bottle must be cleaned after each measurement, the temperature must be kept constant, and precision balances must be used. For precise measurements, it is necessary to apply buoyancy and thermal expansion corrections. In some cases, to ensure filling of the pycnometer, twin capillary tubes are used. The two capillaries, made in glass, are positioned such that fluid can be driven into the vessel under vacuum conditions. Accurate filling to graduation marks on capillary is then made.

The pycnometers have to be light weight, strong enough to contain samples, and nonmagnetic for accurate weighing to eliminate possible ambient magnetic effects. Very high resolution balances have to be used to detect small differences in weights of gases and liquids. Although many pycnometers are made of glass, they are also made in metals to give enough strength for the density measurements of gases and liquids at extreme high pressures. In many cases, metal pycnometers are necessary for taking samples from the line of some rugged processes.

Pycnometers are used, Fig. 6, for measuring density of solid substances, such as carbon black, cement, fibers, ceramics, charcoals, fertilizers, pharmaceutical and powdered materials, *etc.* The density is computed from the mass difference between the pycnometer filled with sample together with a displacer fluid which penetrates into pores of the solid, and with fluid only. In some cases, mercury is used as the displacing liquid. The accuracy increases with the increasing quantity of solid which can be used. In powder technology, pycnometers are used to measure the true volume of the solid materials by employing Archimedes' principle of fluid displacement. The displaced fluid is a gas which can penetrate the finest pores to assure maximum accuracy. Usually, helium is used because of its small atomic dimension, thus penetrating into crevices and pores effectively.

The pycnometers have advantages and disadvantages. The advantages are that if used correctly, they are accurate and can be used for both density and specific gravity measurements. The disadvantages are

1. Great care must be exercised for accurate results
2. The sample has to be taken off-line with consequent time lag in results. This creates problems of relating samples to the materials that exist in the actual process
3. High precision pycnometers are expensive. They require precision weighing scales and controlled laboratory conditions. Specialized techniques must be employed to take samples in high pressure processes and hostile conditions such as offshore installations.

Hydrostatic Weighing Densitometers

These devices are suitable for solid and liquid density measurements only. The density of a solid is often measured by weighing it first in air, and afterwards in a suitable liquid of known density. The latter weighing is done by suspending the solid under the pan of a precision balance by means of a very thin wire. A typical commonly used example of such devices is the Westphal balance, as shown in Fig. 7. If the weight of the plummet in air is W_a , its volume, V , and its weight when suspended in liquid,

Figure 6. Use of a pycnometer for porous or powdered solids. Pycnometers are used for measuring density of solid substances, such as carbon black, cement, fibers, ceramics, charcoals, fertilizers, pharmaceutical, and powdered materials, and so on. In powder technology, pycnometers are used to measure the true volume of the solid materials by employing Archimedes' principle of fluid displacement. The displacing fluid is usually helium gas which can penetrate the finest pores to assure maximum accuracy. In some cases, water, mercury, or other fluids are used as displacers.

W_1 , the equilibrium of vertical forces on the plummet gives

$$W_1 + \rho_1 V - W_a = 0 \quad (11)$$

from which the density ρ_1 at the temperature t may be calculated.

The inaccuracies of this type of device are mainly limited by the irregularity of meniscus around the wire, particularly in the case of water and aqueous solutions. The wetting of the wire may be improved by covering it electrolytically with platinum black.

A common device using hydrostatic weighing of liquids consists of a U-tube which is pivoted on flexible end couplings. A typical example is shown in Fig. 8. The total weight of the tube changes, depending on the density of fluid flowing through it. The change in the weight needs to be measured accurately, and there are a number of methods employed for it. The most common commercial meters use a force balance system. The connectors are stainless steel bellows. In some cases, rubber or other materials are used, depending on the process fluid characteristics and the accuracy required. There are temper-

Figure 7. Hydrostatic weighing densitometers. The density of a solid is often measured by weighing it first in air, afterwards in a suitable liquid of known density. The latter weighing is done by suspending the solid under the pan of a precision balance by means of a very thin wire. A typical commonly used example of such devices is the Westphal balance. Riders are used for precision measurements. Accurate temperature measurement is necessary.

ature, flow rate, and pressure limitations due to bellows, and the structure of the system may lead to a reading offset. The meter must securely be mounted on a horizontal plane for best accuracy.

The hydrostatic weighing methods of liquids give continuous readings for two phase liquids such as slurries, sugar solutions, powders, etc. They are rugged, give accurate results, and are used for the calibration of the other liquid density transducers. However, they must be installed horizontally on a solid base; hence, they are not flexible enough to adapt for any process. Thus, the process must be designed around it.

Balance Type Densitometers

Balance type densitometers are based on gravity and/or weighing principles, and they are suitable for liquid and gas density measurements. Manufacturers offer many different types; four most commonly used ones are discussed below.

Balanced-Flow Vessel. A fixed volume vessel, as shown in Fig. 9, is employed for the measurements. While the liquid or gas is flowing continuously through the vessel, the total assembly is weighed automatically by a sensitive scale, a spring balance system, or a pneumatic force balance transmitter. Since the volume and the weight of the fluid are known, the density

Figure 8. Hydrostatic weighing. This device consists of a U-tube which is pivoted on flexible end couplings. The total weight of the tube changes depending on the density of fluid flowing through it. The change in the weight needs to be measured accurately. There are temperature, flow rate, and pressure limitations due to bellows and the structure of the system may lead to a reading offset. The meter must securely be mounted on a horizontal plane for best accuracy.

Figure 9. Balanced-flow vessel. Liquid or gas flows through a fixed volume vessel. The vessel is weighed continuously by a sensitive scale while the fluid is flowing through it. Since the volume and the weight of the fluid are known, the density or specific gravity can be calculated and scaled in respective units.

or specific gravity can easily be calculated and scaled in respective units. In the design process, extra care must be exercised for the flexible end connections.

Buoyancy Hydrostatic-Weighing Methods. The buoyancy method basically uses Archimedes' principle. A displacer with a known mass and volume is immersed in the liquid whose density is to be measured. Position of the displacer is kept constant by bellows, as exemplified in Fig. 10. Once the mass, the volume, the displacer, the bellow position, and pressure are known, the density of the liquid can be calculated. However, some corrections need to be made for cubicle expansion coefficients of the displacer and the temperature of the process. Buoyancy type densitometers give accurate results, and they are used for the calibration of the other liquid density transducers.

Chain Balanced Float. In this system, a self centering fixed volume submerged plummet is used for density measurements, as illustrated in Fig. 11. The plummet is located entirely under the liquid surface. At balance, the plummet operates without friction, assuming a stable position based on mass balance tech-

Figure 10. Buoyancy hydrostatic-weighing method. A displacer with a known mass and volume is immersed in the liquid whose density is to be measured. The displacer is kept in position by sensitive balancing bellows. Buoyancy type densitometers give accurate results, and they are used for the calibration of the other liquid density transducers.

Figure 11. Chain balanced float. The fixed volume and weight plummet totally suspended in the liquid assumes equilibrium position depending on the density. The force exerted by the chains on the plummet is a function of plummet position; hence, the measured force is proportional to the density of the liquid. Any change in the density process causes the plummet to move to a new equilibrium point. In some cases, the plummet contains a metallic transformer core which transmits changes in the position to be measured by a pick up coil or a linear variable transformer (LVDT).

nique. The effective weight of the chain on the plummet varies, depending on the position of the plummet which, in turn, is a function of the density of the liquid. Any change in the density of the process causes the plummet to move to a new equilibrium point by transferring the chain weight between the reference point and the plummet. In some cases, the plummet contains a metallic transformer core which transmits changes in the position to be measured by a pick up coil or a linear variable transformer (LVDT). When LVDTs are used, the voltage differential, a function of plummet displacement, is calibrated as a measure of variations in density or specific-gravity. A resistance thermometer bridge is used for the compensation of temperature effects on density. The range of the instrument can be from 0.5 g/mL to 3.5 g/mL. Their accuracy is in the region of $\pm 3\%$ of the range. Viscosity limits (50 centipoise) and flow rates of the liquid (2 to 3 L/min) are the main limitations.

Gas Specific Gravity Balance. A tall column of gas is weighed by a float located at the bottom of the vessel. This weight is translated into the motion of an indicating pointer which moves over a scale graduated in units of density or specific gravity. This method can be employed in the density measurements of many gases.

Buoyancy Gas Balance. In this instrument, a displacer is mounted on a balance beam in a vessel, shown in Fig. 12. The displacer is balanced for air, and the manometer reading is noted at the exact balance pressure. The air is then displaced by gas, and the pressure is adjusted until the same balance is restored. The ratio of the pressure of air to pressure of gas is then the density of gas relative to air. This method is commonly applied under laboratory conditions and is not suitable

Figure 12. Buoyancy gas balance. Position of the balance beam is adjusted by a set pressure air; air is then displaced by gas of the same pressure. The difference in the reading of the balance beam gives the specific gravity (SG) of the gas. The pressures are read on the manometer. This method is commonly applied in laboratories and not suitable for continuous measurements.

for continuous measurements.

REFERENCE METHODS

Hydrometers

Hydrometers are direct reading instruments, the most commonly used devices for measurement of density of liquids. They are so commonly used that their specifications and procedure of use are described by national and international standards such as ISO 387. The buoyancy principle is used as the main technique of operation. Almost all hydrometers are made from high grade glass tubing. The volume of fixed mass is converted to a linear distance by a sealed bulb shaped glass tube containing a long stem measurement scale, shown in Fig. 13. The bulb is ballasted with a lead shot and pitch, the mass of which is dependent on the density range of the liquid to be measured. The bulb is simply placed into the liquid, and the density is read from the scale. The scale may be graduated in density units such as kg/m^3 . Hydrometers can be calibrated for different ranges for surface tensions and temperatures. Temperature corrections can be made for set temperature such as 15, 20, 25°C. ISO 387 covers a density range of 600 to 2000 kg/m^3 .

Hydrometers may be classified according to the indication provided by graduations of the scale: density hydrometers, specific gravity hydrometers, percentage hydrometers showing the percentage of solution, for example, sugar, and arbitrary scale hydrometers. Customized scales are also available, for example, lactometers for testing milk, alcoholometers for alcohol levels, *etc.* Many other alternative scales are offered by manufacturers such as specific gravity, API gravity, Brix, Brine, *etc.*

The best way to read a hydrometer in clear liquids is to start with the eyes slightly below the plane of the liquid surface, and slowly raise the eyes until the surface of liquid appears as a straight line. The place where the line crosses the scale is the reading. With opaque liquids, such as oils, it is necessary to read the hydrometer at the top of the meniscus. For accurate readings, the stem must be absolutely clean. Also, the surface of the liquid must be clean and free of dust. With precision grade hydrometers, with long small diameter stems, density values may be read to 0.0001. In general use of hydrometers,

Figure 13. Hydrometer. A fixed weight and volume bulb is placed into the liquid. The bulb sinks in the liquid depending on its density. The density is read directly from the scale. They are classified according to the indication provided by graduations of the scale. The best way to read a hydrometer in clear liquids is to start with the eyes slightly below the plane of the liquid surface, and slowly raise the eyes until the surface of liquid appears as a straight line. The place where the line crosses the scale is the reading. With opaque liquids, such as oils, it is necessary to read the hydrometer at the top of the meniscus.

the uncertainty of readings may be in the region of ± 0.01 .

Hydrometers are low cost devices and are easy to use with a good resolution. However, they have a number of disadvantages, such as

1. They have small span; therefore, to cover a significant range, a number of hydrometers are required.
2. They are made from glass and are fragile. Metal and plastic versions are not as accurate.
3. The fluid needs to be an off-line sample, not representing the exact conditions of the process. There are pressure hydrometers for low vapour pressure hydrocarbons, but this adds a need for accurate determination of pressure.
4. If good precision is required, they are difficult to use, needing surface tension and temperature corrections. Further corrections may be required for opaque fluids.

Column Type Densitometers

These devices are used for liquid density measurements. There are a number of different versions of column methods. As a typical example, a reference column method is illustrated in Fig. 14. A known head of sample liquid and water from their respective bubbler pipes are used. A differential pressure measuring device compares the pressure differences, proportional to relative densities of the liquid and the water. By varying the depth of immersion of the pipes, a wide range of measurement may be obtained. Both columns must be maintained at the same temperature in order to avoid the necessity for corrections of

Figure 14. Reference column densitometer. Two identical tubes, having the same distance from the surface, are placed in water and liquid. Water with known density characteristics is used as a reference. The pressures necessary to displace the fluids inside the tubes are proportional to the densities of the fluids. By varying the depth of immersion of the pipes, a wide range of measurement may be obtained. Both columns must be maintained at the same temperature.

temperature effects.

A simpler and the most widely used method of density measurement is achieved by the installation of two bubbler tubes as illustrated in Fig. 15. The tubes are located in the sample fluid such that the end of one tube is higher than that of the other. The pressure required to bubble air into the fluid from both tubes is equal to the pressure of the fluid at the end of the bubbler tubes. The openings of the tubes are fixed; hence, the difference in the pressure is the same as the weight of a column of liquid between the ends. Therefore, the differential pressure measurement is equivalent to the weight of the constant volume of the liquid. Calibrations can be made with direct relationship to the density of the liquid. This method is accurate to within 0.1 to 1% specific gravity. It must be used with liquids that do not crystallize or settle in the measuring chamber.

U-Tube Method

The unknown density of a liquid may be obtained from the known density of another liquid by placing them in a U-tube as in Fig. 16. By measuring the lengths of liquid columns, l_1 and l_2 , and using the manometer principles, the following equation may be written

$$\rho_1 l_1 = \rho_2 l_2 \quad (12)$$

thus allowing ρ_1 to be calculated. In this method, the liquids must not be miscible. This method gives a quick idea about the density of the liquid and is not usually accurate because the various menisci prevent accurate measurements of the lengths of the liquid columns.

RADIOACTIVE METHODS

Radioactive density measurements are suitable for both liquids and solids undergoing dynamic processes. The principle relies

on the radioactive isotopes decay emitting radiation in the form of particles or waves which may be used for density measurements. For example, gamma-rays passing through the samples under test are absorbed depending on the volume, mass, and density of samples, as illustrated in Fig. 17. The rate of arrival of the rays after the absorption can be measured by using ion or scintillation based detection. By comparing the amount of rays entered into the known volume sample and with the rays detected at the end, the value of absorption may be determined accurately.

Generally, γ -ray mass absorption rate is independent of material composition; hence, they can be programmed for a wide range of materials. Densitometers based on radiation methods can provide accuracy up to ± 0.0001 g/mL. Many of these devices have self-diagnostic capabilities and are able to compensate for drift caused by source decay, thus pinpointing any signalling problems.

If a γ -ray of an intensity J_0 penetrates a material of a density ρ and thickness d , then the intensity of the radiation after passing through the material may be expressed by

$$J = J_0 \exp(-n\rho d) \quad (13)$$

where n is the mass absorption coefficient.

The accuracy of the density measurement is dependent on the accuracy of the measurement of the intensity of the radiation and the path length d . A longer path length through the material gives a stronger detection signal. Hence, for accurate operations, many different arrangements can be made for relative locations of transmitters and detectors, as illustrated in Fig. 18. Generally, the source is mounted in a lead container which is clamped onto the pipe or the container wall. In many applications, the detector is also clamped onto the wall.

The advantages of using radioactive methods are

1. The sensor does not touch sample; hence, there is no blockage on the path of the liquid.
2. Multiphase liquids can be measured.
3. They come in programmable forms and are easy to inter-

Figure 15. Two tube column densitometer. The pressure difference at the differential pressure transmitter depends on the relative positions of the openings of the pipes and the density of liquid. Once the relative positions are fixed, the pressure difference can be related to the equivalent weight of the liquid column at the openings of the pipes, hence the density of the liquid.

Figure 16. U-tube method. Unknown density of a liquid may be obtained from the known density of another liquid by placing them in a U-tube and measuring the lengths of liquid columns. In this method, the liquids must not be miscible. The method is not accurate but gives a quick idea about the density of the liquid.

Figure 17. Radioactive density gage. The gamma-ray passing through samples is absorbed depending on the volume, mass, and density of the sample. The rate of arrival of the rays after absorption is determined by ion or scintillation based detection. The amount of absorption is proportional to the density of samples. Generally, γ -ray mass absorption rate is independent of material composition.

face.

The disadvantages are

1. A radioactive source is needed; hence, it is difficult to handle.
2. For a reasonable accuracy, a minimum path length is required.
3. There may be long time constants, making them unsuitable in some applications.
4. They are suitable only for solid and liquid density measurements.

OPTICAL METHODS

Refractometric Methods

This method is suitable for density measurements of gases and clear liquids. They are essentially optical instruments operating on the principles of refraction of light travelling in liquid or gas media. Depending on the characteristics of the samples, measurement of refractive index can be made in a variety of ways: critical angle, collimation, and displacement techniques are a few methods to mention. Usually, an in-line sensing head is employed, whereby a sensing window, commonly known as a prism, is wetted by the product to be measured. In some versions, the sensing probes must be installed inside the pipelines or in tanks and vessels. They are most effective in reaction type process applications where blending and mixing of liquids takes place. For example, the refractometers can measure dissolved soluble solids accurately.

Infrared diodes, lasers, and other lights may be used as sources. However, this measurement technique is not recommended in applications in processes containing suspended solids, high turbidity, entrained air, heavy colors, poor transparency and opacity, or extremely high flow rates. The readings are automatically corrected for variations in process temperature. The processing circuitry may include signal outputs adjustable in both frequency and duration.

Another version of refractometers is the index of refraction type densitometer. There are many versions of this type available. For example, in the case of position sensitive detectors, the index of refraction of a liquid under test is determined by measuring the lateral displacement of a laser beam. When the laser beam impinges on the cell at an angle of incidence, as in Fig. 19, the axis of the emerging beam is displaced by the cell wall and by the inner liquid. The lateral displacement can accurately be determined by position sensitive detectors. For maximum sensitivity, the devices need to be calibrated with the help of interferometers.

Refractometers are often used for the control of the adulteration of liquids of common use, such as edible oils, wines, and gasoline. They also find applications in industries such as pulp and paper, food and beverage, sugar, dairy, and other chemical

Figure 18. Fixed radioactive densitometer. An elongated path gives longer path length of the radioactive energy through the liquid, hence stronger attenuation. In some cases, the pipe may be enlarged to give longer beam length through the liquid.

Figure 19. Index of refraction type densitometer. Angle of refraction of the beam depends on the shape, size, and thickness of the container, and the density of fluid in the container. Since the container has the fixed characteristics, the position of the beam can be related to density of the fluid. Accurate measurements of the position of the beam are necessary.

processes.

Absorption Type Densitometers

Absorption techniques are also used for density measurements in specific applications. X-rays, visible light, UV, and sonic absorptions are typical examples of this method. Essentially, attenuation and phase shift of a generated beam going through the sample is sensed and related to the density of the sample. Most absorption type densitometers are custom designed for applications having particular characteristics. Two typical examples are (1) UV absorption or x-ray absorptions are used for determining the local densities of mercury deposits in arc discharge lamps, and (2) ultrasonic density sensors are used in connection with difficult density measurements such as density measurement of slurries. The lime slurry, for example, is a very difficult material to handle. It has a strong tendency to settle out and to coat all equipment it contacts. An ultrasonic density control sensor can fully be emerged into an agitated slurry, thus avoiding the problems of coating and clogging. Since the attenuation of the ultrasonic beam is proportional to the suspended solids, the resultant electronic signal is proportional to the specific gravity of the slurry. Such devices can give accuracy up to 0.01%. The ultrasonic device measures the percentage of the suspended solids in the slurry by providing a close approximation of the specific gravity.

FALLING-SLUG METHOD

Drop Method

These methods are useful when only extremely small quantities of liquid or solid samples are available. Small drops of constant volume are put in a liquid which does not mix with the sample. The time necessary for sinking through a given

height is a measure of the density of the drops. In this method, the volume sample may be as low as 0.1 mL.

In another method, a density gradient is established by diffusion of two different liquids into one another. The drops reach an equilibrium position in the mixture, depending upon their density. In both cases, the calibration by drops of known density is necessary.

LEVEL METERS

APPLIED ACOUSTICS: BASIC PRINCIPLES

Acoustics is the science that studies sound (1). Sounds are vibration phenomena (in gas, liquids, and solids) originally limited to the sense of hearing and subsequently extended to ultrasounds and infrasounds (2–5). In the following, the term *noise* will be used as both an undesired sound and as a statistically random oscillation, according to American Standard Acoustical Terminology (6).

Sound Pressure

A sound exists when a perturbation propagates in an elastic medium and causes a pressure variation and particle movement in the medium. When a particle of air is displaced from its mean position, there is a temporary variation in pressure. The pressure variation acts in two ways: by restoring the particle to its original position, and by passing on the disturbance to the next particle. The cycle of pressure increases (compressions) and decreases (rarefactions) propagates through the medium as a longitudinal sound wave, characterized by two important parameters: the pressure (the local increases and decreases with respect to the environment) and the velocity of the air particles that oscillate around a fixed position. The basic definitions of sound are in terms of the magnitude of the fluctuating component of pressure in a fluid medium. The sound pressure $p(t)$ is a scalar quantity, characteristic of the measurement points; it has a dimension of newtons per square meter or pascals. The sound pressure level (L_p) is measured in

decibels (dB):

$$L_p = 20 \log_{10} p/p_0 \text{ dB} \quad (1)$$

where p is the root-mean-square (rms) sound pressure, expressed in micro Pascal, and p_0 is equal to $20 \mu\text{Pa}$.

The rms value of the fluctuating component of pressure is used because most sound consists of random signals rather than pure sine waves. The value $20 \mu\text{Pa}$ is an accepted standard reference value of pressure against which other pressures are compared by Eq. (1). Note that when p equals $20 \mu\text{Pa}$, the sound pressure level is 0 dB. This value was selected somewhat arbitrarily, but it represents the average threshold of audibility for human beings if a 1000 Hz tone is used. That is, the 0 dB level was selected as the lowest pressure fluctuation normally discernible by human beings. The decibel (logarithmic) scale is used as a convenience because of the human ear, sensitivity to noise, which follows an approximately logarithmic law, and the great ranges of sound pressure level of interest in ordinary work (from 10^{-6} Pa to 10^3 Pa). For example, an office with tabulating machines may have an L_p of 60 dB to 65 dB. The average human threshold of pain is about 140 dB. Sound pressure close to large rocket engines is on the order of 160 dB. One atmosphere is 194 dB. The span from the lowest to the highest pressure of interest is thus on the order of 1 to 10^9 .

Sound Intensity

Sound pressure must not be confused with sound intensity, since the first is a scalar quantity, characteristic of the measurement point, and the second is a vector with its direction of propagation. Sound intensity $I(t)$ is a fundamental quantity for sound description (7): It is the product of particle velocity and pressure. As can be seen from the transformation of Eq. (2), it is equivalent for a given point and direction to the temporal average of the energy flux transmitted through a unitary surface perpendicular to the assigned direction in the considered point, and it is then measured in watts per square meter.

$$\begin{aligned} \text{Intensity} &= \text{Pressure} \times \text{Particle Velocity} \\ &= \text{Force/Area} \times \text{Distance/Time} \\ &= \text{Energy}/(\text{Area} \times \text{Time}) = \text{Power/Area} \end{aligned} \quad (2)$$

The acoustic intensity level L_I expressed in decibels is

$$L_I = 10 \log_{10} I/I_0 \text{ decibels (dB)} \quad (3)$$

where I is the time-averaged intensity, expressed in W m^{-2} , and I_0 is equal to 1 pW m^{-2} .

The relationship between intensity and pressure is known precisely only in the case of *free fields* and *diffuse fields*. Given that a sound field is a region where there is sound, fields are classified according to the manner and the environment in which the sound waves travel.

Free Field. The term *free field* describes sound propagation in an idealized free space where there are no reflections. These conditions hold in the open air or in an anechoic room where the sound striking the walls is totally absorbed. Free field

propagation is well characterized in terms of pressure and intensity level drop versus the distance from the source in the direction of sound propagation, as well as in terms of the relationship between sound pressure and acoustic intensity (8):

$$|I| = p^2/\rho c \quad (4)$$

where ρc is the acoustic resistance of the medium (ρ is the density and c the speed of sound in the medium). Having defined that, the acoustic impedance of the medium on a given surface lying in a wave front is the complex quotient of the sound pressure on the surface divided by the flux (volume velocity, or linear velocity multiplied by the area) through the surface; the acoustic resistance is defined as the real component of the impedance.

Diffuse Field. In a diffuse field, sound is reflected so many times that it travels in all directions with equal magnitude and probability. This field is approximated in a reverberant room. Although the net intensity $|I|$ is zero, there is a theoretical relationship that relates the pressure in the room to the one-side intensity, I_x (the intensity in one direction, ignoring the equal and opposite component) (88):

$$I_x = p^2/4\rho c \quad (5)$$

Sound propagation involves energy flow, but there can still be sound pressure even when there is no propagation. An *active field* is one where there is energy flow. In a *pure reactive field* there is no energy flow. A perfect correspondence, which gives rise to the use of the terms *active* and *reactive*, can be stated between pressure, particle velocity, and intensity, on the one hand, and voltage, current, and electrical power on the other hand. In an active field, pressure $p(t)$ and particle velocity $u(t)$ vary simultaneously. A peak in the pressure signal occurs at the same time as a peak in the particle velocity signal. They are therefore said to be in phase, and the product of the two signals gives a time-averaged intensity $I(t)$ (Fig. 1). In a pure reactive field the pressure and the particle velocity are 90° out of phase. One is shifted a quarter of wavelength with respect to the other. Multiplying the two signals together gives an instantaneous intensity $i(t)$ varying sinusoidally around zero. Therefore, the time-averaged intensity $I(t)$ is zero. In a diffuse field the pressure and particle velocity phase vary at random, so the time-averaged intensity is zero.

Sound Power

The sound power W is the energy emitted in the time unit, measured in watts, while the power level L_W expressed in decibels is

$$L_W = 10 \log_{10} W/W_0 \text{ decibels (dB)} \quad (6)$$

where W_0 is equal to 1 pW .

According to the law of energy conservation, the energy flow per time unit that crosses a surface that completely covers a source must be equal to the sound power of that source (except for eventual dissipation losses). The total sound power for a spherical propagation in an elastic media is linked to the sound

Figure 1. Instantaneous intensity $i(t)$ and time-averaged intensity $I(t)$ for different phase shifts between pressure $p(t)$ and particle velocity $u(t)$ highlight the differences between the two quantities and the effect of the phase shift on the $I(t)$ values.

intensity at distance r by the equation

$$W = 4\pi r^2 I = 4\pi r^2 (p_r^2 / \rho c) \quad (7)$$

where p_r is the sound pressure at a distance r .

Loudness

Loudness is a subjective quantity. It is defined as that aspect of auditory sensation in terms of which sounds may be ordered on a scale running from *soft* to *loud*. Loudness is chiefly a function of the level of sound pressure, but it is also dependent on the frequency and the composition of the sound. The range of loudness is divided subjectively into equal-unit steps called *sones*. The loudness of a sound at a given sound pressure level at one frequency may be quite different from the loudness of a sound of the same level at a different frequency. Nevertheless, listeners can adjust the level of one tone to match the loudness of another, and fair agreement among observers is usually obtained. Such experiments provide a useful objective scale of loudness, called loudness level. The loudness level of a tone in *phons* is

numerically equal to the sound pressure level of a 1000 Hz tone that sounds equally loud. The loudness in *sones* (S) can be related to the loudness level in *phons* (P) by the empirical formula

$$S = 2^{(P-40)/10} \quad (8)$$

The equal loudness contours for pure tones of Fig. 2 were obtained from measurements on human beings and show that the frequency response of the human ear is both nonflat and nonlinear (9). The numbers on the contour indicate the loudness level in phons, with 0 phon corresponding to the threshold of audibility. These curves were obtained under free-field conditions, and the ordinate of the curve is free-field sound pressure level. Thus, the ordinate indicates what pressure amplitude must be applied at any given frequency so that the human observer will perceive a sensation of equal loudness. For example, at a 50 phon loudness, a sound level of 58 dB L_p at 100 Hz sounds as loud as one of 50 dB L_p at 1000 Hz. This demonstrates the nonflatness of the ear's frequency response. Its nonlinearity is manifested by the need for a family

Figure 2. Normal equal loudness contours for pure tones. The levels were measured after the listener left the free plane-wave sound field. (ISO R226-1961)

of curves for various loudness levels, rather than just a single curve.

The calculation of loudness is crucial in characterizing loudspeakers, whose quality depends on how much the transduced music or speech is loud with respect to background noise. Namely, the loudness efficiency rating is defined as the ratio of the total effective acoustic power produced by the loudspeaker to the available electrical power; here the total effective acoustic power is measured so that it is nearly proportional to the loudness produced by the loudspeaker in the free field (10).

Reference Levels

Sound pressure, intensity, power, and particle velocity levels (L_p , L_I , L_W , and L_u , respectively), are all measured in decibels. Decibels are a ratio of the specified quantity measured against some reference. As previously stated, the pressure reference level is chosen so that it corresponds approximately to the threshold of audibility. Other reference levels have been approximately related to this by using the free field relations between pressure and intensity, and pressure and particle velocity. In the free field we will obtain the same decibel reading irrespective of whether we measure pressure, intensity, or particle velocity (measured in the direction of propagation). Actually, because round numbers have been chosen for the reference levels, there is a slight difference in levels. The actual difference depends on the value of the acoustic impedance, ρc , of the medium in which the difference is measured. The difference is usually negligible in the air except at high altitudes. To avoid possible confusion with pressure levels, sound power levels are sometimes given in bels (10 dB equals 1 bel).

In the free field the pressure and intensity levels in the direction of propagation are numerically the same. However, intensity measurements in the free field are not needed. In practice, measurements are not performed in the free field, so there will be a difference between the pressure and intensity levels. This difference is an important quantity. It is known variously as the reactivity index, pressure-intensity index, or phase index.

INSTRUMENTS FOR SOUND-LEVEL MEASUREMENTS

Sound-Level Meter

The most commonly utilized instrument for routine sound measurement is the sound-level meter (11,12). This is basic to all sound- and noise-level measurement, particularly that done outside the laboratory. It is actually a measurement system made up of a number of interconnected components. Figure 3 shows a typical arrangement.

The sound pressure $p(t)$ is at first transduced to a voltage by means of the microphone. Microphones generally employ a thin diaphragm to convert pressure to motion. The motion is then converted to voltage by suitable transducers, usually a capacitance, piezoelectric, or electret type.

The output voltage of the microphone generally is quite small and at a high impedance level; thus an amplifier of high input impedance and gain is used at the output of the microphone. This can be a relatively simple ac amplifier, since response to static or slowly varying voltages is not required. Capacitor microphones often use for the first stage a field-effect transistor (FET)-input amplifier built directly into the microphone housing. This close coupling reduces stray capacitance effects by eliminating cables at the high-impedance end.

The weighting networks follow the first amplifier. They are electrical filters whose frequency response is tailored to approximate the frequency response of the average human ear. In fact, the main use of a sound-level meter is not the accurate measurement of pressure but rather the determination of the loudness perceived by human beings; for this reason a flat instrument frequency response is not really desired. The weighting networks of Fig. 3 are electrical filters suitably designed to approximate the human ear's response at different loudness levels so that the instrument reading will respect perceived loudness. Usually three filters are provided: A, B, and C. Figure 4 shows the frequency response of these filters. Some meters also provide a *flat* setting if true pressure measurements are wanted; if a flat setting is not available, the C network is a good approximation of a flat response. Actually, many practical measurements are made by employing the A scale

Figure 3. Simplified block diagram of a sound-level meter.

since it is a simple approach that has given good results in many cases and has been written into many standards and codes. The level of sound pressure measured with a sound-level meter and its weighting network is called sound level to distinguish it from the original sound pressure levels. When A-weighting is used, the sound level is given in dB(A) instead of dB.

Figure 4. Normalized A, B, and C weighting curves.

The output of the weighting network is further amplified, and an output jack is provided to lead this ac signal to an oscilloscope (if observation of the waveform is desired) or to a wave analyzer (if the frequency content of the sound is to be determined). If only the overall sound magnitude is desired, the rms value of the voltage signal must be found. While true rms voltmeters are available, their expense is justifiable only in the highest-grade sound-level meters. Rather, the average value of the ac signal is determined by rectifying and filtering; then the meter measures the obtained dc value on a scale usually calibrated to provide the rms value. This procedure is exact for pure sine waves since there is a precise and known relationship between the average value and the rms value of a sine wave. For nonsinusoidal waves this is not true, but the error is generally small enough to be acceptable for relatively unsophisticated work. The filtering is accomplished by both a simple low-pass RC filter and low-pass meter dynamics. Moreover, the filtering time constant also acts on the meter response time. In particular, most meters have a switch that changes the filtering time constant. The *slow* position (1 s time constant) gives a steady, easy-to-read needle position but masks any short-term variations in the rms of the signal. If these short-term variations in the signal are of interest, they may be visually observed on the meter by switching it to the *fast* (125 ms), *impulse* (35 ms), or *peak* (20 μ s to 50 μ s) position. Figure 5 shows the effect of the different time constant on a sound-level measurement.

Finally, a dc meter calibrated in rms gives the measurement result. Since Eq. (1) establishes a definite relation between sound pressure in μ Pa and dB, the meter is often directly calibrated in decibel.

Integrating Sound-Level Meter

Integrating sound-level meters are designed to measure continuously the *continuous equivalent level* in a defined time interval T , $L_{eq,T}$ (13). The aim of this parameter is to characterize, with a unique measurement data, a variable noise. The $L_{eq,T}$ of a signal is the level of a hypothetical constant level noise that has the same acoustic energy as the original signal in the same period of time and, namely,

$$L_{eq,T} = 10 \log \frac{1}{T} \int_0^T \left(\frac{p(t)^2}{p_0^2} \right) dt \quad (\text{dB}) \quad (9)$$

where p_0 is the reference pressure (20 μ Pa) and $p(t)$ is the sound pressure level of the noise under analysis. Usually A-weighted sound levels, rather than sound pressure levels, are considered and then a $L_{Aeq,T}$ is obtained.

If the noise under analysis is constituted by a sequence of constant levels L_{A1} , L_{A2} , ..., L_{AN} , each one present for a time interval Δt_1 , Δt_2 , ..., Δt_N , respectively, or if the available measures are in this form, it is possible to evaluate the $L_{Aeq,T}$, with $T = \sum_i \Delta t_i$ by the equation

$$L_{Aeq,T} = 10 \log \frac{1}{T} \sum_{i=1}^N 10^{L_{Ai}/10} \Delta t_i \quad [\text{dB(A)}] \quad (10)$$

In the field of ear protection, a more complex formula was employed for a long time and can sometimes still be implemented; this formula has no physical explanation but allows the parameters q [exchange factor, representing the level increment in dB(A) that requires halving the exposure time to

Figure 5. The RC-filtering outputs for different time constants in the case of an impulse noise.

obtain a constant risk] and L_t (threshold level, namely, a level under which the noise damage can be considered absent) to be introduced:

$$L_{eq,T} = L_t + \frac{q}{\log 2} \log \frac{1}{T} \sum_{i=1}^N 10^{\log 2(L_{Ai} - L_t)/q} \Delta t_i \quad (\text{dB}) \quad (11)$$

which gives back the previous equation for $q = 3$ and $L_t = 0$. The value of q is usually fixed on the basis of the reference standards: In the United States a $q = 5$ is suggested. In Europe a $q = 3$ is suggested. The value of L_t is often assumed to be equal to 70 dB.

It is important to emphasize that even if the $L_{eq,T}$ is often referred to as an average noise measurement, a simple arithmetic mean cannot be used to compute its value starting from partial values, since it is a logarithmic average. For example, an 8 h exposure time subdivided into 4 h at 100 dB and 4 h at 80 dB is characterized by an $L_{eq,8h}$ of 97 dB rather than 90 dB. As a further example, two 80 dB sources give a total $L_{eq,T}$ of 83 dB—namely, 3 dB higher than the one produced by each source.

Another useful parameter found on more elaborated integrating sound-level meters is the *sound exposure level*, $L_{EA,T}$,

also measured in dB(A) and often referred to as SEL. This is defined as the level that, lasting for 1 s, has the same acoustic energy as a given noise event lasting for a chosen period of time T . As a measure of acoustic energy, the SEL can be used to compare unrelated noise events, since the time element in its definition is always normalized to one second. The value of T is often chosen as the time interval in which the sound level is no lower than 10 dB of the maximum value, in order to avoid an increase in the measurement time that is not justified by a significant SEL variation.

Some integrating sound-level meters measure the continuous equivalent level over a fixed period of 60 s, $L_{Aeq,60s}$. There is a certain similarity in use between the quantities $L_{Aeq,60s}$ and $L_{EA,T}$, since both are based on measurement performed at fixed time intervals. In addition, for any noise event lasting no more than 60 s, there is a fixed difference between its SEL and its $L_{Aeq,60s}$ (the former is greater by 17.8 dB).

A simplified block diagram of an integrating sound-level meter is shown in Fig. 6. It adds an integrating section fed by the signal already amplified and weighted to the already described features of a sound-level meter (see Fig. 6). This section performs the numeric evaluation of the equivalent sound level on the basis of the previously introduced formulas. It is important here to stress the differences among the average operations performed by this integrating section and those performed by sound-level meters. At first, traditional sound-level meters can average signals for prefixed and, in any case, short time intervals (maximum 1 s for slow operating), whereas integrating instruments can average for hours. Furthermore, integrating sound-level meters equally weight all the sounds occurring in the considered time window, while traditional sound-level meters give a greater weight to more recent sounds. In fact, the time weighting of traditional sound-level meters decreases exponentially; for example, having chosen a slow 1 s time constant, greater weights are given to sounds occurring less than 1 s previously while sound occurring 10 s previously has very little influence on the meter output. The integrating section has both a better capability in following rapid time evolution of the sound pressure and a higher crest factor (ratio between peak and rms values), which can reach 60 dB.

Noise Dose Meter

Noise dose meters are used to measure the continuous equivalent level of randomly fluctuating noise on an 8 h or longer time interval (14). Namely, a noise dose meter measures D , the percentage of daily noise dose that is allowed by the standards. This instrument is a miniature integrating sound-level meter that uses the A-weighting network and allows the desired exchange factor to be selected. The noise dose meter measures continuously and at the same time reads out the dose as a percentage of the maximum allowable (100%) over an exposure period (usually 8 h). When representative data can be obtained in less time, the reading can be converted easily to an equivalent 8-h exposure.

Two kinds of noise dose meters can be used: personal dose meters, carried by a person, and noise dose meters, installed in a fixed place. The former are usually provided with a small microphone located near the ear; the latter, used to control noisy areas, are usually exposed to a sound level lower than that of a microphone installed on a person immersed in the same sound field. This difference, usually contained within

Figure 6. Simplified block diagram of an integrating sound-level meter.

2 dB, is due to the different sound pressure on a microphone located near a reflective surface: The actual increase depends on the noise spectrum, the noise direction, and the installation.

Sound-Level Statistical Analyzer

This kind of instrument allows the sound level to be analyzed statistically in a defined time interval. It was designed to deal with urban noise, especially traffic noise, but it can be used to measure noise in working areas as well. Its measurement principle is conceptually the following: Suppose we want to evaluate the evolution of the sound level in a 50 dB(A) range—for example, from 40 dB(A) to 90 dB(A)—and that this range is subdivided into 25 contiguous classes of 2 dB(A) each. By sampling the sound level at a constant rate (e.g., every 0.1 s) and

Figure 7. Example of sound-level statistical distribution obtained by using a sound-level statistical analyzer: (a) absolute frequency distribution; (b) cumulative frequency distribution [in this example, $L_{90} = 51.7$ dB(A); $L_{50} = 63.9$ dB(A); $L_{10} = 75.8$ dB(A)].

by assigning each sample to the corresponding class, the measurement result is obtained as a number of counts for each class or, since the number of counts can be linked to a time interval, as the time percentage of the total investigation time in which the sound level was contained in each dB(A) interval. For example, if we have a 600 s measurement time in which 6000 samples were acquired (0.1 s sampling time) and the class 58 dB(A) to 60 dB(A) was counted 1200 times, the sound level was contained within 58 and 60 dB(A) for 20% of the total measurement period. The result of the statistical distribution is shown in Fig. 7(a). A cumulative frequency distribution [see Fig. 7(b)], is almost always preferred, thus considering the time percentage during which a certain sound level was exceeded.

On the basis of the information gathered according to this criterion, the meter is able to produce, as a final result, together with the sound-level statistical distribution, the equivalent sound level L_{eq} and the so-called statistical levels, typically L_{90} (sound level exceeded for 90% of the measurement time and consequently representative of background noise), L_{50} (sound level exceeded for 50% of the measurement time and consequently representative of the average level), and L_{10} (sound level overcome for 10% of the measurement time and consequently representative of the maximum sound levels).

A statistical analyzer can be used instead of an integrating sound-level meter to evaluate L_{eq} , taking into consideration that this value is not estimated by means of a real integration but by summing the values obtained by sampling, at a constant rate, the sound level that varies according to the meter time

Figure 8. Filtering section of a sequential frequency analyzer.

constant (slow or fast). This can create problems when dealing with variable or impulsive noises.

Sound-Level Spectrum Analyzer

In some applications a frequency analysis of the acoustic signal is required, in terms of separation of the different frequency components present in the overall signal (15). In fact, the spectrum represents an additional element to the global equivalent sound level expressed in dB(A) to characterize noise correctly, by highlighting the presence of pure tones or high frequencies. Frequency analysis is indispensable for the design of noise control techniques since it allows the main noise sources to be identified and noise-control techniques, materials, and structure to be optimized. This task is carried out by instruments called *spectrum analyzers*.

As far as measurement principles, characteristics, and problems of usage of general-purpose spectrum analyzers as well as of FFT-based digital spectrum analyzers are concerned, the related articles of this Encyclopedia, together with other specialized texts, can be used. In the field of spectrum analysis of acoustic signals, a further possibility is available: performing a sequential frequency analysis, according to Fig. 8. In this case the signal is conceptually applied in parallel to a set of suitable filters. The output for the different bands is read sequentially by an output unit. It is evident that this approach is correct only when a stationary noise has to be measured, or at least a noise that is stationary during the overall measurement time (usually a few minutes). In any case this kind of approach, even if not rigorous, can be used in the absence of more sophisticated instruments to obtain useful qualitative information about the noise spectrum. The frequency range of each filter defines its band or bandwidth; the most commonly used bandwidth in acoustics is the octave (16). An octave is the interval between two frequencies having a ratio of 2, [e.g., from 707 Hz to 1414 Hz (central frequency 1000 Hz, determined as the geometric average between the two frequencies)]. An analyzer that uses this bandwidth is called an octave-band analyzer. Other analyzers use narrower bandwidths to allow a more detailed frequency analysis (e.g., third-octave-band analyzers). Other analyzers use filters with a constant bandwidth in hertz. An ideal filter has a uniform response within its passband and no response out of its passband. Of course this behavior is only approximated by real filters, since their response is not uniform within the passband and not zero outside the passband, giving a meaningful output when relevant frequency components are

present immediately out of the passband. The *effective bandwidth* of a filter is the bandwidth of an ideal filter that has the same maximum response and the same output of the real filter when a white noise is fed into both filters. Most analyzers are designed to have an effective bandwidth that is very similar, practically equal, to the filter bandwidth.

SOUND INTENSITY ANALYZING SYSTEM

A sound intensity analyzing system consists of a suitable probe and an analyzer. The probe measures the pressure at a pair of microphones, while the analyzer performs the integration and calculation necessary to evaluate the sound intensity.

Sound intensity is the time-averaged product of the pressure and particle velocity. While instantaneous pressure can easily be measured by using a microphone, a direct measurement of particle velocity is not common and requires the use of devices like hot wire anemometers or delicately suspended mica disks (17). However, as the particle velocity is related to the pressure gradient (the rate at which the instantaneous pressure changes with distance), a simpler measurement method can be set up using two identical pressure microphones. The method is based on Newton's second law:

$$\rho \frac{\partial \mathbf{u}}{\partial t} = -\nabla p \quad (12)$$

also called Euler's relation, where ρ is the density of air and $\mathbf{u}$ the particle velocity.

In one direction, r , we have

$$\rho \frac{\partial u_r}{\partial t} = -\frac{\partial p}{\partial r} \quad (13)$$

Since the pressure gradient is proportional to particle acceleration, particle velocity can be obtained by integrating the pressure gradient with respect to time.

$$u_r = -\frac{1}{\rho} \int \frac{\partial p}{\partial r} dt \quad (14)$$

In practice, the pressure gradient can be approximated by measuring the pressures, p_A and p_B , at two closely spaced points, A and B, and dividing the pressure difference $p_A - p_B$ by the transducer separation distance Δr , thus giving the following estimate for the particle velocity component u_r in the direction r :

$$u_r = -\frac{1}{\rho \Delta r} \int (p_A - p_B) dt \quad (15)$$

This approximation is valid as long as the separation is small compared with the wavelength ($\Delta r \ll \lambda$).

Practical sound intensity probes therefore consist of two closely spaced pressure microphones, allowing measurement of both pressure and the component of the pressure gradient along a line joining the centers of the microphones. Hence, the magnitude and the direction of the component of the intensity vector along this line is measured.

The probe arrangement of two microphones mounted face to face with a solid spacer in between has been found to have better frequency response and directivity characteristics than

Figure 9. Intensity measurement by two-microphone sound-intensity probe. The difference between intensity (a) and intensity level (b) is shown. The directivity characteristic (cosine characteristic) is also highlighted in (b), where the differences between the measured intensity component and the intensity module are reported in decibels for different angles.

side-by-side, back-to-back, or face to face without solid spacer arrangements. As for directivity characteristics of the sound intensity analyzing system, as already mentioned, it is an intensity vector component and not the intensity vector that is measured by this technique. The consequence is that the theoretical directional characteristic of the sound intensity probe is a cosine function

$$|I_r| = |I| \cos \alpha \quad (16)$$

where α is the angle between the direction of the sound intensity vector and the orientation of the probe (Fig. 9).

For processing the signals from the two microphones, two approaches are in current use today. One approach is a direct method that can be implemented by analog as well as digital techniques. The second approach, the indirect method, can only be implemented by use of a digital technique.

Direct Method

The sound intensity vector component in the direction r is calculated from

$$I_r = -\frac{1}{2\rho\Delta r} (p_A + p_B) \overline{\int (p_A - p_B) dt} \quad (17)$$

where sound pressure is taken as being the mean pressure $(p_A + p_B)/2$ between the two microphones, and where the velocity is calculated from Eq. (15) (the superior line indicates an averaging).

Figure 10 shows a block diagram of a practical real-time sound intensity meter (including third-octave digital filters) that follows the equation step by step. Instruments like this have an analysis range from a few hertz to about 10 kHz.

Indirect Method

A dual channel FFT analyzer can be used for intensity calculations within the well-known FFT-limitations. It can be shown (8) that the intensity can be calculated from the imaginary part of the cross-spectrum G_{AB} between the two microphone signals.

$$I_r = -\frac{1}{\omega\rho\Delta r} \text{Im}(G_{AB}) \quad (18)$$

Today, this forms a commonly used method of calculating sound intensity. However, a computer is required to carry out the final calculations. Unfortunately, this method has certain disadvantages. One of these is that sound measurement is normally specified in octaves and third octaves, and the calculation of these from narrow-band spectra is a time-consuming procedure, usually requiring multipass analysis and synthesis, which cannot be performed easily in real time.

MICROPHONES

The microphone is the first element of each acoustic measurement chain, since it transduces sound pressure variations into corresponding variations of an electric signal (17). While microphone design is a specialized and complex field with a large

Figure 10. Block diagram of a real-time digital sound intensity meter.

amount of technical literature, some of the main considerations will be presented in the section. As for many other transducers, sensitivity, amplitude, and frequency response are characteristics of major interest. However, sound wavelength and the direction of propagation produce effects on transducer amplitude and frequency response that are aspects of dynamic behavior not regularly encountered in other measurements.

The *pressure response* of a microphone refers to the frequency response relating a uniform sound pressure applied at the microphone diaphragm to the output voltage of the microphone. The pressure response of a given microphone may be estimated theoretically or measured experimentally by one of a number of accepted methods (18).

What is usually desired is the *free-field response* of the microphone (namely, the relation between the microphone output voltage and the sound pressure that existed at the microphone location before the microphone was introduced into the sound field). As a matter of fact, the microphone distorts the pressure field because its acoustical impedance is radically different from that of the medium (air) in which it is immersed. For most purposes the microphone (including its diaphragm) may be considered a rigid body. Sound waves impinging on this body give rise to complex reflections that depend on the sound wavelength (frequency), the direction of propagation of the sound wave, and the microphone size and shape. When the wavelength of the sound wave is very large compared to the microphone dimensions (low frequencies), the effect of reflections is negligible for any angle of incidence between the diaphragm and the wave-propagation direction, and the pressure response equals the free-field response. At very high frequencies, where the wavelength is much smaller than the dimension of the microphone, it acts as an infinite wall, and the pressure at the microphone surface (for waves propagating perpendicular to the diaphragm [0° angle of incidence]) is twice what it would be if the microphone were not there. For waves propagating parallel to the diaphragm (90° incidence angle), the average pressure over the diaphragm surface is zero, giving no output voltage.

For simple geometric shapes, such as spheres and cylinders, theoretical results are available; otherwise an experimental characterization of the actual microphone has to be carried out. Note that for sufficiently low frequencies (below a few thousand hertz) there is little change in pressure because the presence of the microphone and the angle of incidence have little effect. This flat frequency range can be extended by reducing the size of the microphone; however, a smaller size tends to reduce sensitivity. The effect of size is directly related to the relative size of the microphone and the wavelength of the sound. The wavelength λ of sound waves in air is roughly $330/f$ m, where f is the frequency in hertz. When λ becomes comparable to the microphone diaphragm diameter, significant reflection effects can be expected.

Each microphone has a random incidence curve that refers to its response to a diffuse sound field (namely, where the sound is equally likely to come to the microphone from any direction, the waves from all directions are equally strong, and the phase of the waves is random at the microphone position). Such a field may be approximated by constructing a room with highly irregular walls and placing reflecting objects of various sizes and shapes in it. A source of sound placed in such a room gives rise to a diffuse sound field at any point in the room. Microphones

Figure 11. Simplified diagram of a capacitor microphone. (1) Diaphragm; (2) back plate; (3) insulator; (4) case; (5) capillary tube for average pressure equalization; (6) protection grid.

calibrated under such conditions are of interest because many sound measurements take place in enclosures that, while not giving perfect random incidence, certainly do not give pure plane waves. Microphone calibrations usually give the pressure response and the free-field response for selected incidence angles, usually 0° and 90° .

Microphones used for engineering measurements are usually capacitor, electret, or piezoelectric types.

A capacitor microphone is constituted by a thin metallic membrane (about $5\ \mu\text{m}$ thickness) that represents the sensing element, mounted in parallel (at about $25\ \mu\text{m}$) from a rigid posterior plate (back plate), thus forming a capacitor (Fig. 11). The capacitor charge is maintained constant by a constant polarization voltage. When the membrane is solicited by sound pressure, a capacitance and, consequently, a voltage variation occur proportional to the sound pressure. Microphones often have a slow leak (capillary tube) connecting the two sides of the diaphragm, to equalize the average pressure (atmospheric pressure) and prevent bursting of the diaphragm. This is necessary because the (slow) hour-to-hour and day-to-day changes in atmospheric pressure are much greater than the sound pressure fluctuations to which the microphone must respond. (Note that the Eustachian tube of the human ear serves a similar function.) The presence of this leak dictates that microphones will not respond to constant or slowly varying pressures. This is usually not a problem since many measurements involve a human response to the sound, and this is known to extend down to only about 20 Hz. Thus the microphone frequency response need only reach this value, not zero frequency. The typical sensitivity is of about 50 mV/Pa.

Electret-type microphones are related to the capacitor types; however, they require no polarizing voltage since their charge is permanently built into the polymer film that forms the diaphragm. Since the unsupported polymer film would sag and creep excessively, a backup plate with raised points is used. Such microphones are less expensive than the capacitor type, can be used in high-humidity conditions (where the capacitor type may arc over), and result in smaller instruments with lower power consumption. A version that preserves the desirable features of an all-metal diaphragm has also been developed.

Piezoelectric microphones use PZT (or lead zirconate titanate) as a bending beam coupled with the center of a conical

diaphragm of thin metal foil. This kind of microphones offers the following advantages compared to a capacitor microphone: less sensitivity to high humidity; greater robustness; response in a wide frequency range, even with a lower regularity; no polarization voltage required; and excellent stability. On the contrary, it has greater vibration sensitivity; greater sensitivity drift with temperature; and electrical characteristics that vary with temperature.

The selection and use of microphones for critical applications require some background in acoustics, which is beyond the scope of this article; fortunately, useful references are available (2,19).

METER CALIBRATION

Calibration of Level Meters

Traditional and integrating sound-level meters, as any other measurement instrument, must be calibrated periodically in order to verify the stability of their functionality (20). In particular, it is strongly recommended to calibrate a sound-level meter at the beginning and at the end of a set of measurements and at least before and after each day's measurement. If the calibration levels do not coincide, measured data can be corrected for differences contained within 1 dB, but data with greater differences will be discarded.

The apparatus used for the calibration is the calibrator (namely, a sound source that can operate on the basis of different principles but represents the transfer standard between national standards and the meter under calibration). Electromechanical and electroacoustic calibrators are normally used; in the former, sound pressure is generated by the oscillation in a phase opposition of two small pistons, driven by a disk cam; in the latter, a stable oscillator supplies a metallic membrane of a piezoelectric drive. The reference temperature (20 °C) and pressure (101.3 kPa) must be assured or the appropriate correction must be applied.

Calibration of Sound Intensity Meters

One of the advantages of using the two-pressure-microphone technique is the ease with which very accurate calibration can be carried out using a pistonphone, which provides a known sound pressure level at a known frequency. As already detailed, the reference values for sound pressure levels and for intensity levels are 20 μ Pa and 1 pW/m², respectively. These reference values have been chosen so that for a freely propagating plane wave, a 0 dB sound pressure level corresponds to a 0 dB sound intensity level.

A calibrated barometer is also necessary to determine the necessary correction for the ambient atmospheric pressure. In fact, both the sound pressure of the pistonphone and the air density are proportional to the ambient pressure. Keeping in mind Eq. (4), the correction term is

$$\begin{aligned}\Delta L_1(p_{\text{amb}}) &= 20 \cdot \log_{10}(p_{\text{amb}}/p_0) - 10 \cdot \log_{10}(p_{\text{amb}}/p_0) \\ &= 10 \cdot \log_{10}(p_{\text{amb}}/p_0)\end{aligned}\quad (19)$$

where p_0 equals 0.101 MPa (1 atm). Therefore, when calibrating the system for use in sound intensity mode, only half the

atmospheric pressure correction indicated on the barometer scale must be applied to each microphone.

The air density is inversely proportional to the absolute temperature T , which leads to the temperature correction term:

$$\Delta L_1(T) = 10 \cdot \log_{10}(T/T_0) \quad (20)$$

where $T_0 = 293$ K (20 °C).

In general, these correction terms can often be ignored since they are relatively small; for example, for a temperature of 40 °C and an ambient pressure of 75 kPa (Mexico City, 2300 m above sea level) the correction term is only 1.0 dB.

FLOWMETERS

FLOW MEASUREMENTS

The measurement of flow is important in many industrial, scientific, and research applications. Flowmeters are used to measure the quantity of moving fluids or solids in open or closed conduits. A large number of different flowmeters are available, and the instrument selected for a particular measurement depends on the physical variables and the cost. Historically, flowmeters were first used for open channel flow measurement of the most common fluid, water. In many industrial applications, the ability to accurately measure flow is important because these measurements can be related directly to overall profitability of the plant. In recent years, the advent of microelectronics in flowmeters has improved their accuracy, ease of use, and maintainability significantly. Nowadays, with the widespread use of microprocessors, intelligent flowmeters are being produced. They allow versatile communication capabilities, automatic compensations for temperature and pressure, alarm facilities, selection of display capabilities, and so on.

Applications of flowmeters may include liquids, vapors, gases, solids, or any combination of these. In some cases, the measurement at a point may be necessary, whereas in the others, measurement of volume flow rates or mass flow rates may be needed. Often, measuring flow with high accuracy over a wide range of operating conditions is necessary. Flow measurements are based on many different physical principles. Some of those principles may include conductivity; capacitive, radiation, thermal, optic, and sonic characteristics; optics and lasers; and various mechanical methods.

Flowmeters are used most often for gas and liquid flow measurements. They can be categorized as either intrusive or nonintrusive. Intrusive flowmeters make contact with the flowing material with either moving parts or nonmoving parts. Positive displacement, variable area, and turbine flowmeters are examples of intrusive flowmeters with wetted moving components. Orifice plate, oscillatory, target, and thermal flowmeters are examples of intrusive types with wetted but no moving components. Nonintrusive flowmeters such as magnetic and coriolis flowmeters do not disturb the material flow, but they still have wetted parts. A subsection of nonintrusive flowmeters has no wetted components, such as clamp on ultrasonic flowmeters or some optical types.

Flowmeter selection depends on the physical requirements of the measurements. They could be employed to measure the volumetric flow, velocity, or mass. For example, a positive displacement flowmeter measures the volume flow. Whereas, magnetic, oscillatory, turbine, or ultrasonic flowmeters measure velocities from which the total flow can be determined. Coriolis and thermal flowmeters measure the mass directly. Apart from these, some flowmeters, such as differential pressure, target, and variable area flowmeters, may be classified as inferential types because they infer the flow through some physical phenomenon (e.g., pressure differences).

In many cases, the selection and application of flow-measuring devices require further information on variables such as pressure, density, viscosity, and temperature in order to obtain an accurate output from the instrument. The information about temperature and pressure is particularly important in gas flow measurements. Most commercial gas flowmeters specify flow ratings in volume at standard conditions of

1 atm and 20°C. However, information on viscosity may carry greater importance in liquid flow measurements, and density is important in solid flow applications. Accuracy of flowmeters is of utmost importance, especially when they are used for measuring expensive fluids like petroleum products. In order to effect correction for pressure and temperature, flowmeters are used in conjunction with flow computers when used for measurement of petroleum products in liquid and gaseous form.

Characteristics of Liquids and Gases

Although liquids and gases are different in many respects, they change shapes in a similar manner under the influence of a deforming force. In general, most liquids cannot be compressed. That is, the change in the volume liquid under pressure may be negligible. Because gases are easy to compress and their densities depend on both temperature and pressure, the compressibility of gases must be considered carefully in flow measurements.

During the flow measurements, the density of a gas may vary significantly depending on the absolute pressure. An increase in the pressure of a gas at constant temperature causes the gas to be compressed to a smaller volume of the same mass. Boyle's Law states that for ideal gases or mixtures of ideal gases at constant temperature, the volume V is inversely proportional to the absolute pressure, that is

$$V = \text{Constant}/P \quad (1)$$

Equation (1) may be rewritten to compare the volumes of an ideal gas at a constant temperature but different pressures P :

$$V/V_0 = P_0/P \quad (2)$$

Charles's Law states that the density of gas will vary significantly with absolute temperature T . Increasing the temperature of a gas at constant pressure causes the gas molecules to increase their activities and motions in relation to each other, thereby increasing the volume and decreasing the density of gas for the same mass. Charles' Law may be stated in the following form:

$$V/V_0 = T/T_0 \quad (3)$$

Charles' and Boyle's Laws can be combined to yield the Ideal Gas Law:

$$PV = nRT \quad (4)$$

where R is the universal gas constant in consistent units and n is the number of moles.

The Ideal Gas Law can also be expressed in the following form for different temperatures and pressures:

$$V/V_0 = (TP_0)/(T_0/P) \quad (5)$$

During gas flow measurements, if the variations in pressure and temperature are small, the temperature and pressure act almost independently of each other. Thus, estimates of reasonable flow accuracy can be obtained by adding percentage temperature and pressure deviations from a given set of conditions.

Corrections are necessary if the temperature and pressure of gas is changing during the process of flow measurements.

Often measuring the mass or volume flow of nonideal gases is necessary simply because they do not act like ideal gases at certain conditions, such as at high pressures or low temperatures or under saturation. Their nonideal behavior may be accounted for by modifying the Ideal Gas Law with a Z factor:

$$V/V_0 = (TP_0Z)/(T_0PZ_0) \quad (6)$$

The Z factor is numerically dependent on operating conditions and can be read from generalized compressibility charts with a reasonable degree of accuracy.

For these reasons, extra care and thought are necessary when measuring gas flow.

In the case of liquid and solid flow measurements, the volumetric effect of temperature on the density of liquid or solid may be expressed as

$$V = V_0(1 + \beta \Delta t) \quad (7)$$

where β is the coefficient of solid or liquid expansion, which is consistent with the temperature units used.

Because the mass is the same before and after the temperature rise, the change in density is inversely proportional to the change in volume and can be expressed as

$$\rho/\rho_0 = V/V_0 \quad (8)$$

Nevertheless, in many applications, the effect of volumetric changes caused by temperature are negligible.

An important factor in the liquid flow measurements is the determination of velocity, which indicates the speed and direction of the flow. When the average velocity is slow, the flow is considered to be laminar. This indicates that material flows in layers with the slower moving layers in the outer edges. As the velocity increases, the flow may become turbulent with the layers disappearing and the velocity across the flowing stream being more uniform. In this case, the term *velocity* refers to the average velocity of particular cross section of the stream.

The nature of the fluid flow can be described by the non-dimensional Reynold's number. The Reynold's number R is found by

$$R = vD\rho/\mu \quad (9)$$

where v is the velocity, D is the inside diameter of the pipe, ρ is fluid density, and μ is the kinematic viscosity.

The Reynold's number is significant to determine whether the flow is laminar or turbulent. Correctly predicting the Reynold's number leads to accurate measurements when appropriate correction factors are applied. Generally, if R is less than 2000, the flow is laminar; if R is greater than 4000, the flow is turbulent. Between these two values, the flow is in the transition region.

MASS FLOW MEASUREMENTS

Mass flowmeters are used extensively in oil and gas, iron and steel, power, water distribution, pharmaceutical, food and drink, and other industries. The techniques employed for mass

flow measurements can be classified to be indirect or direct methods. In indirect methods, the velocity or volumetric flow of fluid is measured by a suitable flowmeter, and the necessary calculations are made by considering such process conditions as density, volume, temperature, and pressure. Some of the devices that can be used in indirect measurements may be venturi, target, vibrating vane, ultrasonic, or electromagnetic flowmeters. The most commonly used direct methods using coriolis and thermal mass flowmeters and will be discussed next.

Coriolis Flowmeters

The coriolis flowmeter is a type of direct mass flowmeter where the output depends on the mass flow rate of fluid passing through. Coriolis flowmeters are used to measure harsh chemicals, low- and medium-viscosity fluids, foods, slurries, and the like. They find limited applications in gas technology because the density and pressure of gases are relatively low. Coriolis flowmeters can also be constructed and configured to measure the volumetric flows and the densities of liquids or gases.

The principle of the flowmeter depends on the conservation of angular momentum, such that if a mass m is moving with a velocity v along a rod, the rod itself is moving with an angular velocity ω , and the mass experiences a Coriolis force of magnitude

$$F = 2mv\omega \quad (10)$$

The direction of the coriolis force is perpendicular to both linear and angular velocities. The coriolis force is created as a result of coriolis acceleration acting on the fluid as the fluid changes position in relation to the movement of the tube. The coriolis flowmeter consists of a vibrating tube, as shown in Fig. 1, in which the coriolis force is created and measured. This force results in the a twist of the tube, and this twist is sensed optically to indicate the mass inside the tube.

Coriolis flowmeters are largely applied to measure fluid flow. These flowmeters can measure flow rates from 0.04 kg/s to 15 kg/s in pipes with diameters of 3 mm to 50 mm. Accuracy

Figure 1. A coriolis flowmeter. The flowmeter consists of a vibrating tube carrying a portion of fluid flowing in the pipe. A force is created as a result of coriolis acceleration acting on the fluid as the fluid changes position in relation to movement of the tube. The direction of this force is perpendicular to both linear and angular velocities. Coriolis force results in the twist of the tube, which can be sensed magnetically or optically to indicate the mass inside the pipe.

better than 0.5% is possible between 5% and 100% of maximum flow rates.

The tube of coriolis flowmeters is constructed from stainless steel and vibrated by a drive mechanism. In a harsh environment, the inside of the tube is lined with Teflon to minimize corrosion and abrasion. Coriolis flowmeters can operate at high temperatures, but they are sensitive to pressure drops in the pipes. The accuracy of these flowmeters is in the region of 0.2% to 0.5% over the designed accurate measurement range. They are manufactured in different ranges and sizes. The selection of these flowmeters depends on the fluid characteristics, pressure drops in the piping systems, liquid friction losses, and so on. Manufacturers usually supply instructions, procedures, and graphs for particular applications. When installed, coriolis flowmeters must be oriented such that the meter is completely full of liquid that is free from air or gas bubbles. In gas applications, care must be exercised to not introduce liquid or condensed gas in the flowmeter.

Thermal Flowmeters

Thermal flowmeters use thermal properties of fluids or gases. Depending on the flowmeter design, they can measure velocity or mass flow. There are many different types of which the thermal dispersion, hot wire anemometer, and constant-heat infusion types are the most widely used flowmeter.

The thermal dispersion flowmeter is based on the heat loss from a heated element placed in the flow path, as illustrated in Fig. 2. The element is heated above the ambient temperature and maintained at constant power. The cooling of the element is proportional to the mass flow, which can be described by King's Law as

$$P = A(T_e - T_f)(C_1 + C_2 v^{1/2}) \quad (11)$$

where P is the heat transfer (W); A is the effective area of the heated element (m^2); T_e and T_f are temperatures of heated element and fluid, respectively; C_1 and C_2 are constants; and v is the local speed of the fluid.

The temperature difference is converted to a linearized mass flow rate signal within the electronics.

Constant-heat infusion flowmeters are used to measure the average mass flow by externally injecting a known amount of heat into the flowing liquid, as shown in Fig. 3. The average

Figure 2. A thermal dispersion flowmeter is based on the heat loss from a heated element in contact with the flowing fluid. The element is heated above the ambient temperature, and the heating is maintained at constant power. Thus the cooling of the element is proportional to the mass flow inside the pipe. These flowmeters are suitable for gas and liquid flow measurements.

Figure 3. A constant-heat infusion flowmeter is based on the heat injected into the liquid, and the temperature is measured up and down the stream. In some cases, the temperature difference is maintained automatically, giving flow rate as a function of heat injected to the flow stream.

mass flow can be calculated by measuring the temperatures upstream and downstream:

$$F = q/c_f \Delta T \quad (12)$$

where F is the mass flow (kg/s), q is the rate of heat added (W), c_f is the specific heat of fluid (J/kg K), and ΔT is the temperature difference measured upstream and downstream in Kelvin.

In one version of the constant-heat infusion flowmeter, a control loop keeps the temperature difference constant. The resulting power input is a linear function of mass flow.

Hot wire anemometers use temperature rise in the flowing liquid. They have probes inserted into the flow stream, as shown in Fig. 4, to measure the temperature of the fluid. The velocity sensor is a fine metal wire made from tungsten, platinum, or nickel. In one version, the current through the sensor is kept constant, and the resistance change is then a measure of local fluid velocity. In the other version, resistance is kept constant, and the change in the input power is related to the local velocity. The heat from the heated probe is removed depending

Figure 4. A hot wire anemometer uses probes inserted into the flowing stream. Current through the sensor is kept constant, and the resistance change is monitored; or resistance is kept constant, and the change in the input power is monitored. These devices are suitable for measuring local flow velocities of fluids.

on the flow rate of the fluid. In some cases, a capillary tube is uniformly heated, and the temperature dissipation is sensed at different points of the tube; thus with a constant power input, the difference in the temperature at the sensing points is a linear function of the mass flow of the fluid.

Thermal flowmeters are used in applications where other types of flowmeters are not suitable, such as where fluids are not dense enough for mechanical sensing. They are usually applied to clean pure gases or mixtures of gases with predictable compositions. Typical applications are air, nitrogen, oxygen, CO₂, and methane. The body of the sensing system is usually constructed from stainless steel, brass, monel, or aluminum. Probes that usually come in replaceable tips are manufactured by using stainless steel. The thermal sensors or heaters are located in the probes. The capillary tubes are usually constructed from constantan to maintain a good thermal conductivity. They can operate at high-temperature applications (e.g., 450°C). The accuracy is typically $\pm 2\%$.

Mass Flow Measurement of Solids

Often mass flow rate measurements of solids are necessary where processing of granular or powdered materials are involved. In some systems, solid materials are allowed to fall from a fixed height from suitable slots on to sensors that can indicate the flow rate. In other systems, the capacitive properties are used as the solids pass through a number of electrodes suitably arranged on the flow path. However, weighing systems are most widely used in solid mass flow measurements. Load cells are often mounted under the conveyor systems to monitor continuously the solids on the conveyor, as illustrated in Fig. 5. The belt speed is sensed by a tachogenerator giving

$$Q = mv/l \quad (13)$$

where Q is the mass flow rate, m is the load cell output, v is the belt velocity, and l is the length of the belt being weighed.

An alternative technique uses isotopes emitting gamma rays. The transmitter and the receiver are placed on the opposite sides of the belt, and the gamma rays are allowed to penetrate through the solid materials. The rate of absorption of the gamma rays is directly proportional to the solid mass on the belt. The flow rate is then calculated by taking into account the belt speed, density, and temperature.

Figure 5. A solid flow-measuring arrangement. A number of load cells are located under the conveyor belt carrying solids. The output of the cells and the conveyor speed indicate the flow rate of solids. In some cases, instead of load cells, gamma ray devices are used, and attenuation through the solids is monitored.

VELOCITY AND VOLUMETRIC FLOW MEASUREMENTS

In many applications, measuring velocity may be necessary, whereas in others volumetric flow is more important. Some flowmeters will give a direct indication of the volume flow (e.g., positive displacement), and others will measure the velocity (e.g., ultrasonic, magnetic, turbine) from which volume flows can be determined. Inferential flowmeters (e.g., differential pressure, target, and variable area) are also used for velocity and volume measurements. These flowmeters can be classified as mechanical including differential, electrical, sonic, or optical types. Here, operational principles and applications of commonly used mechanical flowmeters together with differential pressure types will be discussed first, followed by optical, electrical, and sonic types.

Turbine Flowmeters

Turbine flowmeters, sometimes called fixed-vane flowmeters, are typical mechanical flowmeters. They are known to be highly accurate with good repeatability, particularly for turbulent flow applications. There are many different types such as axial, propeller, and paddle wheel.

The most frequently used flowmeter is the axial type shown in Fig. 6. A multiblade rotor is positioned in the flow stream with the axis of rotation parallel to the direction of the flow. The fluid impinges on the blades causing a rotation with an angular velocity approximately proportional to flow rate. The number of machine cycles per second can be related directly to the volume flow rate by using a constant as the meter factor. Generally, turbine flowmeters are highly nonlinear at low flow rates, and they are not suitable to measure flows that reverse in direction.

In some cases, dual rotors are used to eliminate the errors inherent in the single-rotor designs. The rotors are designed to be as light as possible so that the momentum of fluid is relatively larger. In this way, the rotor can respond rapidly to the changes in the velocity of fluid. The rotation of the rotor is generally sensed magnetically or by tachogenerators. Other techniques such as radiofrequency (RF) methods are also used for sensing rotation.

Turbine flowmeters are manufactured in different ranges and sizes to measure liquid flows from a few centiliters to

Figure 6. A turbine flowmeter consists of a multiblade rotor positioned suitably in the flowing stream of fluid. The fluid impinges on the blades and causes the rotor to rotate with an angular velocity proportional to the flow rate. The rotation of the rotor is sensed mechanically or electrically for further signal processing.

Figure 7. Target flowmeters are used for gas and liquid flow measurements especially in large pipes. A target suspended in the flow stream experiences a force proportional to the square of the velocity of the fluid. The force on the target is usually picked up by strain gauges.

200,000 L/min. The accuracy of these meters is typically about $\pm 0.5\%$. The pressure drop range in gases is from 0.2 psi to 90 psi and in liquids from 1 psi to 20 psi. They are to be installed as per standards in order to achieve the levels of accuracy claimed. Orifice flowmeters are being replaced with these meters in many petroleum and natural gas metering stations.

Target Flowmeters

Target flowmeters, also named as drag flowmeters, are convenient to use for liquid and gas flow measurements in large pipes. They operate on the principle of measurement of force exerted on body. A target is suspended, as shown in Fig. 7, in the flow stream, and the force on that target is the difference between the upstream and downstream pressures, which can be expressed as

$$F = k\rho Av^2 \quad (14)$$

where k is a constant, ρ is the density of fluid, A is the target area, and v is the velocity of the fluid.

The force on the target is sensed by a force balance system or strain gages. The accuracy of these devices is relatively inferior, in the region of $\pm 1\%$ to 2% full scale, mainly as a result of the square root relationship between the flow rate and drag force. These devices are usually applied in turbulent flows with sufficient momentum to exert force on the target. In laminar flow applications, the fluid velocity becomes a function of fluid viscosity, which may necessitate the use of calibration curves. They are sensitive to installation effects requiring straight runs of piping.

Positive Displacement Flowmeters

Positive displacement flowmeters are based on the principle of entrapping a known amount fluid as it passes through the flowmeter. The entrapped fluid rotates the lobes whose rotation in turn generates electrical pulses. Many types of flowmeters such as helical gear, nutating disc, oscillating piston, oval gear, piston, and rotary vane positive displacement flowmeters are available. A typical example of this flowmeter is shown in Fig. 8. The flow of fluid through a volume of fixed size causes rotation of an output shaft. This rotation can be sensed by many methods including optical techniques.

Positive displacement flowmeters are sensitive to viscosity of the fluid. Also, maximum allowable pressures and flow rates are limited. Although they are accurate over a wide flow ranges

Figure 8. A positive displacement flowmeter is based on the principle of entrapping a known amount of flowing fluid. There are many different types available, and they are often used in water-metering applications.

(e.g., 1000:1), friction, inertia, and fluctuating flow rates can cause serious errors. Also minimum measurable flow may also be limited as a result of leakage between the lobe and casing. They have accuracy of the order of $\pm 0.1\%$. These are extensively used in the petroleum industry, especially for tanker loading.

Variable Area Flowmeters

In these flowmeters, a float, which is dynamically balanced by the flowing liquid, is positioned in the flow line, as illustrated in Fig. 9. The upward force on the float as a result of liquid velocity is equal to the weight of the float less the weight of the liquid that it displaces. An increase in the flow makes the metering tube rise. As the float rises, the annular area between the float and the metering tube increases until the upward and downward forces are dynamically equalized. Thus the level of the float is an indication of the flow through the flowmeter.

The metering tubes are available in different sizes and shapes to suit specific application requirements. Often the motion of the float is magnetically sensed. These devices are suitable for pipes that are less than 10 cm in diameter. Pressure of operation is limited by the glass material of the tube. Their accuracy is $\pm 1\%$. Variable area flowmeters are suitable for all kinds of gas and clean liquid applications.

Insertion Flowmeters

In insertion flowmeters, transducers such as differential pressure, magnetic, oscillatory, target, thermal, turbine or ultrasonic are inserted in the flow stream, as shown in Fig. 10. A representative velocity at a critical point is measured to represent the average velocity in the flow stream. After the average velocity is determined, the volumetric flow in the pipe can be calculated. In the applications, piping effects must carefully be considered. These devices are most suitable in determining local velocities of the flowing liquids or gases. Errors in the positioning of the transducers can cause serious errors in measurements.

Figure 9. A variable area flowmeter uses a float dynamically balanced by the flowing fluid. An increase in the flow rate increases the level of the float. The level of the float is sensed mechanically, electrically, or optically. They are suitable in gas and clean liquid applications because contaminated liquids may block the flow path between the float and the container.

Differential Pressure Flowmeters

Differential flowmeters are used extensively for liquid and gas flow measurement applications. It is based on empirical correlation of the relationship between the differential pressure and volumetric flow through a restriction pipe. True flow rate is generally determined by weighing or volumetric collection of fluid over a measured time interval. Theoretical flow is calculated from flow equations using the measured differential pressure and known properties of the fluid. There are many types of flowmeters such as pitot tube, orifice plate,

Figure 10. An insertion flowmeter contains various types of sensors, such as magnetic or differential pressure, that are inserted in the flow stream and that sense the local velocities of fluids. The representative velocity is then averaged to find the volumetric or mass flow rates.

Figure 11. A pitot tube flowmeter inserted in the flow stream arrests fluid flowing in the pipe. The head of the fluid represents the potential energy stored in the tube, which can be related to the velocity. Pitot tube devices are well-established flowmeters, and there are many different versions.

elbow, flow-nozzle, segmental wedge, V-cone, venturi, and bypass flowmeters. Here only a selected few will be discussed.

Pitot tube devices are typical examples of differential pressure flowmeters. This is used for point velocity measurement. A simple example is shown in Fig. 11. The liquid moving with a velocity v is arrested in the tube inserted into the flowing liquid. By using the conservation of energy, the velocity of the fluid may be expressed as a function of head as $v = \sqrt{2gh}$. There are many versions of pitot tubes including multiple openings to the fluid and complex differential pressure transmitters and other complex gauge arrangements. For measurement of flow rate, the Pitot tube is traversed through the pipe diameter and the point velocities are measured. The velocity is integrated and multiplied by the flow area to get the flow rate.

Orifice plate flowmeters operate on Bernoulli's Principle, which states that the sum of the static energy, the potential energy and kinetic energy is conserved in a restriction pipe that is carrying fluid as shown in Fig. 12. Here the fluid flow rate of an incompressible fluid may be written as

$$Q = A_1 v_1 = A_2 v_2 \quad (15)$$

The velocity of fluid increases as the cross-sectional area of the pipe is reduced. Applying Bernoulli's equation to the upstream and downstream location of the orifice gives the pressure difference as

$$P_1 - P_2 = \frac{1}{2} \rho [(D/d)^4 - 1]^2 Q^2 / A_1^2 \quad (16)$$

Equation (16) indicates that the differential pressure generated across an orifice is proportional to the square of the flow through the orifice plate.

Figure 12. Orifice-type flowmeters are most widely used, and they operate on Bernoulli's Principle. The potential energy and kinetic energy indicate the flow rates in a restricted section of the pipe. These devices have accuracy levels of 0.5%.

Figure 13. A venturi flowmeter has a restriction throat. The pressure drop before and in the restriction throat is measured to be related to the flow rate inside the pipe. Venturi flowmeters are accurate and widely used in industry for liquid and gas flow measurements.

The accuracy of orifice plate flowmeters is in the range of 0.5% to 3%. They are suitable in applications with Reynold's numbers from 5000 to 2×10^6 depending upon the size; however, they are highly sensitive to installation effects. Valves, pipe fittings, that can distort the velocity profile leading to inaccurate readings. When installed as per International Standard Organization (ISO) standards, higher accuracies can be obtained. They were used until recently in conjunction with flow computers for custody transfer flow measurement of natural gas.

Venturi flowmeters are a type of obstruction device, as shown in Fig. 13. This classical Herschel venturi has a very long flow element with tapered inlet and diverging outlet. Inlet pressure is measured at the entrance section. The inlet diameter is reduced to a throat section, and the static pressure is measured at this section. Venturi flowmeters find applications in fluid flows having a Reynold's number as high as 100,000. These flowmeters give relatively small pressure drops and are highly accurate, about 0.5%. They are not affected by velocity profiles. The construction and applications of venturi devices have been standardized by international standards (e.g., ISO 5167 and DIN 1952). These flowmeters find many applications in power, water, and water treatment industries.

Bypass flowmeters are obtained by employing a bypass stream created by differential pressure in the main stream. A flowmeter in the bypass stream measures the flow as illustrated in Fig. 14. The flow in the bypass stream is then inferred to the main stream. The accuracy of the system is limited by the accuracy of the bypass flowmeter. In many critical applications, the bypass flowmeter is used to increase the accuracy of the primary flowmeter, which is located in the main stream.

Figure 14. A bypass flowmeter is obtained by providing a bypass line to the main flow stream. The pressure drop of the bypass stream is inferred to the flow characteristics of the main stream. These flowmeters are often used as backup measurements in conjunction with main flowmeters in some critical and sensitive applications.

Figure 15. A vortex-shedding flowmeter is based on the creation of vortices in the flow stream. A suitably shaped bluff body is placed in the flow stream, and the frequency of vortices is measured by various techniques such as pressure or ultrasonic methods. They are suitable for applications using low-viscosity fluids.

Vortex-Shedding Flowmeters

Mathematically, the phenomenon of vortex shedding is described by the von Karman Effect. When a bluff body is placed in a flow stream, as the fluid passes the body, vortices are shed alternately from the back side of the body. The vortex shedding of the device is illustrated in Fig. 15. The frequency of the vortex shedding is directly proportional to the velocity of liquid. The frequencies of vortex shedding are monitored by appropriate sensors. The fluid parameter that describes the operation of this device is a nondimensional Strouhal number S

$$S = f_s d / v \quad (17)$$

where f_s is the vortex shedding frequency, d is the diameter of the bluff body, and v is the velocity.

Writing

$$Q = Av \quad (18)$$

where A is the flow area, and substituting for v gives

$$Q = A f_s d / S \quad (19)$$

The Strouhal number is constant for particular shapes of bluff body. For the body in Fig. 15 the number is about 0.88 for Reynold's numbers from 10^4 to 10^6 .

To measure the frequencies of the vortices, various forms of sensors are used. These sensors include diaphragms, magnetic sensors, pressure sensors, suitable torque tubes, and ultrasonic methods. Measurements by vortex shedding can indicate instantaneous flow rates or totalized flow rates over a known time interval. The meters are calibrated by the manufacturers for specific pipe sizes. They give the best results for low-viscosity fluids and unsuitable for most high-viscosity liquids. Manufacturers specify special installation requirements of their devices.

These flowmeters are available in different sizes, and they can handle from a few liters of flow to 15,000 L. They are used in liquid, gas, and vapor applications with relatively steady flow rates. The overall accuracy for gases is in the region of 1% to 2%. Accuracy in liquid applications is about 0.5%.

There are many different versions of devices based on vortex-shedding principle, including some devices using two bluff bodies to make stronger vortices. An improved version of the vortex-shedding transducers is the velocity probes. In this case, sensors are mounted together with the bluff body in a section of a short tube. This assembly can be inserted in various sections of the flow field to measure the local velocity.

OPTICAL METHODS

Optical methods are extensively used in flow measurements involving analytical applications. The properties of light are used to measure the flow of liquids and gases. Some of these properties may include shadowing, relative illuminations, deflections, interference, and Doppler shift. There are many different flowmeters based on optical principles. Flowmeters based on the laser Doppler effect will be discussed next.

Laser Doppler Anemometers

Like Pitot tubes, laser Doppler anemometers are also used for point velocity measurements. In laser Doppler anemometers, the properties of scattering of a laser beam are utilized. For the correct operation of the device, the fluid must contain particles to scatter laser beam. A typical example of such devices is shown in Fig. 16. The laser beam is focused on a small volume element, and the scattered beams are received by an appropriate arrangement of lenses. The scattered light experiences a frequency shift directly proportional to the velocity. The scattered and unscattered beams are combined through a beam splitter. The resultant beam is put through a photomultiplier tube to give an output proportional to flow velocity. The data from the photomultiplier is processed carefully by employing appropriate signal processors.

He-Ne gas lasers operate at a frequency of 5×10^{14} Hz (wavelength of 632.4 nm) and are preferred over argon lasers. There are laser flowmeters that measure more than one velocity component simultaneously. Laser techniques are useful to determine turbulence and other flow phenomena. Focused laser beams can measure flows of samples as small as tens of cubic micrometers. The use of this is generally limited to laboratory studies related to point velocity measurements. Moreover, it requires the pipe carrying fluid to be transparent to the laser beam.

ULTRASONIC FLOWMETERS

In ultrasonic flowmeters, acoustic waves detect the flow of liquids and gases in pipes. There are a few different types, such as the Doppler effect, transit time, correlation, and ultrasonic vortex types.

Figure 16. A laser Doppler anemometer is based on scattered laser beams. As the laser light encounters particles in the flowing fluid, it gets scattered. Some of the scattered light is picked up by suitably located lenses. The frequency shift of the returned light depends on the velocity of particles in the fluid.

Figure 17. A Doppler effect ultrasonic flowmeter is based on the reflection of ultrasonic beams from particles or air bubbles carried in the flowing fluid. For signal processing, proper amplification, filtering, modulation, and demodulation of returned signals is necessary.

In *Doppler effect flowmeters*, ultrasonic signals of a fixed frequency are transmitted through the flowing fluid, and the frequency shift of the returned signals is measured. The transmitted signals can be continuous or in pulse-modulated form. Such impurities as solids, bubbles, or any other discontinuity in the liquid reflect the signals back to the transmitter. A simplified example of this flowmeter is depicted in Fig. 17. The frequency of the reflected signal shifts from the transmitted frequency in proportion to the velocity. The frequency f_r of reflected signals can be expressed as

$$f_r = f(c + v \cos \theta)/c \quad (20)$$

where f is the frequency of transmitted ultrasonic wave, c is the velocity of sound in the still fluid, v is the relative velocity of fluid with respect to transmitter, and θ is the angle of transmission with respect to direction of fluid flow.

Particles reflecting the ultrasonic signals act as a source moving with a velocity v relative to the receiver. Now the frequency of reflected signals to the receiver may be expressed as

$$f_{rr} = f_r c / (c - v \cos \theta) \quad (21)$$

It can further be proved that the frequency shift between the transmitted and received signal is

$$\Delta f = f_{rr} - f = (2fv \cos \theta)/c \quad (22)$$

The particles scatter the transmitted signal in all directions; therefore, the received signals by the receiver are attenuated severely. During the signal-processing stages, the receiver signals are amplified to the level of transmitted signal and added to the transmitted signals. This gives an amplitude modulated signal with a carrier frequency of $(f + f_{rr})/2$ and a modulating frequency of $\Delta f/2$. Rectification of the output of the adder and low-pass filtering gives a demodulated signal proportional to fluid velocity v .

The *transit time* ultrasonic flowmeters are based on the measurement of the difference in travel time between pulses transmitted along or against the fluid flow in a pipe. A typical arrangement is shown in Fig. 18. Transducers 1 and 2 act as transmitters and receivers. As transmitter 1 sends a pulse, the corresponding transit time may be expressed as

$$t_d = L/(c + v \cos \theta) \quad (23)$$

Figure 18. A transit time ultrasonic flowmeter uses the time of flight between two transducers. The two transducers are used as transmitters and receivers alternately. The transit time difference can be directly related to the flow rate of the fluid. Because the time difference is small, careful signal processing is necessary for accurate measurements.

where t_d is time taken for pulse to travel from transducer 1 to 2, L is the distance between transducers, c is the velocity of sound in still fluid, v is the velocity of the fluid, and θ is the angle between transducers with the pipe.

When transducer 2 sends a pulse, the corresponding transit time becomes

$$t_u = L/(c - v \cos \theta) \quad (24)$$

From these two equations, the differential time ΔT can be found as

$$\Delta T = t_d - t_u = (2Lv \cos \theta)/c^2 \quad (25)$$

The differential time ΔT is very small, of the order of a few hundred nanoseconds. Therefore, carefully designed electronic circuits are necessary for a reasonable accuracy. In some systems (e.g., sing around systems) transmitters continuously switch between transmitter and receiver modes, which leads to better accuracy. There are two different types—wet and clamp-on. In the wet type, the transducers are inserted in the stream making direct contact with the fluid. In the clamp-on type, the transducers are attached to the pipes externally. The clamp-on types are used for rough estimate of flow in pipes of large diameters.

Ultrasonic *cross-correlation flowmeters* consist of two transducers sensing fluctuations in the properties of the fluid. For example, the properties of the fluid may be variations in the acoustic impedance resulting from the presence of particles and air bubbles. The variations in the sensing of the fluid properties are randomly changing but present in each sensor. Therefore, the delayed version of the output signal $x(t)$ of sensor 1 is correlated with the output $y(t)$ of the sensor 2 through a correlator to determine the cross-correlation function. The output of the correlator has a maximum value proportional to L/v against delayed versions of $x(t)$. The received signals are amplified, demodulated, and filtered to eliminate the high-frequency carrier signal. The remaining demodulated signals are amplified and input to the correlator to determine the flow rates. There are many other cross-correlation flowmeters based on different techniques and sensors such as capacitance transducers, electrodes, and infrared or optical sensors. The fluid properties that

may be used for measurements can be densities, temperatures, conductivity, acoustic impedance, and the like.

Ultrasonic transducers are available for gas and liquid flow measurements. The accuracy of these devices can vary between $\pm 0.5\%$ and 10% of full-scale (FS). The liquid must contain solid particles or air bubbles in the stream for Doppler-type flowmeters to operate effectively. The amount of solid particles must not exceed a certain limit (e.g., 30%) so that ultrasonic energy can penetrate into the stream for the measurement of average velocity. Also, for accurate results, the particles must also flow with the same speed as the liquid. The time-of-flight type of ultrasonic transducers are more suitable for gas applications.

ELECTROMAGNETIC FLOWMETERS

Magnetic flowmeters have been widely used in industry for many years. Unlike many other types of flowmeters, they offer true noninvasive measurements. They can measure reverse flows and are insensitive to viscosity, density, and flow disturbances. Electromagnetic flowmeters can rapidly respond to flow changes and are linear devices for a wide range of measurements. Recently, the technological refinements have resulted in much more economical, more accurate, and smaller instruments than the previous versions.

The underlying principle of the electromagnetic flowmeter is Faraday's Law of Electromagnetic Induction. This law states that if a conductor of length l (m) is moving with a velocity v (m/s), perpendicular to a magnetic field of flux density B (T), then the induced voltage e across the ends of conductor may be found by

$$e = Blv \quad (26)$$

The application of Faraday's Law to electromagnetic flowmeters is shown in Fig. 19. The magnetic field, the direction of the movement of the conductor, and the induced electromotive force (emf) are all perpendicular to each other. The induced voltages are linearly proportional to the mean velocity of liquids or to the volumetric flow rates.

Figure 19. Operational principle of an electromagnetic flowmeter is based on Faraday's Law, which states that a voltage is induced in a conductor moving in a magnetic field. In electromagnetic flowmeters, the direction of movement of conductor, the magnetic field, and the induced emf are perpendicular to each other in x , y , and z axes. Electrodes S_1 and S_2 experience a virtual conductor resulting from liquid in the pipe.

In the case of electromagnetic flowmeters, the conductor is the liquid flowing through the pipe, and the length of conductor is the distance between the two electrodes, which is equal to the tube diameter. The velocity of the conductor is proportional to the mean flow velocity of the liquid. Hence, the induced voltage becomes

$$e = BDv \quad (27)$$

where D (m) is the diameter of pipe. If the magnetic field is constant and the diameter of the pipe is fixed, the magnitude of the induced voltage will only be proportional to the velocity of the liquid. If the ends of the conductor, in this case the sensors, are connected to an external circuit, the induced voltage causes a current i to flow. The current can be processed suitably as a measure of the flow rate. The resistance of the moving conductor may be represented by R to give the terminal voltage v_T of the moving conductor as $v_T = e - iR$. Using modern amplifiers with very high input impedance, the current i is minimized to such an extent that v_T is almost equal to e .

Electromagnetic flowmeters are often calibrated to determine the volumetric flow of the liquid. The volume of liquid flow Q (L/s) may be related to the average fluid velocity as

$$Q = Av \quad (28)$$

Writing the area A (m²) of the pipe as

$$A = \pi D^2/4 \quad (29)$$

gives the induced voltage as a function of the flow rate

$$e = \frac{(4BQ)}{(\pi D)} \quad (30)$$

This equation indicates that, in a carefully designed flowmeter, if all the other parameters are kept constant, then the induced voltage is linearly proportional only to the liquid flow.

Many different types of electromagnetic flowmeters are available, and all are based on Faraday's Law of Induction. The two most commonly used electromagnetic flowmeters are the ac and the dc types.

Alternating Current Flowmeters

In many commercial electromagnetic flowmeters, an alternating current of 50 Hz to 60 Hz in coils creates a magnetic field in the liquid flowing in the pipe. A voltage is induced in the liquid as described by Faraday's Law of Induction. A typical value of the induced emf in an ac flowmeter fixed on a 50 mm internal diameter pipe carrying 500 L/min is about 2.5 mV.

Historically, ac magnetic flowmeters were the most commonly used types because they reduced polarization effects at the electrodes. In general, they are less affected by the flow profiles of the liquid inside the pipes. They allow the use of high-power amplifiers with low drifts and high-pass filters to eliminate slow and spurious voltage drifts that emanate mainly from thermocouple and galvanic actions. These flowmeters find many applications as diverse as measuring blood flow in living specimens. Miniaturized sensors allow measurements on pipes

and vessels as small as 2 mm in diameter. In these applications, the excitation frequency is higher than industrial types, varying between 200 Hz and 1000 Hz.

A major disadvantage of the ac flowmeters is that the powerful ac field induced spurious ac signals in the measurement circuits. This necessitates periodical adjustment of zero output at zero velocity conditions. Also, in some harsh industrial applications, currents in the magnetic field may vary as a result of voltage fluctuations and frequency variations in the mains. The effect of fluctuations in the magnetic field may be minimized by the use of a reference voltage proportional to the strength of the magnetic field to compensate for these variations. To avoid the effects of noise and fluctuations, special cabling and calibration practices recommended by the manufacturers must be used to ensure accurate operations.

Readily available are ac flowmeters operating at 50 Hz, 60 Hz, or 400 Hz. In general, ac flowmeters can operate at 10 Hz to 5000 Hz. High frequencies are preferred in determining the instantaneous behavior of transients and pulsating flows. Nevertheless, in applications where extremely good conducting fluids and liquid metals are used, the frequency must be kept low to avoid skin effects. On the other hand, if the fluid is a poor conductor, the frequency must not be so high that dielectric relaxation is not instantaneous.

Direct Current Flowmeters

Direct current or pulsed magnetic flowmeters excite the flowing liquid with a field operating at 3 Hz to 6 Hz. As the current to the magnet is turned on, a dc voltage is induced at the electrodes. The signals observed at the electrodes represent the sum of the induced voltage and the noise, as illustrated in Fig. 20. When the current in the magnetic coils is turned off, the signal represents only the noise. Subtracting the measurement of the flowmeter when no current flows through the magnet from the measurement when current flows through the magnet effectively cancels out the effect of noise.

If the magnetic field coils are energized by normal direct current, then there occur several problems such as polarization, which is the formation of a layer of gas around the measured electrodes, as well as electrochemical and electromechanical effects. Some of these problems may be overcome by energizing

Figure 20. The signals observed at the electrodes represent the sum of the induced voltage and the noise. When the current in the magnetic coils is turned off, the signal across the electrodes represents only the noise. Subtracting the measurement of the flowmeter when no current flows through the magnet from the measurement when current flows through the magnet effectively cancels out the effect of noise.

the field coils at higher frequencies or ac. However, higher frequencies and ac generate transformer action in the signal leads and fluid path. Therefore, the coils are excited by dc pulses at low repetition rates to eliminate the transformer action. In some flowmeters, by appropriate sampling and digital signal-processing techniques, the zero errors and the noise can be rejected easily.

The zero compensation inherent in the dc magnetic flowmeters eliminates the necessity of zero adjustment. This allows the extraction of flow signals regardless of zero shifts due to superious noise or electrode coating. Unlike ac flowmeters, larger insulating electrode coating that may shift the effective conductivity significantly without affecting performance can be tolerated. It can be said that as long as effective conductivity remains high enough, a dc flowmeter will operate satisfactorily. Therefore, dc flowmeters are less susceptible to drifts, electrode coatings, and changes in the process conditions in comparison to conventional ac flowmeters.

Because of the slow pulsed nature of operations, dc magnetic flowmeters do not have good response times. However, as long as there are not rapid variations in the flow patterns, zero to full-scale response times of a few seconds do not create problems in the majority of applications. Power requirements are also much less because the magnet is energized part of the time. This gives an advantage in size reduction and in power saving of up to 75%.

Application of all types of magnetic flowmeters can be realized only on conductive liquids such as acids, bases, slurries, foods, dyes, polymers emulsions, and suitable mixtures that have conductivities greater than minimum conductivity requirements. Generally, magnetic flowmeters are not suitable for liquids containing organic materials and hydrocarbons. As a rule of thumb, the magnetic flowmeters can be applied if the process liquids that constitute a minimum of about 10% conductive liquid in the mixture.

For electromagnetic flowmeters to operate accurately, the process liquid must have minimum conductivity of $1 \mu\text{S}/\text{cm}$

to $5 \mu\text{S}/\text{cm}$. Most common applications involve liquids whose conductivity is greater than $5 \mu\text{S}/\text{cm}$. Nevertheless, for accurate operations, the requirement for the minimum conductivity of liquid can be affected by length of leads from sensors to transmitter electronics.

The wetted parts of a magnetic flowmeter include the liners, electrodes, and electrode holders. Many different materials such as rubber, Teflon, polyurethane, and polyethylene are used in the construction to suit process corrosivity, abrasiveness, and temperature constraints. The main body of a flowmeter and electrodes can be manufactured from stainless steel, tantalum, titanium, and various other alloys. Liners are selected mainly to withstand the abrasive and corrosive properties of the liquid. The electrodes must be selected such that they cannot be coated with insulating deposits of the process liquid during long period of operations. The main problem in electromagnetic flowmeter is due to the electrodes getting coated over a period of time, thereby leading to malfunctions. Present day flowmeters have means to overcome this by sensing high frequency pulses to the electrodes, thereby the coating gets removed automatically.

During the selection of electromagnetic flowmeters, the velocity constraints should be evaluated carefully in order to secure accurate performance over the expected range. The full-scale velocity of the flowmeter is typically 0.3 m/s to 10 m/s. Some flowmeters can measure lower velocities with somewhat deteriorated accuracy. Generally, employment of electromagnetic flowmeters over a velocity of 5 m/s should be considered carefully because erosion of the pipe and damages to liners can be significant.

A good electrical grounding of magnetic flowmeters, as illustrated in Fig. 21, is required to isolate relatively high common-mode potential. The sources of ground potential may be in the liquid or in the pipes. In practice, if the pipe is conductive and makes contact with the liquid, the flowmeter should be grounded to the pipe. If the pipe is made from nonconductive materials, the ground rings should be installed to maintain contact with the process liquid. Improper grounding results in excessive common-mode voltages that can severely limit the accuracy and damage the processing electronics.

Figure 21. Good grounding of electromagnetic flowmeters is absolutely essential to isolate noise and high common-mode potential. If the pipe is conductive and makes contact with the liquid, the flowmeter should be grounded to the pipe. If the pipe is made from nonconductive materials, the ground rings should be installed to maintain contact with the process liquid. Improper grounding results in excessive common-mode voltages that can severely limit the accuracy and damage the processing electronics.

Table 2. Accuracy and Applications of Flowmeters

Flowmeter	Liquid			Accuracy (%)	Reynold's Number	Example Standards
	Clean	Slurry	Gas			
Coriolis	Yes	Yes	Yes	±0.2–1.0	No limit	
Magnetic	Yes	Yes	No	±0.5–1.0	No limit	ISO 6817, ASME 16Mt
Orifice plate	Yes	Yes	Yes	±0.5–3.0	>1,000	ANSI/ASME MFC 3M, ISO 5167
Oscillating vane	Yes	Yes	Yes	±0.5	Depends on size	
Pitot tube	Yes	No	Yes	±5.0	No limit	ASME/MFC SC16
Positive displacement	Yes	No	Yes	±0.5–1.0	<8,000	OIML R31
Target	Yes	Yes	Yes	±0.5–2.0	>1,000	
Thermal mass	Yes	Yes	Yes	±1.0	No limit	ISO TC30
Turbine	Yes	No	Yes	±0.5–1.0	Viscous	ASME/ANSI 4M
Ultrasonic	Yes	Yes	Yes	±1.0–5.0	No limit	ANSI/ASME MFC 5M
Variable area	Yes	No	Yes	±0.5–1.0	Viscous	
Venturi	Yes	No	Yes	±0.5–2.0	<75,000	ASME/ANSI ISO 5167
Vortex	Yes	No	Yes	±0.5–1.5	<10,000	ASME/ANSI MFC 6M

The accuracy of conventional magnetic flowmeters is usually expressed as a function of full scale, typically 0.5% to 1% FS. However, dc flowmeters have a well-defined zero because of the automatic zeroing nature; therefore, they have percentage rate of accuracy better than ac types, typically at 0.1% to 2% rate.

CALIBRATION, ACCURACY, PRECISION, AND STANDARDS

There are many manufacturers of flowmeters, as listed in Table 1. They are used in diverse industries such as oil and gas, iron and steel, power, food and drink, water distribution, pharmaceutical, agricultural, mineral processing, and manufacturing.

In the past, the flowmeter repeatability rather than accuracy was the main concern. However, nowadays, with the use of microprocessors together with improved transducers, better accuracies are possible. For example, it is possible to obtain mass flowmeters having accuracies of 0.2% to 0.5% after having compensated for temperature and pressure effects. A list of flowmeters together with their accuracy and suitability for various applications are given in Table 2.

It is necessary to calibrate flowmeters because of the possible changes in fluid properties. In field applications where characteristics of fluids change often or mixtures of fluids are used, frequent rechecking and recalibration of flowmeters may be necessary for continual and accurate operations. There are a number of national and international codes of practice for calibrating flowmeters. A number of organizations such as ASME, ISO, and British Standards codify standards about flowmeters. The standards are codified for accuracy of components, calculating precision, bias errors, in situ testing, uncertainty analysis, and the like. The American Petroleum Institute (API) standards pertain to measurement of liquid petroleum products, and American Gas Association (AGA) standards pertain to measurement of natural gas. Also, a number of committees are looking into flow measurement standards such as ISO/TC28/SC2/WG6 of Israel and the United States and BSI/PCL/2/9 of the United Kingdom. Calibrations of flowmeters are done in a standards laboratory. Flow being a derived quantity, its calibration should be traceable to the fundamental units of Length, Mass, and Time (L, M, and T). The gravimetric methods of calibration as per ISO 4185 is the method for calibration of flowmeters used for liquid application. The Bell power is used for primary calibration of gas flowmeters.

DYNAMOMETERS

The dictionary defines a dynamometer as (1) a device for measuring mechanical force, as a balance, and (2) a device for measuring mechanical power, especially one that measures the output or drive torque of a rotating machine. The prefix “dynamo-” itself is a variation of “dyna-,” which is a learned borrowing from Greek meaning “power,” and is used in the formulation of compound words, such as dynamometer. According to the US Patent Office, however, dynamometers include a very wide range of measuring instruments. Some manufacturers refer to only “complex” devices, which incorporate load sensors or transducers in their structure as dynamometers.

The classical usage of the word dynamometer is primarily for power measurement. In such a dynamometer, power is determined as the product of the measured torque and angular velocity. Currently, and more generally, the term dynamometer and load transducer are used synonymously, and they cover load measurement instruments ranging from the simple to the more complex. For example, a simple device measuring grip strength of the human hand is known as a grip dynamometer. Also, terms such as load sensor, load cell, force transducer, and force platform (plate) are being used to cover the same range of instruments. For completeness, a brief description of specialized dynamometers as power measurement instruments is given first, followed by a more detailed discussion of dynamometers as load transducers in general.

POWER MEASUREMENT

Two types of mechanical power measuring devices exist: (1) those absorbing power and dissipating it as heat and (2) those transmitting the measured power. These are called, respectively, absorption dynamometers and transmission dynamometers. Common absorption dynamometers are the Prony brake, the electric generator, the water brake, and the magnetic or eddy-current brake. Figure 1 schematically depicts a Prony brake. A Prony brake is typically used for wheels smaller than 0.6 m (24 in.) in diameter, where the power to be absorbed is relatively small. As the brake is applied, the force, f , perpendicular to the cantilever beam is measured. Simultaneously, the angular velocity of the wheel is also monitored. The product of the angular velocity, the measured torque (i.e., force, f , times moment arm, L), and the appropriate unit conversion constants gives the instantaneous power. The other absorption dynamometers work in a similar way, where a load is applied to impede the rotating shaft while both the load applied and the angular velocity of the shaft are measured.

Many types of transmission dynamometers have been used in the past, but currently only the torsion dynamometer and the cradle-mounted electric motor (i.e., chassis dynamometer)

Figure 1. Schematic of a Prony brake.

are in use. Torsion dynamometers directly measure the torque transmitted through a shaft using a torque transducer placed in series with that shaft. When the power output of an electric motor is in question, this can also be determined by measuring the reaction forces transmitted to the floor at the motor supports. Naturally, in both systems the angular velocity of the shaft also needs to be measured.

FORCE AND TORQUE MEASUREMENT

The force applied to a body is measured by measuring its physical effect on that body. This can take the form of a balance, where the unknown force is balanced against the known gravitational force of a standard mass, or against a magnetic force developed by interaction of a current-carrying coil and a magnet. Alternatively, the physical effect measured can be the elastic deformation of a body. Relating force to an acceleration via a known mass, or relating it to fluid pressure, is a variation of the latter method and will not be discussed separately. A simple example of an instrument where force is measured by relating it to a deformation is a spring scale, where the spring deforms proportional to the applied force. All of the above methods can be successfully used if the force to be measured is static or slowly varying. However, if the force is dynamic, the method of measuring deformations is used. These measured deformations are extremely small, and such a measuring device is generally referred to as a force transducer or a dynamometer.

A simple mathematical model is used to establish the input-output relationship of a force transducer. Figure 2 shows a physical model of a force transducer, where the system is idealized as a known mass, m , carried by a spring of known stiffness, k , and a damper with a known constant, b . This relationship, along with the resulting transfer function in the Laplace domain, is seen as a simple second-order relationship as

Figure 2. Idealized model of an elastic force transducer.

follows:

$$m\ddot{x}_o = -kx_o - b\dot{x}_o + f$$

$$\frac{x_o}{f}(s) = \frac{K}{s^2 + \frac{2\zeta s}{\omega_n} + 1} \quad (1)$$

The dynamic response characteristic parameters of natural frequency, damping ratio, and sensitivity are found to be the following:

$$\omega_n = \sqrt{\frac{k}{m}} \quad (\text{natural frequency})$$

$$\zeta = \frac{b}{2\sqrt{km}} \quad (\text{damping ratio}) \quad (2)$$

$$K = \frac{1}{k} \quad (\text{sensitivity})$$

As can be seen in Eq. (2), the stiffness, k , is used to determine each of the above parameters, because it is inversely proportional to the damping ratio and sensitivity and is directly proportional to the natural frequency. Therefore, the stiffness is very important in transducer behavior and design.

So far, only a force acting in a known direction has been discussed. More generally, all six components of a load acting on a body can be considered, where the force vector and the moment vector are each expressed with their three orthogonal components. A transducer which measures more than one component of the load is called a multicomponent load transducer or is referred to by the number of its components (i.e., a six-component load transducer).

Torque is a special case of a moment acting about the long axis of an elongated member. It causes shear deformation of this member, and thus it requires a somewhat different measurement method. Because torque measurement is usually carried out as an independent measurement on a shaft, torque transducers are commonly looked upon as a separate class of single-component load transducers.

Different sensing technologies are used to measure the elastic deformations of a transducer element. These include strain gauges, piezoelectric crystals, piezoresistive elements, and capacitive transducers. Of these, the former two are the most commonly used methods in load measurement technology, and they will be discussed here.

Strain-Gauged Transducers

Strain-gauged transducers are used to measure both static and dynamic loads. These devices use either metal-foil gauges or semiconductor gauges. Metal-foil strain gauges are produced by etching the gauge pattern into a thin sheet of metal foil deposited onto a plastic backing. Typical sizes vary from a few millimeters to several centimeters. Semiconductor strain gauges are generally smaller in size and have a higher sensitivity. However, they are fragile and relatively brittle, and they are more temperature-sensitive than metal-foil gauges. Semiconductor gauges have mainly been used in miniature transducers, the availability of which are increasing as technology advances.

Strain gauges are applied to the body of an elastic member of a transducer using adhesive so that when the elastic member deforms, the length of the strain gauge, and therefore its

Figure 3. Wheatstone bridge.

electrical resistance, changes proportionally. When a constant current is applied across the gauge, the change in length is seen as a change in voltage proportional to the strain induced. Strain gauges are made to be sensitive to changes in length along a principal direction, but insensitive in the transverse direction. Whether a transducer is designed to measure a single load component or multiple load components, strain gauges used for each load channel are wired in a Wheatstone bridge configuration. This not only allows measurement isolation of the desired load component, but also compensates for deformations resulting from temperature changes. A Wheatstone bridge is depicted in Fig. 3, where each resistance represents one of the strain gauges used in the transducer. Also shown are the input and output voltages. When the bridge is balanced (i.e., $R_1 = R_2$ and $R_3 = R_4$) the output voltage is zero. In a typical transducer the nominal gauge resistances are equal, so $R_1 = R_2 = R_3 = R_4 = R$, where standard values for R are 120 Ω , 350 Ω and 1000 Ω ; the most commonly used value is 350 Ω . The bridge output voltage, as a function of individual gauge strains, is given as

$$e_o = \frac{V \cdot G_f}{4} [(\epsilon_1 - \epsilon_2) + (\epsilon_3 - \epsilon_4)] \quad (3)$$

where, the ϵ 's are the individual strains, V is the excitation or supply voltage, and G_f is a material property of the gauge called the gauge factor. The gauge factor is the relationship of the strain to resistance change (i.e., the sensitivity of the gauge) and is expressed as

$$G_f = \frac{\frac{\Delta R}{R}}{\epsilon} \quad (4)$$

Typical foil gauges would have a gauge factor of approximately 2, while the gauge factor for semiconductor strain gauges can be as high as 100.

When selecting a material to be used for a transducer elastic element, we need to consider mechanical properties, thermal properties, and machinability of the material. Linear elastic load response with minimal hysteresis is one of the most desirable mechanical properties for a transducer material. As for thermal properties, the thermal conductivity contributes to the transducer accuracy and stability. The most commonly used materials include SAE 4340 steel, 631 (17-4 PH) stainless steel, and 2024-T4 and 7075-T6 aluminum. A comprehensive list can be found in Ref. 1.

Strain-gauged transducers involve a considerable design trade-off. From a natural frequency point of view, which influences the capability of measuring dynamic forces, the transducer element needs to have as high a degree of stiffness as

Figure 4. Single-component force transducer. (a) Strain gauge location and orientation, (b) Wheatstone bridge, (c) stress (strain) distribution in beam, and (d) bending moment diagram.

possible. On the other hand, higher sensitivity requires greater deformations and thus a lower degree of stiffness. Bridging the gap in this design trade-off are high-end electronics. Today, electronics providing a high signal-to-noise ratio (SNR) allow for sensitive transducers which have relatively stiff elastic elements.

Considering single-component force transducers, a relatively low capacity transducer would typically utilize a bending beam member as the spring element. Figure 4(a) depicts such a member with gauges located at A and B; this member is loaded by the force to be measured, f . In Fig. 4(b) the Wheatstone bridge is shown, where the numbers correspond to the gauge designations in Fig. 4(a). Note that the bridge output is proportional to the difference between strains measured at levels A and B. Figure 4(c) shows the stress (or strain) distribution in the beam at the two levels, and Fig. 4(d) shows the bending moment diagram for the beam. Strain at A is proportional to the moment at the same location (i.e., $f \cdot a$), and similarly the strain at B is proportional to $f \cdot b$. The difference between the strains at the two levels, therefore, is proportional to $f \cdot (a - b)$. Thus, the output of the bridge is independent of the location of the force. This makes it possible to design a transducer as depicted in Fig. 5, where the force can act anywhere on the surface provided. To increase sensitivity without decreasing stiffness, very often the bending beam is weakened at the locations where the strain gauges are attached. Two examples of such a design are shown in Fig. 6.

Using a shear beam, as shown in Fig. 7(a), would be an appropriate solution when the force to be measured is relatively high and the above design is not satisfactory. The gauges are positioned at 45° angles to the long axis of the beam (on

Figure 5. Adapted single-component force transducer.

both sides). Figure 7(b) shows the shear stress distribution on the gauged surface, and Fig. 7(c) is the same shear stress acting on a small area where the gauges are located. If the element of Fig. 7(c) is rotated by 45° , the compressive and tensile stresses of Fig. 7(d) are obtained. Therefore, gauge 1 would be subjected to compression, while gauge 2 would be subjected to tension, and the difference between the two gauge readings would still be proportional to the applied force. When we combine all four gauges (both sides), a full Wheatstone bridge with an output proportional to the force is obtained. It is again possible to modify the cross-sectional geometry by reducing the beam thickness at the gauge location, thus increasing the sensitivity without significantly affecting the stiffness of the beam. References 1 and 2 provide design variations based on the above principles.

The beam of either Fig. 4 or Fig. 7 can be instrumented on the currently blank adjacent sides to measure the force perpendicular to the one depicted. Furthermore, another set of gauges, as shown in Fig. 8 (gauges on the opposite side of the beam are not shown), can be used to measure the force along the long axis of the beam. It should be noted, however, that the configuration of Fig. 8 usually provides the highest stiffness and the least sensitivity. One way of increasing sensitivity in this direction would naturally be reducing the cross-sectional area. This could be achieved without significantly lowering the stiffness in the transverse direction by using a hollow geometry such as

Figure 6. Example cross-sections to increase sensitivity without decreasing stiffness.

Figure 7. Shear beam single-component force transducer. (a) Strain gauge location and orientation, (b) shear stress (strain) distribution in beam, (c) unit area shear stress, and (d) rotation of unit area to obtain normal stresses.

a tube. By selecting a suitable ratio between the wall thickness and the diameter of the tube, it is usually possible to find a satisfactory solution to measure all three force components with the desired resolution.

A tubular cross section is also very suitable for torque measurement. Referring to Fig. 9, note that the gauges are oriented to measure the shear due to the torque only, and any shear due to a transverse force (similar to the one in Fig. 7) is eliminated. Actually, a detailed analysis of the stresses caused by all possible loads applied to the end of the tube will show that the gauge configuration of Fig. 9 is only sensitive to the torque.

Piezoelectric Load Transducers

Certain materials respond to an applied electrical charge by mechanically deforming. Alternatively, an electrical charge is

Figure 8. Gauge location and orientation for normal stress measurement.

Figure 9. Torque transducer. (a) Gauge location and orientation. (b) Wheatstone bridge.

developed if the material is mechanically stressed. These actions are referred to as piezoelectric effects, and materials which exhibit this behavior are called piezoelectric materials. Quartz is a piezoelectric material with high stability and is normally used in building piezoelectric load transducers.

The piezoelectric properties of quartz crystal are directional, and axial and shear force components can be isolated by orienting the material in the transducer. Figure 10 shows a quartz crystal with disks cut out to be sensitive to compression (disk a) and shear (disk b). When a disk is placed between metal electrodes and subjected to a force, a charge, q , is produced. This charge is proportional to the deformation of the crystal, and thus it is also proportional to the force applied. Simultaneously, a voltage is developed between the electrodes. Therefore, the voltage output can be amplified and calibrated to measure the force applied.

Normally, a pair of disks is used to measure each load component. Using the disks in pairs doubles the sensitivity and permits simple electrical contact by a central electrode. By stacking three pairs of disks, one pair for the axial load and one pair for each of the two orthogonal shears, a three-component force transducer can be obtained. This type of transducer must be assembled with a compressive preload, which prevents the disks from separating from the metal plate electrodes during tensile loading.

Figure 10. Quartz crystal. (a) Normal force orientation and (b) shear force orientation.

Figure 11. Six-component piezoelectric dynamometer made out of four three-component load transducers.

Six-component transducers can be built by placing four such three-component load transducers at four corners of a platform. Figure 11 (commonly called a piezoelectric dynamometer) shows such a configuration, where each load cell is numbered from 1 to 4, and the load direction is indicated by the direction of each coordinate axis. Thus, the two subscripts of each load component uniquely identify the force. The 12 outputs of the transducer are combined inside the transducer such that eight signals are actually output. These eight channels represent the four individual vertical force components (F_{z1}, F_{z2}, F_{z3} , and F_{z4}); two shears in the x -direction ($F_{x1} + F_{x2}$ and $F_{x3} + F_{x4}$), and two shears in the y -direction ($F_{y1} + F_{y4}$ and $F_{y2} + F_{y3}$). In order to get the three force and the three moment components, the output needs to be further reduced as follows:

$$\begin{aligned}
 F_x &= (F_{x1} + F_{x2}) + (F_{x3} + F_{x4}) \\
 F_y &= (F_{y1} + F_{y4}) + (F_{y2} + F_{y3}) \\
 F_z &= (F_{z1} + F_{z2}) + (F_{z3} + F_{z4}) \\
 M_x &= (F_{z1} + F_{z2}) - (F_{z3} - F_{z4})(b/2) \\
 M_y &= (-F_{z1} + F_{z2}) + (F_{z3} - F_{z4})(a/2) \\
 M_z &= [(F_{x1} + F_{x2}) - (F_{x3} + F_{x4})(b/2) \\
 &\quad + [(F_{y2} + F_{y3}) - (F_{y1} + F_{y4})(a/2)
 \end{aligned} \tag{5}$$

Piezoelectric transducers have the advantage of having high sensitivity and high rigidity. Typical stiffness properties of these crystals result in natural frequencies as high as 30,000 Hz. However, the governing natural frequency is normally that of the members supporting the transducer, which is usually much lower than that of the quartz alone. A disadvantage of piezoelectric transducers is that they are not inherently suited for static measurements. This is due to the charge developed in the quartz under load gradually leaking, causing signal decay eventually to zero. Then, if the applied load were released, the transducer will erroneously indicate a load in the opposite direction equal to the amount of the decay.

As stated previously, the applied force, f , to a piezoelectric transducer causes a deflection, x . A potential voltage, E , is produced from the resulting charge buildup. This can be

Figure 12. Piezoelectric transducer.

expressed as

$$E = \frac{q}{C_{cr}} \quad (6)$$

where C_{cr} is the crystal capacitance of the piezoelectric material and is defined as

$$C_{cr} = \frac{\phi A}{t} \quad (7)$$

In Eq. (7), ϕ is the dielectric constant of the crystal, A is the area of the plates, and t is the distance between the plates. Figure 12 shows such a piezoelectric transducer. A piezoelectric constant, k , relates the applied force, f , to the resulting charge, q as shown:

$$q = kf \quad (8)$$

Using Eq. (8) in Eqs. (6) and (7) results in the following relation for the potential voltage, E :

$$E = \frac{kft}{\phi A} \quad (9)$$

In order to quantify the applied force the induced, or potential, voltage, E , must be measured. A charge amplifier is typically implemented due to the induced voltage's small magnitude. This leads to another complication in that the charge may leak back through the crystal. Figure 13 depicts the circuits required to determine the behavior of a piezoelectric transducer. Figure 13(a) shows the crystal itself, while Fig. 13(b) is a schematic of the cabling and amplifier. In Fig. 13 the charge

Figure 13. Equivalent circuits for (a) piezoelectric transducer and (b) amplifier and cables.

Figure 14. Equivalent circuit for piezoelectric transducer, amplifier, and cables.

generator is represented as a current generator, and the current source i_s is the time derivative of the charge generated, C_{cr} is again the crystal capacitance, C_{cb} is the capacitance of the connecting cables, C_a is the capacitance of the charge amplifier, R_a is the internal amplifier resistance, R_l is the sensor leakage resistance, and E_o the resulting output voltage to be measured.

Figure 14 is the equivalent circuit of the transducer, cabling and amplifier. From this circuit:

$$i_s = \frac{dq}{dt} = k \frac{df}{dt} \quad (10)$$

$$R = \frac{R_a R_l}{R_a + R_l} \quad (11)$$

In a piezoelectric force transducer, R_l is usually on the order of $10^{11} \Omega$; however, there are commercially available systems with higher R_a and R_l values resulting in up to $10^{14} \Omega$ total resistance, R . Systems with this high a total resistance have a very slow leakage rate and therefore enable quasi-static force measurement.

Analyzing the equivalent circuit of Fig. 14 results in the following current loop equation:

$$i_s = i_c + i_r \quad (12)$$

The output voltage is then expressed as

$$E_o = E_c = \int \frac{i_c}{C} dt = \frac{\int (i_s - i_r) dt}{C} \quad (13)$$

$$CE_o = \int (i_s - i_r) dt$$

After differentiation and substitution we obtain

$$C \frac{dE_o}{dt} = i_s - i_r = k \frac{df}{dt} - \frac{E_o}{R} \quad (14)$$

This differential equation can be put in standard form and then expressed in the Laplace domain as

$$(RCs + 1)E_o = (Rks) f \quad (15)$$

or as a first-order system input-output relationship, or transfer function:

$$\frac{E_o}{f}(s) = \frac{K\tau_s}{\tau_s + 1} \quad (16)$$

where

$$\tau = RC \text{ (time constant)}$$

$$K = k/C \text{ (static sensitivity)}$$

Figure 15. Response of a piezoelectric transducer to constant force input. (a) Input, (b) response for relatively high time constant, and (c) response for a relatively low time constant.

Figure 15(a) shows a constant force input, f , for a time of T . With these initial conditions for the time periods from 0 to T and from T to infinity, Eq. (16) can be solved:

$$E_o = \frac{kf}{C} e^{-t/\tau} \quad \text{and} \quad E_o = \frac{kf}{C} (e^{-T/\tau} - 1) e^{-(t-T)/\tau} \quad (17)$$

The response of Eq. (17) is shown in Fig. 15(b) and 15(c). These figures show undershoot of the response and also show that as the time constant decreases, the signal response decay increases. This is the reason for the need of a high time constant in piezoelectric force transducers.

The amplifier properties, along with the dimensions and physical properties of the piezoelectric material, determine the actual time constant of the transducer system. However, there are a limited number of ways to increase the time constant. By the relation above, an increase in either R or C will increase the time constant. A shunt capacitor or a series resistor at the amplifier can achieve this; however, the sensitivity of the transducer would decrease if a shunt capacitor were used. Therefore, much like strain-gauged transducers, there is a design trade-off with piezoelectric transducers as well. This trade-off is between the high time constant required for static measurement and the desired quasi-static sensitivity.

Cross-talk

Generally, in the measuring range of a transducer, relationships between the loads and signals are linear, and calibration parameters are given by constant values. Ideally, each output channel of a transducer would only be sensitive to the load component that it is designed to measure. However, manufacturing tolerances as well as some design considerations cause a transverse sensitivity or a cross-talk between the channels. For example, in a six-component load transducer, the force in the x -direction might be sensitive to some or all of the other five outputs of the transducer. Thus, F_x would be expressed as a linear combination of these signals:

$$F_x = c_{11} \cdot s_1 + c_{12} \cdot s_2 + c_{13} \cdot s_3 + c_{14} \cdot s_4 + c_{15} \cdot s_5 + c_{16} \cdot s_6 \quad (18a)$$

or

$$F_x = c_{ij} \cdot s_j \quad (18b)$$

where c_{1j} ($j = 1$ to 6) are the calibration constants, and s_j ($j = 1$ to 6) are the six output signals. The relationship between the six signals and the six load components can be expressed as

$$\{F_x F_y F_z M_x M_y M_z\}^T = [c_{ij}] \{s_1 s_2 s_3 s_4 s_5 s_6\}^T \quad (19)$$

where each load and signal vector is a column vector, and the calibration coefficients, c_{ij} , are given in a 6×6 matrix. Typically, the nondiagonal terms of the calibration matrix represent the cross-talk between the channels.

In most commercially available multicomponent transducers the cross-talk terms are less than 1% or 2% of the main calibration constants. This was common practice when data were primarily recorded by chart recorders and correcting for cross-talk usually involved a tedious process. Current means of data acquisition and processing has removed this requirement, thus providing designers with more possibilities of creative load transducer configurations.

Users may incorrectly assume that the load components which are not measured by a transducer do not affect the measured components. However, this is usually not guaranteed. For example, a single axis tension or compression transducer might give erroneous results in the presence of shear forces.

Calibration

Transducer calibration normally involves applying a known force, and relating the output of the transducer to the magnitude of this force. Applying methods of good experimental procedure, the applied load is incrementally increased up to the working limit of the transducer, then again incrementally decreased to zero. The linearity as well as any hysteresis present in the transducer should then be verified. If the transducer is to measure a dynamic load, the frequency response, or the first natural frequency of the transducer also needs to be determined. It is desirable to have the natural frequency of the transducer at least four or five times higher than the maximum frequency content of the applied load.

In calibrating a multicomponent transducer, at least as many independent load sets as the number of channels involved

must be applied. If higher number of independent load sets are applied, then the calibration matrix can be obtained using a least-squares fit. If $\{F_k\}$ is the k th independent load set and $\{s_k\}$ is the corresponding output signal set, then

$$[F_1 F_2 \dots F_k] = [c_{ij}][s_1 s_2 \dots s_k] \quad (20)$$

where c_{ij} are the elements of the unknown calibration matrix. For example, for a six-component transducer where the number of output channels is also six, the calibration matrix would be a 6×6 matrix. In the case of a transducer having eight outputs representing the six loads (i.e., the three forces and three moments), like most piezoelectric six-component transducers, a 6×8 calibration matrix would be used.

Representing $[F_1 F_2 \dots F_k]$ by $[F]$, and similarly representing the signals by $[s]$, Eq. (20) can be written as

$$[F] = [c_{ij}][s] \quad (21)$$

Post-multiplying both sides by the transpose of $[s]$, $[s]^T$, and then post-multiplying by the inverse of $\{[s][s]^T\}$, the calibration matrix is obtained:

$$[c_{ij}] = [F][s]^T \{[s][s]^T\}^{-1} \quad (22)$$

In order to determine whether there is any advantage to using more calibration points than the minimum required, the authors used up to 50 independent load sets in calibrating six-component load transducers used in gait analysis (i.e., force plates). For these particular transducers, any number of load sets larger than 15 have not been found to improve the accuracy of the calibration matrix. Although this number of load sets does not necessarily apply to all six-component transducers, it provides a guideline for establishing a successful calibration procedure.

TORQUEMETERS

Torque, or moment about an axis, is measured in several industrial situations and, increasingly, in consumer products. A common experience of torque measurement is the use of a torque spanner for tightening a wheel-nut on an automobile. The torque being applied is indicated on a scale, and the device usually operates through the bending of a rod. The meaning of torque as the product of a force and lever length is clear in this situation, and it is measured in Nm (newton meters). The axis about which the torque is applied is that of the stud on which the nut is tightened. Usually, the term *torquemeter* is taken to mean a device for the measurement of the torque in a rotating shaft, but this is not necessarily so, and other situations need to be instrumented. Measurement may be required in testing small motors or in aircraft or tanks, and in many other situations. Thus the range of requirements is very large in terms of torque range, sensitivity, accuracy, physical size, and, increasingly, of cost. Because of this, several different techniques have been developed successfully for different applications. Continuing work is mainly in the search for low-cost high performance devices for use in industrial control systems and consumer products. The overall picture is complicated because it is not always appropriate to purchase a torquemeter but rather to design it as an integral part of the experimental rig or commercial product, and there are well-established principles for doing this. In some cases, the torquemeter will also be required to act as a mechanical load, absorbing energy. In other cases, it will be important that the device does not change the operation of the system significantly through loading or through its own mechanical flexibility. There are torquemeters in use which were installed a long time ago and which continue to give good service because of their ruggedness and reliability. The user needs to be aware of these, although generally, many of these would not be installed today on grounds of cost and lack of operational flexibility. This is particularly true for the measurement of shaft torque, and this is the type of measurement which is considered first.

THE MEASUREMENT OF SHAFT TORQUE

A typical application of a shaft torquemeter incorporating a mechanical load is for the measurement of the torque/speed characteristics of a motor or engine in performance testing. In older, mechanical instruments, the integration of the two functions, the measurement and the loading, often forms an essential part of the design. The simplest and most direct device is the Prony Brake (Fig. 1), in which the rotating shaft carries a narrow drum. Braking is applied to this by means of a brake band, or possibly by friction blocks, and a screw mechanism, A, tightens this to increase the braking effect. The torque applied by the brake mechanism is measured in a number of ways, the traditional way being to use a spring balance as shown in the Fig. 1. The torque acting on the drum is $(F_1 - F_2)r$ Nm and is transferred to the lever which has a fulcrum midway between the points where the belt is attached. The belt is tightened by the screw mechanism indicated in order to increase the braking torque. The torque is then balanced by the force F which is shown on the balance and which acts on a lever of length R . Thus, the torque is FR Nm. Normally, this would be plotted against the shaft speed as the brake is tightened to give

Figure 1. The Prony Brake. In this type the screw arrangement “A” is used to tighten the belt. “B” is the fulcrum of the lever. The force F shown on the spring balance is a measure of the torque.

a characteristic of the motor or engine driving the shaft for a particular supply voltage or fuel supply. The Prony Brake is generally used for small power levels at lower speeds because of the problems of conducting the heat away and sustaining the large forces involved at high power levels.

In essence, the Prony Brake transfers the torque in the rotating member to a static member where it is more easily measured. Other methods are also utilized to carry out this transfer. These include a hydraulic device, essentially an inefficient centrifugal pump, an air fan, various electromagnetic techniques, depending, for example, on eddy current losses, and the use of a generator with a resistive or other load to absorb the energy. Again, in each case, the reaction torque is measured. In these cases, a spring balance is not normally used but rather strain gauge load cells in the supports with the advantage that the torque can then be recorded automatically. Some of the methods depend on nonlinear properties in carrying out the power transfer and can be difficult to use over wide ranges of torque. Currently, the more basic devices such as the Prony Brake have applications, but it is now simpler to use a commercially available torque meter which is inserted into the shaft, the energy being absorbed in an appropriate way which for higher powers would be an electrical generator. This also has the advantage of being easily incorporated into an automated test system. It should not be forgotten that the simplest method may be to measure the reaction torque on the motor. This has the drawback that the inertia of the motor spoils the response of the measurement to fast changes in the torque.

Transmission Torque Measurement

In applications where the energy is transmitted rather than being absorbed in the measuring instrument, a commercial device inserted in the shaft is again the simplest solution, but in many laboratory situations and consumer products, it is better to integrate the device into the overall design. In the latter case, this would usually be on the grounds of convenience,

Figure 2. Shaft torsion. The torque T causes the torsion θ and shear α . The principal axes are shown at “A” and at the concealed point “B”. Strain gauges would be placed at these positions.

physical size, or cost. The techniques used depend on measuring the small distortions caused by the stresses related to the applied torque. Figure 2 shows the torsion, which is evaluated either by measuring the distortion of the surface or the twist between the ends. The former can be measured using strain gauges attached to the surface, this being a well-developed technology, and suitable gauges exist tailored to this situation. When a shaft is twisted, the directions of greatest stretch and compression on the surface are at 45° to the axis of the shaft, these being known as the principal axes of the surface strain. Figure 2 shows these, and strain gauges would be applied to take account of these. Combination gauges are available to measure strains in more than one direction at a point and are called rosettes. It is important that the gauges are attached to the surface in such a way that a signal can be derived which represents the torque but which does not respond to shaft bending, compression, or stretching. Attaching gauges on opposite sides of the shaft as indicated and differencing the signals eliminates the spurious responses, and standard electronics is available to process the signals. The problem is passing power and signals to and from the rotating shaft. In the past, sliprings have been used satisfactorily, but noncontacting methods are preferred for avoiding electrical noise and for long-term reliability. This has been achieved electromagnetically and optically. Usually, it is best to mount some of the electronics on the shaft so that the overall performance can be independent of the efficiency of the transmission across the gap. For example, the signal can be coded in a digital form. Alternatively, the magnetostrictive effect is exploited to measure the surface strain. This effect is the compression (or possibly extension) experienced when a ferromagnetic material is magnetized. The application of a stress to the material modifies this effect, and this can be measured. If the material is isotropic, that is, uniform in all directions, then there is no preferred direction to the effect, but for materials in a crystalline form, there are preferred directions. If the shaft, or a ribbon wrapped round it, is of suitable material, the effect can be exploited to measure the strain. Considering the principal axes of the strain, the magnetic permeability of isotropic materials is usually increased along the direction of greatest compression and decreased along the direction of greatest stretch. This can be detected by a coil system in proximity to the shaft, placed and oriented to take account of the directions of principal strain shown in Fig. 2.

If the shaft is known to be rotating, then direct measurement of the twist between the ends of the shaft section is most simply carried out by detecting the time difference for corresponding points on each end to pass fixed points. The methods used are electromagnetic, optical, and capacitive. It would be simplest to place small magnets on the shaft and pick up signals

in coils as they passed. However, it has been found to be better to use gear teeth on the shaft surrounded by static internal teeth. For ferromagnetic materials, the rotation changes the magnetic properties of the system through the ease with which the magnetic flux passes between the outer and the inner parts. This is detected by a coil. Optically, the path of a light beam is interrupted by lines on a disk mounted on the shaft. If electrical capacity is used, then some protrusion on the shaft can be detected as it passes an electrode. In the applications where the shaft may sometimes be stationary, it is still possible to arrange for signals to be generated in similar ways, but the interpretation is more difficult, and greater care is needed to obtain good performance. It should not be forgotten that for some electric motors the measurement of the input current, possibly allowing for the phase in the case of alternating current may give a sufficiently good measure of the torque supplied.

STATIC TORQUE MEASUREMENT

There are applications which are essentially static and are exemplified by a robot wrist. To apply feedback in the control of a robot arm, it is useful to know the forces and torques in the wrist connecting the arm to the gripper. Tasks which require feedback include the insertion of a peg in a hole, force-controlled assembly of mechanical parts, and screwing parts together. It also allows the detection of jamming. In general, the measurement of torque is more important than that of force, and this is discussed here; Fig. 3 shows the three torques about the three axes. The methods used depend on the small distortion of the wrist caused by the forces and torques. Because the movement is limited, the connections are by flexible cables, and there is no problem of power and signal transfer. Strain gauges are normally used, and the design skill lies in applying these to a suitable mechanical structure in such a way that the various forces and torques can be distinguished, possibly using a microcomputer. Again, the use of rosettes helps in this. There are many works on strain gauge technology, and the reader is referred to Ross (1) for a helpful introduction. Workers have also used magnetic inductance to detect the small distortions, magnetic circuits being sensitive to small changes in air gaps. Other workers have explored the use of electrical capacity in order to make compact devices at low cost. In all these cases, the possibility of integrating the electronics and incorporating it in the wrist is attractive. Falkner (2) has established that this is possible for driving a capacitor type of wrist sensor. In this, a remote host computer interrogates the sensor and receives

Figure 3. Torques about the three axes.

a digital signal in return. Workers in this field usually design and instrument their own devices. Static torque may also be measured on a large scale, including heavy machinery, industrial processes and construction equipment, and in these situations strain gauge technology is well-tried and usually most appropriate.

PRINCIPLES OF OPERATION

In this section, torque meters are discussed in fuller detail with more detailed analysis of the principles. As pointed out earlier, it is necessary to understand instruments which may no longer be current but which continue in use and which are perfectly satisfactory. This is certainly the case for many of those which absorb the power, and these are the first to be considered.

Power Absorbing Torquemeters

The Prony Brake has been discussed in the introduction and demonstrates the principle very clearly, the torque being transferred to a stator where it can be measured more easily. The hydraulic and electrical types are discussed more fully here, the former transferring the torque in one of two ways. There is the friction type in which disks on the rotor rotate between disks on the stator. The gaps are designed to be small to increase the friction, the velocity gradient in the fluid then being large. The friction is controllable by the quantity of fluid, usually water, in the device, although it will depend on the speed. The water will also be used for cooling to remove the heat generated. The nonlinearity of the effect can make operation difficult as speed instabilities are possible for some power sources. The second type works through agitation of the fluid and is essentially an inefficient centrifugal pump, the rotor comprising a disk with vanes on each side. This operates as a centrifugal pump for the fluid which is impelled into the stator vanes from where it is recirculated. The fluid gains and loses kinetic energy, thus generating heat. Control of the braking effect can be through varying the quantity of fluid and valves for controlling the fluid flow. Again, water is usually used and is circulated for cooling. The rotor revolves between fixed stator blades to which the torque is transferred. Again, the device is nonlinear and may not be easy to control. But in each case, relatively small devices can absorb large powers because of the cooling facility. The outer casing is mounted in bearings so that it would be free to rotate but for the constraints of the mounting which is instrumented to measure the forces. In Fig. 4, the torque is $(F_1 r_1 - F_2 r_2)$ Nm.

Figure 4. The reaction torque on the motor mounting. The torque is $(F_1 r_1 - F_2 r_2)$.

For simplicity, the principle is demonstrated by showing only two of the mounts. Devices have also been used which employ a fan working with air in a situation in which heat is generated, and the energy is absorbed.

The use of electrical braking for the torque transfer offers greater flexibility and the simplest method is that in which the shaft drives a generator which has a variable resistive load. Reducing the resistance increases the output current and increases the load and torque transmitted. It is also possible to feed the power into the mains. The casing of the generator is mounted in bearings, and the torque is measured as above. An alternative method of transferring the torque is through eddy current loading and, in devices using this principle, the rotor comprises a metallic disk of magnetic material. There are large teeth on this rotor which sweep past the inner surface of the field magnet during rotation. The relative motion causes rapid fluctuations in the magnetic flux passing between the rotor and the stator depending on whether they are opposite one another. This, in turn, causes eddy currents which flow near the surface in the stator. This process absorbs energy, and the eddy currents flow in such a way as to retard the rotor. The torque transferred is controlled by varying the magnetization of the stator through variation of the current in the stator coils. The torque will also depend on the speed of the rotor at lower speeds, but a useful feature is that the torque saturates above a critical speed and is then mainly dependent on the field current. This makes for smooth, controllable operation. The dissipation of the heat generated is usually achieved through water cooling, adding a complication in use. As in other devices, the reaction torque on the stator is measured using a strain gauge load cell or a linear voltage differential transformer to give the output. In the latter case, there is a spring to resist motion, and the small compression or extension is measured. Care must be exercised to ensure that the electrical leads and the cooling pipes do not contribute to the torque and cause an error. The reader is referred to Ambrosius (3) for further details of these instruments.

Direct Shaft Torque Measurement

These methods all depend on the torsion, or twist, of a length of shaft when the torque is applied. No power is absorbed. In Fig. 2, the torsion θ is given by

$$\theta = (32/\pi)(l/Gd^4)T \text{ rad} \quad (1)$$

with the shear angle α given by

$$\alpha = (16/\pi Gd^3)T \text{ rad} \quad (2)$$

where

d = the shaft diameter (m)

l = the shaft length (m)

G = the modulus of rigidity (N/m^2)

and T = the applied torque (Nm)

As an example, for steel, $G = 7.7 \cdot 10^{10} \text{ N/m}^2$ so that a length 100 mm of a shaft of diameter 25 mm would twist approximately 3.3 mrad when a torque of 100 Nm was applied. This is equivalent to a movement of approximately 0.33 mm at the surface. A sensitivity of 1% of this corresponds to a surface movement of $3.3 \mu\text{m}$. Clearly, if the shaft is made thinner at this

section or a longer section is used, then the twist is greater, and the measurement is easier. The problem is that excessive flexibility causes distortion of the system being measured. In some cases, depending on the characteristics of the power source and the load, flexibility may lead to resonances building up. In other cases, the flexibility might reduce the response to higher frequencies in the measurement. For the use of strain gauges or magnetostriction, which depend on the local surface distortion, the angle α is critical but not the length l . Strain gauges are considered first.

Strain Gauges. This is a well established technology, and the correct use in this application takes account of the strain pattern in a twisted shaft. There is a shear on the surface which is perpendicular to the axis and if there is no bending of the shaft or any axial strain, then there is a strain system which has maximum and minimum values along the principal axes at 45° to the axis of the shaft. These are shown in Fig. 2 and are the most sensitive directions for detecting the surface distortion with strain gauges. The strain theory is discussed in Ross (1), and for the strain angle α , the principal strains σ_1 and σ_2 are $\pm(\alpha/2)$. In the example given above, these are ± 163 microstrain. Details of the operation of strain gauges are given in the appropriate section of this encyclopedia, and the gauges are placed to detect the principal strains, probably using a rosette which comprises more than one element. The gauges on the opposite side of the shaft are utilized to avoid spurious operation when the four gauges are connected into a bridge as shown in Fig. 5. The bridge output is

$$V = [(R_2 R_3 - R_1 R_4) / 4R^2] E \quad (3)$$

where the resistors all have nominal value R , and the small size of the increments due to the strain are taken into account. For pure torsion, the strains $\pm(\alpha/2)$ cause proportional changes in the resistors of $\pm K(\alpha/2)$ where K is the gauge factor of approximate value 2 for most materials used. Thus, R_1 becomes $R(1 + K\alpha/2)$ etc., and

$$V = (K\alpha/2)E \quad (4)$$

The torque is given by

$$T = (\pi G d^3 / 8K)(V/E) \quad (5)$$

If the shaft is under longitudinal tension or compression, the output is unaffected because all the gauges are affected in the same proportion. Similarly, bending of the shaft affects the resistances in such a way that there is no contribution to the output. The required gauges are readily available but require

Figure 5. The strain gauge bridge. Unbalance between the resistances $R_1 - R_4$ of the strain gauge elements causes an output voltage V .

care in mounting, and the electronics units are also available. The problem is how to connect the power and signals to the rotating shaft. The most direct method is through sliprings, but these can cause electrical noise and would not be considered reliable in the long term. IML (Table 1) manufactures a range of noncontacting strain gauge torquemeters. Electromagnetic coupling has proven successful, and Zabler, Dukart, Heintz and Krott (4) describe a system for detecting the torque in the steering column of an automobile as part of a power assisted steering system. The particular requirements are low cost associated with high reliability and high performance. The last mainly concerns the stability of the null position because the output forms the error signal for the servo system. The non-contacting power and signal transfers are achieved through annular transformers. The inner annulus rotates, but the outer one is static, and the transformer action is unaffected by the rotation. The researchers decided against the simplest configuration in which the ac power supply was transmitted by one transformer and then fed the bridge. The other would take the output of the bridge, and the electronics would all be off the shaft. This arrangement was considered sensitive to noise for the low output signal and to the variations in sensitivity during rotation when the gap would vary using normal manufacturing tolerances. Rather, the electronics was mounted on the shaft supplied by one of the transformers. The bridge output was amplified and converted to a pulse width modulated form for minimum noise sensitivity when transmitted across the gap. In this application, special strain gauge elements were used to reduce cost. This approach resulted in a robust and high performance system.

Magnetostrictive Devices. In these devices the change in the magnetic permeability of certain materials when stressed is exploited. In principle, the effect is considerably more sensitive to strain than the strain gauge effect. This is discussed by Beihoff (5). Exploiting this depends on successfully subjecting the material to the strain. With strain gauges, the technology for attaching the gauges is well developed, but attaching a thicker, more rigid, material is more difficult. The alloys which are useful in this context are nickel-iron, nickel-cobalt, and high nickel steels. One solution is to manufacture a section of shaft from this material and give it the required thermal mechanical pretreatment. This appears to be expensive, and there may be a compromise over the mechanical properties. More usually, a layer is attached in the form of a ribbon. As explained earlier, the directions of maximum positive and negative stress are in directions at 45° to the axis, and the physical arrangement needs to take account of this. The simplest approach is the coil arrangement shown in Fig. 6. If there is no torsion, then the inductances of the two arms B and C are balanced, and there is no output from the electrical bridge. If

Figure 6. Magnetostrictive torque measurement. This device compares the properties of the surface along AB and along AC. Unbalance is detected by the difference in the signals in coils E and F. This figure is reproduced from *A Survey of Torque Transduction Methodologies for Industrial Applications* by B. Beihoff in the Proceedings of the 1996 Annual Pulp and Paper Industrial Technology Conference. © 1996 IEEE.

there is torsion present, one inductance is increased, and the other decreased, unbalancing the bridge and resulting in an output signal that depends linearly on the torsion over a useful range. Koga and Sasada (6) report an instrument using a more advanced coil system. Figure 7 shows the figure of eight coils and their orientation with respect to the principal axes on the adjacent shaft. This ensures that the overall measurement of the effect is localized. Sections A and B with sections C and D of the magnetic core form one inductor with coil E. Sections A and C with sections B and D with coil F form the other, and the lack of balance again gives the required signal. The compact design is mainly to reduce the effects of variations in the gap between the sensor and the shaft and variations in the magnetic properties of the shaft. The effective sensor for each of the principal axes uses the same region of the shaft surface. The inductance is particularly sensitive to very small variations in the gap because of the high relative permeability of the core material. In the work described, two sensors are used on opposite sides of the shaft which is of carburized steel. They use a carrier frequency of 60 kHz, and for a torque range of ± 400 Nm with a 25 mm shaft, the linearity is $\pm 0.6\%$. In this first work, there are fluctuations in the performance, including those which are caused by rotation of the shaft. An alternative way of measuring the magnetostrictive effect is to exploit the

Figure 7. A more compact arrangement for magnetostrictive torque measurement. This figure is reproduced from *Static Characteristics of Torque Detection from Carburized Steel Shafts* by F. Koga and I. Sasada in the *IEEE Trans. Magn.* 31 (6): 1, 1995. © 1995 IEEE.

coupling between two adjacent coils as suggested by Sasada and Koga (7). One sets a magnetizing field parallel to the axis, and the other detects any magnetization of the shaft at right angles to the axis. When there is no torsion, there is no signal, but the torsion causes anisotropy in the permeability and magnetisation at right angles to the axis. This has been found to be proportional to the torsion over a useful range.

Phase Measurement. Devices which depend on the time difference in signals picked up from the two ends of the shaft section when it is rotating use electromagnetic, optical, or capacitive pick-ups. This may also be thought of as the measurement of the phase difference between the two signals. In general, such devices will not operate while the shaft is stationary or rotating very slowly. An example of an electromagnetic system is the range of Torquetronic torque meters manufactured by Torquemeters Ltd. (Table 1). The essential mechanism comprises internal and external gears with teeth. The outer contains a coil, and the magnetic circuit around the coil changes as the teeth rotate and pass through positions in which they are opposite to each other. If, for example, there is a constant current fed into the coil, then a voltage is generated as the magnetic circuit changes. The manufacturers point out that the use of several teeth in this way compensates for problems associated with any radial movements. The possible torque range of this device depends on the shaft dimensions, and meters with ranges as high as 75,000 Nm are available. These particular devices also record the speed. The problem of lack of signal if the shaft is stationary will not matter in many applications, but it is overcome in a range of devices in which the outer teeth are rotated, the coil still being stationary.

The simplest optical system suitable in a laboratory situation is the use of a stroboscope enabling the twist to be seen visually. A commercial instrument by Amsler is described in Ambrosius (3) with particulars of its source. The power is transmitted through the torsion rod which, at one end, has a disc attached with gradations around the edge. Concentric with this rod and outside it is a tube which is not subject to any torque. This carries the information about the angular position of the other end to another smaller flat ring which also has a graduated edge. The two scales are adjacent, and the torsion causes relative motion of the two scales, a vernier scale being used for accuracy. To inspect the scales during rotation, a synchronized stroboscope is used. Clearly, it would not be feasible to inspect the scales for a general static position, and the device depends on rotation. Measurements are best made for steady torques, and it is not possible to automate the operation of the device.

Other Optical Devices. Another type of optical torque meter uses mirrors. Again, rotation is required for successful operation. The principle is that if a light beam is reflected off two parallel mirrors in sequence, then the direction of the ray is unaltered; although, of course, it will be shifted sideways. The meter is designed so that one mirror is attached to one end of the flexible shaft and the other to an outer cylinder which is connected to the other end in a similar manner to the optical instrument described above. The two mirrors are at the same position at the end of the shaft. A collimated light ray, possibly from a laser, strikes the mirrors in turn for a small part of the time of rotation. During this time, the change in direction depends on the lack of parallelism, equivalent to the angle of

twist of the shaft. The transmitted ray is focused onto a scale, and the position of the light spot corresponds to the twist in a linear manner. Further details are given in Adams (8).

Beyond this, the simplest system is one that depends on the rotation of the shaft and uses a disk mounted axially on the shaft at each of the two positions. Each contains a pattern of radial lines and is otherwise transparent. Units comprising light-emitting diodes and photo cells detect the motion of a disk, and the twist in the shaft gives a phase difference at the two positions. This is measured as described above. A different approach is required if the shaft is stationary or slow moving, and to overcome this problem, Hazelden (9) has developed an optical sensor for use in an electrical power assisted steering system. In this, the light passes through both the disks which are close to each other, the patterns being designed so that there are two outputs whose ratio determines the torsion, taking account of sign. This arrangement makes the signal independent of the light intensity. An optical sensor is suited to the electrically noisy environment. The performance is not claimed to be suitable for general instrumentation but it is adequate for this application and capable of being manufactured at the low cost which is demanded.

Inductive Devices. The principle of these instruments is the variation of the transformer coupling between two coils through the variation in the magnetic circuit caused by the distortion of the shaft. There are concentric cylinders attached to each end of the flexible section of the shaft. These contain slots arranged so that when there is no twist, they just do not overlap so that there is no coupling between the coils. The deformation caused by twisting causes overlap and creates the magnetic circuit allowing coupling. With careful design, the coupling is proportional to the applied torque, and it is also possible to make the system detect the direction of the torque so that the electronics generates a dc output signal of sign depending on the direction. This device has no lower speed limit. Vibrometer (Table 1) manufactures a range of instruments using this principle with measurement ranges of ± 1 to ± 500 Nm. The bandwidth is 1 kHz. The linearity is of the order of $\pm 0.2\%$ over a wide range of environmental conditions.

Capacitive Devices. Capacity has been exploited to detect the shaft torsion, and the methods to be described are ones in which the variable capacitor or capacitors form part of the rotating shaft. An older design developed by the Royal Aircraft Establishment, Farnborough, is described in (10). In this, there are two concentric cylinders, one connected to each end of the shaft so that one is inside the other with a small gap. The torsion causes a small relative twist which is detected by teeth, or serrations, on the outside of the inner element and on the inside of the outer element. When these coincide, the capacity between the inner and outer is a maximum and reduces as the relative angular position moves from this state. By using square teeth and a very small gap, there is a region in which the capacity varies linearly with the angle, and this is used. The capacity is measured from outside the device through sliprings and a bandwidth up to 80 kHz is reported. On those applications where vibrations are being looked at, long-term drift will not matter. In other cases, it is better to use a bridge technique to remove temperature and other effects. The technique is also sensitive to stray capacities. Today, sliprings would be considered a possible source of unreliability.

An alternative use of capacity is that developed by Falkner (11). The torsion between the ends of the flexible section of shaft is detected through two capacitors. The plates of these are connected to the ends in such a way that the torsion increases the gap in one and decreases it in the other. Capacitors are more sensitive to gap changes than to relative lateral motion of the plates. The two capacitors form a bridge and the three connections to the bridge are connected capacitively to the stator through rings with small gaps, thus maintaining the requirement for no contact. Such bridges have been found to be very stable and sensitive at the submicrometer level. In this situation, the performance is affected by these coupling capacitors, but it is the stability of their values which is critical. They are made as large as practical, which can be shown to reduce these effects. The prototype is extremely sensitive and has a range of ± 0.9 Nm with nonlinearity better than $\pm 1\%$ of full scale. There is some residual variation in the readings as the shaft is rotated, the sensitivity and zero reading each varying $\pm 1\%$ of full scale. There would be no difficulty in designing a stiffer torsion device to operate at higher torque levels.

Static Torque Measurement

The situation has already been described above in the introduction and represented diagrammatically in Fig. 3, and again the robot wrist example is considered first. The most obvious approach is to use strain gauges on an appropriate mechanical configuration. For example, gauges could be arranged around a metal wrist block. In this case, the signals obtained would each contain information about more than one of the torques and forces present, but the use of the appropriate rosettes and bridges as described above would help the situation. There is also the possibility of using a microprocessor program to distinguish the individual outputs. More satisfactory is the use of a metal cross, in which case the arm and the gripper are joined to the center and the outside of the unit which is designed to give enough flexibility for useful signals. In this case, the arms are instrumented with the gauges on all the faces, and inevitably, there is some mixing of the signals so that it becomes essential to use a microprocessor. Such a device has been made commercially by Lord Automation (Table 1) with an accuracy of approximately $\pm 2\%$ and some residual cross-coupling. Other workers have used inductance and capacity to detect strain in the wrist. An example of the former is by Piller (12), the compliant element being essentially three helical springs between two plates. Any force or torque applied to this causes a small distortion, and the signals from a set of inductive pick-offs are interpreted to distinguish the forces and torques. Falkner (2) has used capacity in a wrist in which the compact mechanical design allows complete separation of the three forces and the three torque signals. Small distortions occur, each of which depends solely on one of these parameters. Each measurement is made capacitively. Figures 8 and 9 show the two types of basic elements used for the torque measurement. That, in Fig. 8, works on a torsion bar which the applied torque twists, unbalancing the capacitor bridge comprising the two capacitors shown. The antiphase drive signals are applied to the two fixed plates, and the signal pick-off is the moving element A. In Fig. 9, the device responds to twist about the axis to unbalance the capacitor bridge. Again, the

Figure 8. A capacitive torque sensing element. "A" is a torsion bar and torque unbalances the capacitor bridge "B." This material has been reproduced from the Proceedings of the Institution of Mechanical Engineers, Part C, *J. Mech. Eng.* **206**: 1992, by A. H. Falkner by permission of the Council of the Institution of Mechanical Engineers.

two moving plates are connected together to form the pick-off. In each case, torsion increases one capacitor and reduces the other, and the signal measures the amplitude of the torque and, through the phase, the sign. A compact three-axis torque sensor has been built using two elements of the type shown in Fig. 8 and one of the type shown in Fig. 9. To simplify the electronics, it is possible to multiplex the drive signals to the bridges and make the outputs common. The use of square waves makes the multiplexing simple using integrated electronic circuits of the complementary metal-oxide-semiconductor family. A prototype application specific integrated circuit has been made to drive the circuit and interface to a computer with the objective of fitting the electronics in the device and having the simplest possible electrical connections. Otherwise, it is possible to use long leads with no electronics in the device. It has been found

Figure 9. In this configuration, axial torque causes torsion through the flexing of the leaves "C." This material has been reproduced from the Proceedings of the Institution of Mechanical Engineers, Part C, *J. Mech. Eng. Sci.* **206**: 1992, by A. H. Falkner by permission of the Council of the Institution of Mechanical Engineers.

that the capacitor bridges are extremely stable in this situation, and overall performance is at the 1% level. The correct mechanical design results in complete isolation of the axes. For larger scale applications, including heavy equipment, the robust, well-tried techniques based on strain gauges are most appropriate.

CURRENT DEVELOPMENTS

The above shows that there are a number of well-tried methods available for measuring shaft torque and for measuring torque in static situations, such as the robotic wrist. The requirements vary, but the present emphasis in research is towards low-cost devices with high performance. The latter includes accuracy, sensitivity, and linearity as well as noise immunity and wide bandwidth. Environmental conditions vary, but there may be a requirement for operation over a wide temperature range and for ruggedness. In the case of an automobile power assisted steering system, for example, the device is expected to operate with little maintenance over many years in a hostile environment. The system must be designed so that any failure is safe in the sense that no assistance would be supplied, rather than a false turning which the driver could not control. To meet these challenges, there is work in the development of existing techniques and in the investigation of new ideas. It is difficult to predict which will be most successful, but it is always likely to be the case that a range of techniques will be used. The availability of application specific integrated circuits in electronics, which are inexpensive even in small quantities, means that as much complication as possible should be in the electronics with the simplest possible electrical and mechanical components. It is possible to incorporate a microprocessor to measure nonlinearities and temperature and compensate for these. This can remove the need for tight mechanical tolerances and materials specifications. These developments have led to falling costs across instrumentation in general and have made possible the use of new techniques. There is also interest in fully integrated sensors for many purposes. In these, micromachining of mechanical parts is undertaken on the silicon chip which contains the electronic circuitry. The wide range of adhesives now available may make an important contribution. Below is a survey of the current research which appears to be of most promise.

Magnetostrictive Devices

There is considerable activity in the field of the magnetostrictive sensors. This centers around the selection of the material itself and the use of ribbons as well as treatment of an existing shaft. Otherwise, compact pick-ups are being developed. For ribbons, the work is directed to the choice of material and the problem of attachment to the shaft. An example is work by Hase, Shoji and Wakamiya (13). The gluing process requires raising the temperature, and during the cooling, the differential coefficient of expansion results in a compressive stress in the ribbon. This compression is biased in direction, and this direction will coincide with a principal axis. The magnetic properties are affected in a way which can be exploited to arrive at a device with uniform characteristics over a wide temperature range. Hirose, Takagi, Mori and Imura (14) describe the following process for the fabrication of an amorphous magnetic alloy

layer. A crystalline layer of the alloy is attached to the surface by silver brazing and then melt quenched by laser irradiation. It is found that the easy direction of magnetization is along the direction of the laser scanning. This feature is exploited by making this direction along one of the principal axes at 45° to the shaft axis (Fig. 2). A further refinement is to make the treated area in stripes in this direction. The coil structures required are described above in the section on magnetostrictive devices, and research is directed to making these more compact. In particular, Rombach, Steiger and Langheinrich (15) have developed a micromachined torque sensor in which a magnetic layer and coils are deposited on the slice of silicon containing the electronic circuitry. The magnetic layer becomes the core of the coil and this is the equivalent of the Torquemaster (Table 1) devices which are described above. The manufacture could be highly automated. One objective is the compensation for variations in the gap between the shaft and the sensor which occur with normal machining tolerances. This is achieved by measuring the field in different positions around the sensor head to allow compensation.

Surface Acoustic Waves

Devices are being developed based on the effect on the propagation of surface acoustic waves of strain in the material used. The purpose is to develop instruments which require the minimum part on the rotating shaft and which can be treated as a part of an electrical circuit on the stator. In this case, the signal is connected by the electrical capacity of the gap, this being easy at the very high frequencies used. The corresponding impedances are relatively low, and the overall system is robust. It has been known for a long time that sound waves propagate in the surface of isotropic, elastic materials. It is possible to interface from electrical signals to the acoustic signals using a piezoelectric substrate, and devices which include resonators and filters can be fabricated in a small space because the wavelengths are small. A strain sensor depends on the effect of strain in the substrate on the wave velocity and is mounted on the shaft along one of the principal axes. For the case of a resonator, this affects the frequency, independently of the gap spacing. Typical frequencies are 200 MHz to 400 MHz corresponding to convenient physical dimensions of 1 or 2 mm. Hall, Wang and Lonsdale (16) describe how they have mounted the resonant element on the shaft. The coupling is capacitive as described above so that the resonator forms part of the circuit. Inductive coupling would be an alternative. The overall resonant frequency is measured using well established electronic techniques to give a measure of the strain. In the work reported, the emphasis has been on overcoming the sensitivity of the sensor to the temperature by using various configurations and cements for attaching the sensor. The current situation is that successful development would result in a very useful instrument, but further work is needed.

Other Developments

In the devices in which the sensor is mounted on a rotating shaft, the use of light to transfer the signal, and even the operating power, is attractive. The system can be designed so that variations in the light intensity are not important. In the case of the power, a simple regulated power supply is needed on the shaft. Electronic circuitry is available that consumes an

extremely small amount of power of the order of a few mW or less, and the main user of power will be the light emitting diode which transmits the signal back. The whole system becomes feasible with small standard optical devices. To ensure the noise immunity and tolerance to light power variations, a pulse code or digital code is used. The practical problem is arranging for light to be transmitted at all angular positions of the shaft. An example is given by Mu and He (17) in which they use a standard strain gauge bridge and report that the signal is transmitted in Hamming code using infrared light. The overall accuracy for measuring the torque is $\pm 0.1\%$. Dezhong and Zesheng give another example (18). They use light in the visible spectrum, and the power is picked up by a ring of photocells which allows operation in daylight or through an optical fiber. The modulation technique is to use a multivibrator with two strain elements switched alternately into the timing circuit leading to a form of pulse width modulation. The signal is transmitted by a light emitting diode back to a ring of photo diodes and the demodulator compares the width of alternate pulses. The electronics uses standard low power integrated circuits, and the linearity is of the order of $\pm 1\%$.

There are current developments in the capacitor techniques for measuring the torsion. Cooper (19) describes an instrument in which a variable capacitor on the shaft forms part of a tuned circuit, all the other elements being on the stator, and the coupling being capacitive. The capacity variation is achieved by using the torsion to move a dielectric material in the gap of the capacitor, thus varying its value. The units have been designed to fit in a small, hand-held electric screwdriver, the signal being required for feedback in the control of the operation. To achieve a linear relationship between the torsion and the overall output, the capacitance forms part of a multivibrator circuit so that simple digital counting leads to the torque value. The sensitivity is 0.005 Nm and the linearity is $\pm 0.6\%$ but the reported results show that further work is required to remove sensitivity to environmental conditions and to the angular position. It is suggested that a bridge technique might be helpful in this respect. Falkner (20) has investigated how capacity can be exploited with the minimum changes to the shaft. From the point of view of ease of manufacture, splines which already exist, in many cases, are suggested, but if the shaft may sometimes be stationary, then a timing method will not work. The only signals available are capacities to the grounded shaft, these varying with angular position. These can be measured at the two ends from internal splines on the stator. Although these readings will, in general, be different, there is ambiguity in the interpretation, and readings at or near the peak values are not very dependent on the position. To overcome this, a system of four external elements at each end is proposed which generates a signal whose phase depends on the angular position passing through 360° for each spline pitch. Then, the phases are compared at each end to give the torsion without ambiguity. Assessment of this proposal awaits the making of a prototype. Other techniques which have been investigated include the Faraday effect, the piezoelectric effect, and the use of the Hall effect to measure unbalance in magnetic bridges.

Reading List

References 4 and 5 in the Bibliography contain useful surveys which would be helpful in selecting the appropriate technique for a particular application. Reference 3 surveys older equipment which may still be encountered. Reference 1 gives the mathematical background to the stresses generated when torque is applied. Most technical libraries hold several books on instrumentation and measurement and many contain work on torque sensing. It is also suggested that information from the first three manufacturers listed in Table 1 is very helpful.

Coventry University

WEIGHING

The term “weighing” usually implies a measurement of mass. The mass of a body is a measure of the amount of substance it contains. A direct measurement of mass is not simple, but we are accustomed to sensing the mass of a body in terms of its weight, that is, how “heavy” it is. The weight of a body is dependent on its mass and also on the strength of the gravitational field in which it is located. Comparison of the weight of one body with the weight of another in the same gravitational field is a relatively simple task, and because much of our experience occurs within a common gravitational field, that of the earth, we can use the process of comparison of weights as a means of measuring mass. But in doing so we must be careful not to confuse mass and weight, remembering that they are essentially different quantities.

There are ways of measuring mass that do not rely on the presence of a gravitational field. One can for example measure the *inertial mass* of a body by measuring a change in momentum. But these methods are only appropriate in special circumstances and will not be described here.

As we shall see below, the measurement of weight is essentially the measurement of a force—specifically, the force exerted by a body in a gravitational field on its support. The second part of this article concentrates on the measurement of force, with particular reference to force measurements for the purpose of weighing.

MASS AND WEIGHT

We should first establish the meaning of the terms mass and weight. Mass is a measure of the amount of substance in an item. Everything has mass, and the mass of a body is independent of its other properties. Unfortunately, human beings cannot detect mass. However we are sensitive to the force that results from a body’s mass. This force is revealed in two ways, either by the inertia of the body (inertia is the tendency of a body to resist a change in motion), or by the attraction between bodies. The attraction between bodies provides the most common means of measuring mass, through weighing.

All bodies are attracted to one another. The strength of the gravitational attraction between two bodies results in an acceleration of each towards the center of mass of the other. In the case of a body whose mass we wish to measure in the earth’s gravitational field, the acceleration of the earth toward the body will not be apparent (and will be very small), so we need only consider the acceleration of the body toward the center of mass of the earth.

A body supported on the surface of the earth senses the acceleration of gravity but does not move. Instead it exerts a force on its support. This force is what we call weight. In the absence of an atmosphere the weight of a body is equal to the product of its mass and the gravitational acceleration it is subjected to. (The earth’s atmosphere complicates matters by creating an upward force proportional to the volume of the body, effectively reducing its weight. We shall discuss this issue in detail below).

So we have seen that while mass is a fundamental quantity of a body, weight is dependent on mass and on the presence of a gravitational field. In common usage the term “weight” is often used incorrectly to mean “mass,” a practice that causes much confusion when discussing the measurement of mass by

weighing. For the remainder of this article we shall carefully distinguish these two quantities and use the correct term for each.

However, we must also be aware that the word “weight” can have another meaning. We have already seen that it can mean the attracting force between a body and the earth. It can also mean an artifact used in weighing as a reference standard of mass. This can lead to confusion, so care must be taken to ensure that the meaning is clear (1).

A BRIEF HISTORY OF WEIGHING AND MASS STANDARDS

A History of Weighing

Weighing, by which we mean using a balance to measure the weight of a body or to compare the weight of two bodies, has been done for thousands of years. Images from the earliest civilizations in the Middle East show weighing using a beam balance. The process has continued almost unchanged until the present day. As recently as the medieval times, monetary value was measured by weighing. The coin in use in Britain was the silver penny, chiseled in two for a halfpenny and in four for a quarter-penny or farthing (fourthing). The pennyweight was 1/240 of the “pound of Troyes” (named after a city in France which was the center of mercantile trade in the twelfth century). This pound was 5760 grains—barleycorn grains selected in a precise manner. The *troy* weight system (20 pennyweights to the troy ounce and 12 ounces to the pound) was used for all precious materials and for bread, the price of which was controlled by law from the twelfth until the nineteenth century. (In 1280, a “farthing loaf” weighed about $3\frac{1}{2}$ pounds.)

A later system of weights introduced the “haber de peyse” or *avoirdupois* pound, which was eventually fixed at 7000 grains, and divided into 16 ounces each of 16 drams. The only direct connection between the values of the troy and avoirdupois systems is the grain of barleycorn.

Another important measure of wealth in Britain was wool, which by the fifteenth century accounted for over half of the country’s export trade. For this, larger measures of weight were needed, and the lowest value in common use was the stone, which varied in value for many years but eventually settled at 14 avoirdupois pounds. Two stones made a quarter, and four quarters a hundredweight. Three hundredweights made a sack.

Fine weighings were needed for medicines, and for that purpose the *apothecaries’* measure was based on the Troy ounce—20 grains to the scruple, three scruples to the drachm, and eight drachms to the ounce (2).

When dealing with all these different systems of weight measurement, the benefit of a single, universally accepted system soon becomes apparent. The metric system, based on the kilogram, is now in use in most of the world.

The Birth of the Metric System

In 1790 King Louis XVI of France commissioned his country’s leading scientists to recommend a consistent system for weights and measures. The report that the French scientists (Lagrange, Lalande, Laplace, Borda, Monge, and Condorcet) presented to the Academy of Sciences on March 19, 1791 recommended a system based on a unit of length, the meter, equal to one ten-millionth part of the arc of the Earth’s quadrant, pole to Equator. The unit of mass would be equal to the mass of a

defined volume of water *in vacuo* at its freezing point. Legislation authorizing construction of this new system of units was passed on March 26, 1791, and the metric system of measurement was born (2).

After the 1791 report, measurements were made to decide an appropriate volume of water for the standard of mass. In 1775 it was agreed that the unit would be the mass of one cubic decimeter of water at a temperature of 4°C (which is approximately the temperature at which the density of water has a maximum value). This unit would be called a kilogram, and the mass of one cubic centimeter of water would be called a gram.

Brass weights were made whose mass was equal to the new unit, the kilogram, then later a weight of platinum was made, and adjusted to the value for the new unit (18,827.15 French grains). This platinum weight became known as the *Kilogramme des Archives*, and was effectively the standard of mass for most of Europe. It was soon realized that the mass of this kilogram artifact was not exactly that of a cubic decimetre of water; thus the link between mass and volume measurements was effectively broken.

International interest in measurement standards grew quickly, and in 1870 and again in 1872 the French government called meetings to discuss the construction and distribution of new metric standards. At a third meeting, in 1875, eighteen countries subscribed to a treaty, called the *Convention du Metre*, by which the *Comité International des Poids et Mesures* (CIPM) and the *Bureau International des Poids et Mesures* (BIPM) were set up, to be responsible for the custody and verification of metric standards. The convention agreed that a new kilogram weight should be made using an alloy of platinum and iridium (90%:10%). After many attempts in France, a successful casting of the alloy was made by George Matthéy of Johnson, Matthéy and Co. of London, and in 1879 three cylindrical pieces of the alloy were delivered to a French metallurgist, St-Claire Deville. The cylinders were hammered in a press, and then polished and adjusted and finally compared with the *Kilogramme des Archives* by M. Collot, a maker of weights and balances. By 1883 the CIPM were convinced that one of the cylinders “was indistinguishable in mass from that of the *Kilogramme des Archives*,” and this weight was chosen as the international prototype of the kilogram (3).

A further 40 one-kilogram weights had been ordered from Johnson, Matthéy & Co. in 1882 and were delivered in 1884. After reheating and hammering to increase their density, these were adjusted to be close in mass to the newly selected international prototype. In 1889 each signatory of the *Convention du Metre* (by now 20 countries) was allocated one of these weights. The allocation was made by lot, the United States being given Copy No. 20 and the United Kingdom receiving Copy No. 18. The certificate that accompanied Copy No. 18 on its first journey to the United Kingdom gives its mass as 1 kg + 0.070 mg, with an uncertainty of ± 0.002 mg, and its volume as 46.414 ml at 0°C. To this day Kilogram 18 is the cornerstone of measurements of mass in the United Kingdom. At its last calibration at the BIPM in 1997 its mass was found to be 1 kg + 0.061 mg ± 0.004 mg, and its volume at 0°C (calculated from the original value in milliliters) as 46.4149 cm³.

The Unit of Mass in the SI System

The unit of mass in the International System of Units (SI) is the kilogram, which is abbreviated kg. The value of the kilogram

is defined as being “equal to the mass of the international prototype of the kilogram” (4). The kilogram is unique in the SI system of units in being the only unit whose definition is based on a physical artifact.

GRAVITY AND DENSITY

Gravity

Sir Isaac Newton described gravity in terms of the attracting force between two bodies, which is proportional to their masses and inversely proportional to the square of the distance between them. However, in considering the gravitational field of the earth and its effects on bodies that we are weighing, we need only consider the attraction of the body to the earth, which depends on the mass of the body and its distance from the center of the earth.

The earth is not quite spherical, having its greatest diameter at the equator. In addition, the earth is rotating on its axis, which creates a “centrifugal” force acting at 90° to the direction of spin and proportional to the speed of rotation. It therefore follows that the value of gravitational acceleration will be smaller at the equator than at the poles. The value of gravitational acceleration at any latitude, at sea level, may be calculated using the following formula:

$$g = g_e(1 + 0.005\,302\,4 \sin^2 \Phi - 0.000\,005\,8 \sin^2 2\Phi) \text{ m} \cdot \text{s}^{-2} \quad (1)$$

where

g = gravitational acceleration at desired location ($\text{m} \cdot \text{s}^{-2}$)

g_e = gravitational acceleration at the equator = $9.780\,327 \text{ m} \cdot \text{s}^{-2}$

Φ = latitude of location (deg)

The correction for altitude is $-3.088 \times 10^{-6} \text{ m} \cdot \text{s}^{-2}$ per meter above sea level. The above formulae give the best simple method of calculating the gravitational acceleration at a location where it has not been measured, and will almost always give results within $1 \times 10^{-3} \text{ m} \cdot \text{s}^{-2}$ and usually within $5 \times 10^{-4} \text{ m} \cdot \text{s}^{-2}$ (5).

The actual value of gravitational acceleration at a particular point will differ from that given by the equation above, due principally to the variability of the density of the earth from place to place. If an accurate determination at a particular location is required, a measurement can be made using appropriate apparatus. Also, in many countries the value of gravitational acceleration has been mapped for the entire country (by the British Geological Survey for the British Isles), and a value can be obtained on request.

Density

Density is the mass per unit volume of a substance, expressed in kilograms per cubic meter ($\text{kg} \cdot \text{m}^{-3}$). All substances, whether solid, liquid, or gas, have density, and an accurate knowledge of the density of the body being weighed and the density of the air at the time of weighing is essential to the accurate measurement of mass.

The density of a solid object can be determined by weighing it suspended in a liquid of known density and noting the apparent

loss in weight by comparison with its weight in air. The density of a liquid or gas can most easily be measured by reference to the apparent loss in weight of an artifact of known mass and volume immersed in it (often the change in apparent mass difference between two bodies of similar mass but different volume is used to give a smaller uncertainty of measurement).

The density of air can be measured as for other gases, but is commonly derived from a knowledge of the composition of the air and measurements of physical parameters. Air is composed of oxygen, nitrogen, water vapor, and a host of minor constituent gases, the most abundant of which are argon and carbon dioxide. A formula for the calculation of air density has been recommended by the CIPM and is internationally recognized (6).

Use of this formula requires measurement of temperature, pressure, and humidity, and for the highest accuracy of carbon dioxide content. The uncertainty of the calculated value of air density will depend on the uncertainty of measurement of the contributing parameters and on the uncertainty of the formula itself.

WEIGHING IN AIR—THE BUOYANCY EFFECT AND THE CONVENTIONAL VALUE

Archimedes' Principle and the Buoyancy Effect

The *weight* of a body is equal to the attractive force between it and the earth. We could measure this force and then divide it by the gravitational acceleration to determine the body's mass. We can measure the force by putting the body on the pan of a balance. But there is a complication.

Many centuries ago, the Greek philosopher Archimedes realized (while sitting in his bath, it is said) that when a body is immersed in a fluid, the fluid exerts an upward force on it that is equal to the weight of the fluid displaced by the body. When the upward force from the fluid is greater than the downward force due to gravity, the body will float on the surface of the fluid; otherwise it will sink, but part of its weight will be supported by the fluid. This discovery has since become known as Archimedes' principle. The magnitude of the upward force experienced by the immersed body is proportional to its volume and to the density of the fluid. We call this upward force the buoyancy force, or simply buoyancy.

When we think of fluids, we usually imagine liquids. But gases are also fluids and behave in the same way. We live immersed in a gas, which we call air. Air has a density, which, although only about one-thousandth of that of water, causes a significant buoyancy on most materials, the effect being greater on materials of lesser density. For any body in the earth's atmosphere, the force exerted on its support (= mass $\times$ gravitational acceleration) is reduced by the upward buoyancy force [= volume $\times$ density of air $\times$ gravitational acceleration, or (mass $\times$ density of air/density of body) $\times$ gravitational acceleration].

The result of this buoyancy effect is that a given mass of a more dense material exerts a greater force on its support than the same mass of a less dense material. Thus the two identical masses have different "weights." Hence one may deduce that to use the principle of weighing to determine mass, one must have a knowledge of the density of the materials being weighed and of the density of the air at the time of weighing. But it is unusual to have any accurate knowledge of the density of

most items that are to be weighed, and the measurement of air density requires sophisticated instrumentation or calculation.

Conventional Value of Mass

To solve this problem a *conventional value of mass* has been defined. In doing so it is supposed that all items have the same density, and the air density in which the weighing is made is also assumed to have a fixed value. The conventional value of mass will not always be the same as the true mass, but for most practical purposes it will be close enough. The chosen density values on which the conventional mass value is based are 8000 kg·m⁻³ for the item's density (because this is close to the density of stainless steel, iron, and brass, materials that are commonly used to manufacture weights) and 1.2 kg·m⁻³ for the air density (because this is typical of the air density at sea level in most parts of the world). Put simply, "For a weight taken at 20°C the conventional value of mass is the mass of a hypothetical reference standard weight of density 8 000 kg m⁻³ which it balances in air of density 1.2 kg m⁻³" (7).

For many practical purposes, weighings whose result is stated in conventional-value terms are quite satisfactory, although the true mass of the object being weighed may differ from the reported conventional mass. In particular, for the purposes of trade, commodities may be bought and sold using conventional mass with no net gain to the manufacturer, wholesaler, or buyer, provided the convention is consistently applied.

It is sometimes necessary to make a correction to the measured conventional value of mass, to allow for the difference in the density of the object being weighed or the difference in the density of the air at the time of weighing from the conventionally agreed values. Then we have

$$M_c = M_i \left[1 + \left(\frac{1}{\rho_w} - \frac{1}{8000} \right) (\rho_a - 1.2) \right] \quad (2)$$

where

M_c = corrected conventional mass value (kg)

M_i = indicated conventional mass value (kg)

ρ_w = density of artefact being weighed (kg·m⁻³)

ρ_a = density of air at the time of weighing (kg·m⁻³)

From Eq. (2) it can be seen that the correction is zero when either the density of the object or the air density at the time of weighing is equal to the conventionally agreed value. Knowing the normal range of air density (from meteorological data) and the range of density of materials to be weighed, it is possible to determine the limit of uncertainty for which there is no need to apply the correction.

It is also possible to deduce the true mass of an object from its conventional mass provided the density of the object is known:

$$M = M_c \left[1 + 1.2 \left(\frac{1}{\rho_w} - \frac{1}{8000} \right) \right] \quad (3)$$

where

M = true mass of object (kg)

M_c = conventional value of mass (kg)

ρ_w = density of object (kg·m⁻³)

From Eq. (3) it can be verified that the conventional mass value of an object whose density is $8000 \text{ kg}\cdot\text{m}^{-3}$ is identical to its true mass.

WEIGHING METHODS AND EQUIPMENT

Weighing is performed for a variety of purposes, ranging from retail trade activities such as selling food to the public, through food preparation and packaging, chemical analysis, and wholesale trading to industrial product preparation and process control. For simple trade and analytical weighing the requirement is usually to have a suitable balance or weighing machine available for a variety of weighing tasks, while for industrial applications the weighing system is more likely to be a purpose-built, permanently installed part of the processing plant.

In many cases the design of balances and simple weighing systems does not differ greatly from the design of process weighing plants, but from the user's viewpoint the purchase of a balance is a very different issue from the specification of an industrial processing plant. A balance can be purchased directly, and is usually selected on the basis of a manufacturer's specification, whereas the design of processing plant requires specialist engineering skills.

Force measurement systems and industrial weighing applications are discussed later. Let us first consider the use of a balance for simple weighing activities.

Balances and Weights

A balance may be based on mechanical principles, such as the position of a loaded beam or the extension of a spring element, or on electrical principles linked to the measurement of force, or on a combination of both. Types of balances are discussed in detail elsewhere in this encyclopedia (see **BALANCES**), so here we shall concentrate on the method of use of a balance, rather than on the detail of its design and operation.

A mechanical balance may involve a balanced beam offering two weighing pans, one on either side of the balance point, or it may be of single-pan design. An electronic balance will usually be a single-pan device. On a two-pan balance it is possible to measure the difference between the masses of two bodies directly, while a single-pan device can be used to give an indication of the mass of a single body. The single-pan device may also be used to measure mass difference by sequentially weighing one object and then the other. Typically a two-pan balance is used to compare the mass of an unknown weight with that of a calibrated reference weight, whereas with the single-pan device the reference weight is used to calibrate the balance, after which the unknown weight can itself be calibrated. The majority of balances currently available for purchase are single-pan electronic devices, so these will be examined in depth. But a large number of two-pan balances are still in use, so these are also discussed below.

Two-Pan Balances. Two-pan balances may be *damped* so that the swing of the beam quickly dies away, but more commonly they are *free-swinging*, so that the beam continues to swing for a period of time before finally coming to rest. On a damped balance a reading can be obtained quickly but the sensitivity to very small changes of load may be much reduced. The free-swinging balance may be allowed to come to rest before a reading is taken, but that is very time-consuming. An alternative

approach is to record the extremes of the beam swing in each direction and predict the final resting point from these. With care this method can produce satisfactory results with a significant saving of time. The same number of swings must be recorded for each weighing. Typically the first swing in either direction is ignored to allow the oscillating system time to establish a free oscillation; then three swings to one extreme interspersed with two to the other extreme are recorded. Analysis of the resulting data predicts the eventual rest point of the beam.

The most common method of use for a two-pan balance is to place a known reference weight in one pan and the unknown weight in the other pan. If the two weights are similar, the balance will indicate the mass difference, usually by means of a mechanical pointer or an optical scale. The balance must be calibrated so that the user can interpret the reading of the scale in terms of mass difference, and the calibration must be repeated regularly because the mechanical characteristics of the balance may change with time. Calibration of a two-pan balance is most easily achieved by observing the change in reading when a small, known mass is added first to one pan and then to the other.

If the lengths of the arms of the balance beam differ, the measurement result will be biased to one pan or the other. On a perfect balance, if the loads in the two pans are exchanged, the balance indication should remain the same except for a change of sign. But it is rarely the case that a balance is so perfectly set up, so it is common to take two readings, exchanging the weights between the pans before the second reading. The resulting mass difference is the mean of that obtained from the two readings. However, this method places some reliance on the stability of the balance during the time of the weighings, and two-pan mechanical balances are subject to a number of time-dependent effects. Therefore, for the smallest uncertainty of measurement the second weighing can be made a second time, before the weights are returned to their original pans and a fourth weighing is made. This *double-double weighing* method offers the best measurement uncertainty for a balance of this type.

Single-Pan Balances. Single-pan balances may be purely mechanical in operation, or involve electric force measurement. They may have a pan suspended below the weighing system, in which case access to the pan is hindered by the suspension mechanism, or be of "top-pan" design where the loading receptacle is freely accessible from above. Regardless of the operating principle, the method of use is similar.

The balance will be equipped with an indicator system to display the measured value. This may be as simple as a pointer attached to a spring or lever, observed against a printed scale, or as complex as an electronic digital display. The display mechanism will probably indicate in a unit of mass; nevertheless, all such systems require calibration to ascertain the difference between the displayed value and the true mass of the weight in the scale pan. Calibration can be performed using a suitably calibrated external weight, or may be dependent on the use of one or more weights built in to the weighing system (the "auto-cal" feature of many modern electronic balances). In either case it is necessary to know the uncertainty of the calibration weight, and where internal weights are used it is prudent to calibrate the device, or at least make occasional checks, using an external reference weight.

It is important to realize that, once calibrated, a single-pan balance is making measurements of force, and the indicated value will be dependent on the buoyancy effect, but more importantly on the value of gravitational acceleration. For this reason the balance should be calibrated in the location in which it will be used. (One major distribution company, selling balances manufactured and calibrated high in the mountains of China, received complaints of inaccuracy from a purchaser in a sea-side town in northern England.) The use of an internal reference weight to reset the *span* (the reading corresponding to full load) helps to overcome these problems, but if the internal weight is used to set the span of the balance, it cannot also be used to provide a calibration. Transportation of a balance is likely to affect its performance, hence adding further impetus to the requirement to calibrate in the location of use.

Other factors affecting the performance of single-pan balances are *hysteresis* (a difference in reading for the same load approached from a smaller load and from a larger load) and *eccentricity* (a difference in reading arising from placing the load toward one side of the pan, rather than centrally). These issues can be investigated during the calibration of the balance, while at the same time the sensitivity, linearity, and repeatability of loading are assessed.

The measurement uncertainty obtained using a calibrated balance to make measurements of unknown loads can often be improved significantly by using the same balance, together with an appropriate set of calibrated reference weights, to make comparison measurements. If done properly this approach can eliminate the uncertainties arising from nonlinearity, hysteresis, and long-term drift of the measuring system, and careful loading will minimize eccentricity effects. A measurement of the unknown weight is followed immediately by measurement of one or a group of reference weights of similar value. The closer the value of the reference weight(s) to the unknown, the less reliance is placed on the linearity of the balance. Repeated measurements allow assessment of repeatability, and comparison with a second reference weight adds confidence in the measurement. This method of substitution weighing is often referred to as *Borda's method*.

Weights. Weights, or reference mass standards, are available in a range of accuracy classes. The most widely recognized international classification of weights is that recommended by the International Organization of Legal Metrology in International Recommendation 111, "Weights of Classes E₁, E₂, F₁, F₂, M₁, M₂, and M₃," (8). Class E₁ weights are of the very highest metrological quality, typically used only by calibration laboratories of the highest order. These weights are made of non-magnetic stainless steel, and handled with extreme care, using tongs or gloved hands to avoid contamination. Class E₂, and F₁ weights, also made of nonmagnetic stainless steel and handled only with gloved hands, are commonly used as transfer standards to calibrate weights of lesser classes. Class F₂ weights are typically used as working standards in an industrial laboratory, while class M weights, commonly made from cast iron, are used as working standards in the field.

Weights of any class require periodic recalibration to ensure that they have not become damaged or contaminated. Weights should be handled with an appropriate amount of care—greater for the higher-class weights. Weights of class F₂ and below will often be recorded as being within a given tolerance of their nominal value, and this must be taken into account when assessing

the uncertainty of measurement of any weighings made with reference to them. Weights of the higher classes will usually be accompanied by a certificate stating their measured conventional values with associated uncertainties. The certified values should be used in all calculations associated with these weights.

Industrial and Process Weighing

For routine weighing of a variety of objects it is a simple task to purchase a balance and a set of weights from a supplier. But for weighings associated with industrial processes it is necessary to design the weighing apparatus as an integral part of the process equipment, which requires expertise both in the functional issues of the particular process, and in the selection, installation, use, and maintenance of appropriate force-measuring devices and systems. The remainder of this article is devoted to force measurement systems and transducers and their application to industrial and process control weighing.

FORCE

Force is a measure of the interaction between bodies. Force takes a number of forms, including short-range atomic forces, electromagnetic, and gravitational forces. Force is a vector quantity, with both direction and magnitude. If the forces acting on a body in equilibrium are summed around the periphery of the body, then they add to zero. If there is any resultant force acting, then the body is not in equilibrium and it will accelerate so that the rate of change of the body's momentum is equal to the force. If the body is held stationary in some way, then there will be a reaction acting on the body from the support structure that is equal in magnitude and opposite in direction to the force imposed. Although the definition of force units is based on acceleration of a free body, most force measurements are made on bodies in equilibrium, and are therefore measures of forces within a structure. The basis of most force measurements is that a physical support or link in a structure is replaced with a device that measures the forces acting at that point.

The SI unit of force is the newton (N); this is defined as the force that would give to a mass of one kilogram an acceleration of one meter per second per second. In practice, it is not convenient to accelerate 1 kg at 1 m·s⁻² to generate 1 N. Instead, the practical realization of the unit of force makes use of known masses that, when subjected to the effect of local gravitational acceleration, exert a known force on an earth-located support. The mechanical structure to handle and control such masses is known as a deadweight machine.

FORCE MEASUREMENT SYSTEMS

A force measurement system is made up of a transducer and associated instrumentation. The transducer is subjected to the force to be measured, and some resultant change in the sensing element of the transducer is measured by the associated instrumentation. The instrumentation may power the transducer in some way and may also process the output from the transducer before it is shown on an indicator. For many types of force measurement system, the term "load cell" is in common usage in place of "force transducer."

The instrumentation may be as simple as a dial gauge or as complex as a computer with associated analog-to-digital converters and excitation circuitry. The indicated value is the output of the force measurement system, which may be in units of force or other units such as volts. If the indicated value is not in units of force, then the user may need to perform a calculation based on a calibration to calculate the force value.

For the measurement made using a force device to be of any use, the uncertainty of that measurement must be known. Performance criteria for a force measurement system are described by the manufacturer in terms of a specification, which gives limits within which the behavior of the instrument can be expected to fall. However, this performance is generally given for a production series, and cannot be relied upon for a specific device unless verified by calibration.

Characteristics of Force Measurement Systems

Many physical principles are involved in the operation of different force measurement systems. The performance of these systems can, however, be described by a number of common characteristics, and the behavior of the system may be expressed graphically by plotting the indicated output value against the force applied to generate that value. It is then usual to fit a straight line to the resulting curve; deviation from this line is referred to as *nonlinearity*, and generally the largest such deviation is the value given for nonlinearity in the system specification. The difference of readings between the increasing and decreasing forces at any given force is called the *hysteresis*. The largest value of hysteresis is usually at the midrange of the system. Sometimes it may be useful to combine the nonlinearity and the hysteresis in a single figure. This is usually done by drawing two lines parallel to the best-fit line such that these lines enclose the increasing- and decreasing-force curves. The difference of output between the lines is halved and stated as combined error.

Any difference between the indicated value of force and the true value is an *error* of measurement, and may be expressed as percentage of actual force applied or percentage of full-scale output. *Full-scale output*, also known as *span* or *rated output*, is the output at rated capacity minus the output at zero applied force. *Sensitivity* is defined as the full-scale output divided by the rated capacity of a given load cell.

The ability of a force measurement system to measure force consistently is covered by the concept of *repeatability*. Repeatability is defined as the measure of agreement between the results of successive outputs of a force measurement system for repeated applications of a given force. The tests should be made by the same observer, with the same measuring equipment, on the same occasion, without mechanical or electrical disturbance, and calibration conditions such as temperature, alignment of loading, and the timing of readings held constant as far as possible. Although many manufacturers quote a value for repeatability as a basic characteristic of a transducer, it should not be considered as such. The value obtained for a transducer in a given machine will depend not only on the characteristics of the device itself, but also on temperature gradients, the resolution and repeatability of the electric measuring equipment, and the degree to which the conditions of the tests are held constant, all of which are characteristics of the test procedure.

In contrast to repeatability, *reproducibility* is defined as the closeness of agreement between the results of measurements

of the same force carried out under changed conditions of measurement. Note that a valid statement of reproducibility requires specification of the conditions changed and may include changes in the principle of measurement, method of measurement, observer, measuring instrument, reference standard, location, conditions of use, and time.

A force measurement system will take some time to adjust fully to a change in force applied, and *creep* of a force transducer is usually defined as the change of output with time following a step increase in force from one value to another. Most manufacturers specify the creep as the maximum change of output over a specified time after increasing the force from zero to the rated force. *Creep recovery* is the change of output following a step decrease in the force applied to the force transducer, usually from the rated force to zero. For both creep and creep recovery, the results will depend on how long the force applied has been at zero or the rated value respectively before the change of force is made.

The frequency response of a force transducer is affected by the nature of the mechanical structure, both of the transducer itself and of its mounting. A force transducer on a rigid foundation will have a natural frequency of oscillation, and large dynamic errors occur when the frequency of the vibration approaches the natural frequency of oscillation of the system. If dynamic forces (ones that vary with time) are to be measured, the frequency response of the force measurement system must be capable of following the changing force. If a transducer is to be used with fluctuating forces applied, its fatigue life should also be considered.

The temperature coefficients of both the output at zero force and the sensitivity quantify the effect of temperature changes on a given system. A force measurement system may need to be kept at constant temperature, or set up well in advance to settle into the ambient conditions, if high-accuracy measurements are required. In some cases the temperature gradients within the measurement installation can create a problem even when the average temperature is stable.

Other influence quantities such as humidity, pressure, electrical power changes, or radio-frequency interference may have analogous effects to those of temperature and may be considered in a similar manner.

In general, a force transducer has two interfaces through which a force is applied. These may be the upper and lower loading surfaces of a compression force transducer or the upper and lower screw threads of a tension device. At each interface, there will be a force distribution, which will depend on the end loading conditions. A change in these loading conditions may therefore cause a change in the force distribution, resulting in a change of the sensitivity of the transducer, even though the resultant force at the interface remains unchanged. Depending on the design of the transducer, the change of sensitivity caused by a change of end loading conditions can be significant in comparison with all other effects.

The long-term stability of the sensitivity of force measurement systems is clearly important if they are to be used to compare the magnitude of forces at different times, perhaps months or years apart. This stability will be determined by several factors, including the stability of the force transducer's many components, the protection of the sensing components or other parts against humidity, and the conditions under which the system is stored, transported, and used.

FORCE TRANSDUCERS

There are many types of force transducer, and these may be used with instrumentation of varying complexity. Most force transducers employ some form of elastic load-bearing element or combination of elements. Application of force to the elastic element causes it to deflect, and the deflection is then sensed by a secondary transducer, which converts it into an output. The output may be in the form of an electric signal, as in strain-gauge and linear variable differential transformer (LVDT) load cells, or of mechanical indications, as in proving rings and spring balances.

The method of measuring the distortion of the elastic element varies considerably. The most often used method is to make measurements of the surface strain; when this is undertaken with electrical resistance strain gauges, such a transducer is known as a strain-gauge load cell. Strain-gauge load cells are the most common commercially available type of force transducer.

Another commonly used type of force transducer is based on the piezoelectric phenomenon exhibited by certain crystalline materials, where an electric charge is generated on the crystal surface, the amount of charge being proportional to the applied force. Many other physical relationships are also used, and force transducers based on these are described later.

Strain-Gauge Load Cells

Each such load cell contains an elastic element to which a number of electrical resistance strain gauges are bonded. The geometry and modulus of elasticity of the element determine the magnitude of the strain field produced by the action of the force. Each strain gauge responds to the local strain at its location, and the measurement is determined from a combination of these individual strain values.

The rated capacities of strain-gauge load cells range from 1 N to more than 50 MN, and they can be used with high-resolution digital indicators as force transfer standards. The shape of the elastic element used in load cells depends on a number of factors, including the range of force to be measured, dimensional limits, final performance, and production costs.

Figure 1 shows a selection of different elastic elements and gives their typical rated capacities. Each element is designed to measure the forces acting along its principal axis, and to be unaffected by side forces. The arrows in the figure indicate the principal axis of each element.

The material used for the elastic element is usually tool steel, stainless steel, aluminum, or beryllium copper. The ideal material exhibits a linear relationship between stress and strain with low hysteresis and low creep in the working range. There also has to be high level of repeatability between force cycles to ensure that the load cell is a reliable measuring device.

In electrical terms, all electrical resistance strain gauges may be considered as a length of conducting material, such as a wire. When a length of wire is subjected to a tension within its elastic limit, its length increases, with corresponding decrease in its diameter and change of its electrical resistance. If the conducting material is bonded to an elastic element under strain, then the change in resistance may be measured and used to calculate the force from the calibration of the device.

The foil strain gauge is the most widely used type. It has significant advantages over all other types of strain gauge and

is employed in the majority of precision load cells. It consists of a metal foil pattern mounted on an insulating backing or carrier, which provides electrical insulation between the foil and the elastic element, facilitates handling, and presents a readily bondable surface. A large variety of foil gauges are now commercially available to the transducer designer and general user.

Semiconductor strain gauges are manufactured from strips of semiconducting silicon of either the *n* or the *p* type. The output sensitivity of a semiconductor gauge is very high compared to a foil gauge. It is also, however, nonlinear in strain and highly temperature-sensitive. The gauges exhibit essentially no creep or hysteresis and have an extremely long fatigue life. This type of gauge is widely used on small transducers such as accelerometers and pressure sensors, whose sensing element may be micro-machined out of a single piece of silicon.

Thin-film strain gauges are produced by sputtering or evaporating thin films of metals or alloys onto the elastic element. A thin-film strain-gauge system may have up to eight layers of material. There are a number of such force transducers available, covering a range of 0.1 N to 100 N, in the form of a single- or double-bending beam configuration. These devices are highly cost-effective when produced in large quantities due to the manufacturing techniques involved. This makes them ideally suited for use in large-volume products such as shop scales and pressure transducers.

The wire strain gauge was the original type of resistance strain gauge, though now widely replaced by cheaper foil or thin film types. However, the wire strain gauge is still used extensively for high-temperature transducers and stress analysis, and is available in a wide range of materials.

The nominal resistance of a strain gauge varies with the type and application. Wire gauges have resistances in the range of 60 Ω to 350 Ω , foil and semiconductor gauges from 120 Ω to 5 k Ω , and thin-film types around 10 k Ω . Selection criteria may include size, self-heating, and power requirements. If several load cells are to be connected together, then matched resistance may be important.

The strain gauge converts the strain produced by the applied force into resistance change. To maximize the response of the load cell, it is normal to connect one or more strain gauges aligned to respond to a compressive strain and another set aligned with a tensile strain. When connected electrically as a Wheatstone bridge configuration, this has the added advantage of minimizing the effects of environmental changes, such as temperature, which act equally on all the gauges. The resistance change is detected by measuring the differential voltage across the bridge.

A Wheatstone bridge is normally formed by four strain gauges, although it is not uncommon to use two strain gauges for a *half bridge*, or more than four on elastic elements of complex shape. In the latter case, half the total number of strain gauges are subjected to compressive strains and the other half to tensile strains. The voltage output from the bridge, when excited by an input voltage, is linearly related to the resistance change of the strain gauges and is therefore a function of the force applied to the element. The rated output of a load cell is commonly standardized to a nominal level, usually 2 mV/V (2 mV output at rated load per 1 V input), but it can range from 1 mV/V to 5 mV/V.

A shunt resistor may be needed to perform a shunt calibration, and this is often fitted in the signal conditioning unit to be

Figure 1. Various types of load cell: (a) compression cylinder, 50 kN to 50 MN; (b) compression cylinder (hollow), 10 kN to 50 MN; (c) toroidal ring, 1 kN to 5 MN; (d) ring, 1 kN to 1 MN; (e) S beam (bending or shear), 200 N to 50 kN; (f) double-ended shear beam, 20 kN to 2 MN; (g) double-bending beam (simplified), 500 N to 50 kN; (h) shear beam, 1 kN to 500 kN; (i) double-bending beam, 100 N to 10 kN; (j) tension cylinder, 50 kN to 50 MN.

switched across one arm of the bridge when required. Typical shunt calibration resistor values used for a 350 Ω bridge are 40 k Ω and 80 k Ω , which equate to approximately 90% and 45% of full load on a 2 mV/V transducer.

A load cell is part of a measurement chain, and it requires an excitation voltage to be supplied, as well as amplification and conditioning of the output signal, before it can be meaningfully displayed or used in a control system. Normally a system excites the load cell with direct current (dc) voltage and amplifies the output through an instrumentation amplifier. This chain features wide frequency bandwidth, high stability, and relatively low cost.

In industrial applications, the distance between the load cell and the measuring instrument may be considerable, possibly hundreds of meters. The voltage drop along the connecting cable and its dependence upon temperature can contribute to the system error. This additional error can be remedied by the use of a six-wire connection technique. The excitation voltage is measured at the load cell, rather than at the instrument, and maintained at a constant preset level.

An alternative to dc excitation is the alternating current (ac) system, which excites the load cell with an ac signal. The output is processed through an ac amplifier, a synchronous demodulator, a filter, and a dc amplifier. A high-level dc signal is obtained, suitable for direct analog display or for conversion to a digital display with the use of an analog-to-digital converter. Such a system offers higher immunity to thermal effects in the instrumentation and thermoelectric effects in the transducer, high noise rejection, good zero-force output stability, and ease of achieving isolation between the signal output and the load cell. However, in view of the complex measuring chain, these systems tend to be costly.

A strain-gauge load cell has two distinct temperature coefficients, one on zero-load output and one on full-scale output. The former is caused by the effect of temperature on the strain-gauge resistance, the mismatch between the expansion coefficient of the gauge and the spring element to which it is bonded, and the out-of-balance condition in the bridge wiring. The effect on full-scale output is mainly caused by the temperature dependence of the modulus of elasticity of the spring element material. Temperature compensation gauges can reduce the load cell's temperature coefficients to very low levels.

It is usually necessary to protect the elastic element, its strain gauges, and associated electronic components, since many load cells are exposed to harsh industrial environments. The way the load cell is housed depends on its intended application, and there are a wide range of shapes and sizes, including cylinders, rectangular and circular beams, and tension devices like turnbuckles. The housing must allow for suitable fixings such as bolts or cradles and is critical in determining the correct transfer of the force to the elastic element. The housing used for this purpose also fulfils other functions, such as limiting the side forces on the element and protecting the various electric components.

Piezoelectric Crystal Force Transducers

When a force is exerted on certain crystalline materials, electric charges are formed on the crystal surface in proportion to that force. To make use of the device, a charge amplifier is required to integrate the electric charges to give a signal that is proportional to the applied force and big enough to measure. These devices are known as piezoelectric crystal, or quartz, force transducers.

These sensors are different from most other sensing techniques in that they are active sensing elements. No power supply is needed, and the deformation to generate a signal is very small. This provides the advantage of high-frequency response of the measuring system without introducing geometric changes into the force measuring path.

When packaged as a load washer and compressed under a force of 10 kN, a typical piezoelectric transducer deflects only 0.001 mm. The high-frequency response (up to 100 kHz) enabled by this stiffness and the other inherent qualities of the piezoelectric effect makes piezoelectric crystal sensors very suitable for dynamic measurements.

Extremely fast events such as shock waves in solids, or impact printer and punch press forces, can be measured with these devices. Piezoelectric sensors operate with small electric charge and require high impedance cable for the electrical interface. It is important to use the matched cabling supplied with a transducer.

Piezoelectric crystal sensors are primarily designed for applications using a pretensioned bolt that allows the measurement of forces in both tension and compression. The preloading is important to ensure optimum linearity, and the sensor must be calibrated after mounting. An extension of this principle is the use of force-measuring pins, which are placed within the structure of a machine and respond to the forces within the structure.

There is a small leakage of charge inherent in the charge amplifier, which is called *drift* of the signal. So while piezoelectric force transducers are ideally suited for dynamic measurements, they cannot perform truly static measurements.

Piezoelectric crystal sensors are suitable for measurements in laboratories as well as in industrial settings. The measuring range is very wide, and the transducers survive high overload (typically > 100% of full-scale output). The sensors' small dimensions, large measuring range, and rugged packaging make them very easy to use. They can operate over a wide temperature range and survive temperatures of up to 350°C.

Hydraulic Load Cells

The hydraulic load cell is a device filled with a liquid (usually oil), which has a preload pressure. Application of the force to the loading member increases the fluid pressure, which is measured by a pressure transducer or displayed on a pressure gauge dial via a Bourdon tube.

When used with a pressure transducer, hydraulic load cells are inherently very stiff, deflecting only about 0.05 mm under full force conditions. Although capacities of up to 5 MN are available, most devices fall in to the range of 500 N to 200 kN. The pressure gauge used to monitor the force can be located several meters away from the device by the use of a special fluid-filled hose.

Hydraulic load cells are self-contained and need no external power. They are inherently suitable for use in potentially explosive atmospheres and can be tension or compression devices, but are sensitive to temperature changes.

Pneumatic Load Cells

The operating principles of the pneumatic load cell are similar to those of the hydraulic load cell. The force is applied to one side of a piston or a diaphragm of flexible material and balanced by pneumatic pressure on the other side. This counteracting

pressure is proportional to the force and is displayed on a pressure gauge.

Other Elastic Devices

The *loading column* is probably the simplest elastic device, being simply a metal cylinder subjected to a force along its axis. The change in length of the cylinder is measured directly by a dial gauge and lever system, or other technique. The *proving ring* is functionally very similar except that the element is a circular ring, and the deformation is usually measured across the inside diameter. These transducers have the advantage of being simple and robust; their main disadvantage is the strong effect of temperature on the output.

An LVDT may be used within a load cell to measure the displacement of an elastic element instead of using strain gauges. The LVDT is essentially a transformer that provides an ac output voltage as a function of the displacement of a separate movable magnetic core. The lack of friction and the low mass of the core result in high resolution and low hysteresis, making this device ideal for dynamic measurement applications.

Capacitive load cells use a capacitance sensor to sense the displacement of an elastic element. In most cases the sensor consists of two parallel plates standing opposite each other. The changing length of a spring member produces a change in the gap between two plates, and hence a change in electric capacitance. In the case of small weighing instruments, such as domestic scales, the spring also provides parallel guidance of the scale's platform.

An optical strain gauge can be formed in a manner similar to a wire strain gauge by the use of optical fibers. The deflection of the elastic force-bearing member with the optical strain gauge bonded to it will result in length changes in the optical fibers. If monochromatic light is used to feed two optical strain gauges experiencing different strains, then the phase difference between the two beams emerging from the gauges is a function of the applied force.

The interference optical load cell uses a high-resolution displacement measuring method. A fork-shaped spring is deformed by the force, the deformation being in the region of 40 μm , and the change of the aperture of the fork is measured by a Michelson interferometer. For the same resolution, the maximum elastic deformation, and with it the strain of the material, need not be as large as in the case of the strain-gauge load cell. The deformation element is made of quartz, which has a very low temperature dependence. The hysteresis and creep of these systems are both particularly small.

Vibrating Elements

In the case of the tuning-fork load cell, the force transducer consists of two parallel band splines, which are connected at their ends and vibrate in opposite directions in resonance. The mode of vibration is like that of a tuning fork and the resonance frequency changes if the element is subjected to a tensile or compressive force. The excitation of the vibration and the reciprocal reception of the vibration signals are carried out by two piezoelectric elements close to the vibration node of the tuning fork.

The vibrating-wire transducer consists of a taut ferromagnetic wire that is excited into transverse vibrations by a drive coil. These vibrations are detected using a pickup coil. Both coils have permanent magnet cores, and once the wire has been

excited to its resonance frequency for a given tension, it is maintained at this frequency by connecting the two coils through an amplifier to form a self-oscillating system. Each resonance frequency is a measure of the wire's tension and, hence, the applied force at that instant. The advantage of the vibrating-wire transducer is its direct frequency output, which can be handled by digital circuitry, eliminating the need for an analog-to-digital converter.

Magnetoelastic Devices

The magnetoelastic force transducer is based on the effect that when a ferromagnetic material is subjected to mechanical stress, the magnetic properties of the material are altered and the change is proportional to the applied stress. Due to its sturdy construction, high signal level, and small internal resistance, the magnetoelastic load cell can be used in rough and electrically disturbed environments such as rolling mills. The rated capacities of these devices are in the range from 2 N to 5 MN.

Dynamic Balance Devices

Gyroscopic load cells exploit the force sensitivity of a gyroscope mounted in a gimbal or frame system. A commercially available gyroscopic load cell incorporates a dynamically balanced heavy rotor on a spindle, itself mounted in the inner frame of a two-gimbal system. The arrangement has three orthogonal axes of rotational freedom and has the axis of origin at the center of gravity of the rotor. The force to be measured by the transducer is applied through the lower swivel, and a couple is produced on the inner frame, causing the gimbals to precess. The time taken for the outer gimbal to complete one revolution is then a measure of the applied force. The gyroscopic load cell is essentially a fast-responding digital transducer and is inherently free of hysteresis and drift.

The force balance uses a feedback circuit to compare the electrical output with the force input. A typical system has attached to the force input member an electric coil, which operates in the flux gap of a permanent magnet. An electric current passed through the coil generates a restoring force in opposition to the applied force. A displacement transducer is used to sense the displacement of the force input member, its output being amplified and used to control the current in the coil until the restoring force exactly balances the applied force and restores the force input member to its original position. The coil current to achieve this balance is proportional to the applied force and is measured as a voltage sensed across a resistor in series with the coil. These types of device have good dynamic performance, small deflection, and relative insensitivity to environmental conditions. They are inherently stable and accurate, and as a result are often considered for use as secondary standards. This type of device is mainly a competitor for the mechanical analytical balance in mass determination.

APPLICATIONS

There are many different applications of force measurement systems in industry, too numerous to describe here. One of the main applications is the weighing of products during manufacturing—this is known as process weighing. Batch mixing, truck loading, packing, and vessel filling of liquids, gases,

or solids are all processes requiring accurate determination of weight. Many process weighing situations use load cells to measure forces, from which the weight of product is derived. One pitfall is that, while determination of the force may be straightforward, the interpretation of the gravitational component acting on the mass may not be so simple, as described in the following example of vessel weighing.

If a vessel can be mounted at all support points on force transducers, and if the associated pipework and fittings do not take some of the force, the weight may be derived from the total force measured. Often, however, to reduce cost, the vessel may be mounted on one load cell and two dummies, or two load cells and two dummies, and the force is assumed to be equally distributed between the active and nonactive points.

Weighing of a three-legged tank/vessel with one active force transducer in this way leaves the measurement at the mercy of variations in center of gravity due to nonlevel loads, nonuniform vessel cross section, agitation of the contents, and external wind forces. Accuracy of weighing with these systems is usually poor (although acceptable sometimes for level measurement) even if the material in the tank is self-leveling or a liquid. The effects of pipework, fittings, and nonlinear deformation of the tank will cause movement of the center of gravity between the empty and full conditions, as well as affecting the total force seen by the measurement devices (9).

System Design

The choice of force measurement system can only be made after considering the specific details of the application. The designer should consider the range of force to be measured, the number of loading points, the direction of the forces (and whether in tension, compression, or both), and the duration and rate at which the force is applied to the transducer. As a result of these considerations, the choice can be made on what type of transducers can be used, how many will be required and of what capacity, whether uni- or bidirectional, and whether single or multiaxis.

The choice of instrumentation also needs to be made. The frequency and number of data to be collected need to be considered, as well as the nature of the indicator and any links to a data acquisition or control system. The environment in which the force measurement system has to work can have a significant effect on its performance. Parameters to be considered include the temperature, vibration, humidity, corrosive nature of the atmosphere, variation in ambient pressure, and freedom of movement required by the displacement of all the force measurement transducers.

The design should also ensure that there are no parallel load paths (known as force shunts) that may take some of the force that is supposed to be measured by the transducer. Force shunts can be present all of the time (as through pipework connections) or may occur when the movement of the system is arrested by overload stops. The end fittings of the transducer should be designed both to minimize side loads and to allow the force to be passed to the transducer along a well-defined axis, normally the principal axis of the transducer.

Calibration and Traceability

Even with good transducers and a good system design, the measurement cannot be relied upon without some check on the performance of the system. Unexpected installation effects, degradation of the equipment over time, or user abuse may all

lead to a measurement that has a greater uncertainty than the designer planned. Consequently, calibration is required to ensure that the force measurement meets the needs of the user and achieves the required degree of uncertainty.

Traceability to authoritative standards is the best way to ensure accuracy of measurements, and leads to consistency of measurements among users at different times and locations. A standard force is less easy to visualize than a standard mass and, by its nature, must be created by a machine rather than having a separate existence as an artifact. Not only must the magnitude of the force be known to the required uncertainty, but also its direction and the conditions of its application to the transducer under test (10,11).

Machines capable of undertaking force calibrations are known as force standard machines, and they may be categorized as either primary or secondary. Primary standards in force measurement are generally deadweight machines whose uncertainty can be directly verified through physical principles with respect to the fundamental base units of mass, length, and time. Secondary standards are machines that can reliably reproduce forces and can be compared with primary standards by the use of a force transfer standard. Examples of secondary standards are lever, reference load cell, hydraulic amplification, and hydraulic strain-gauged column machines. The instrumentation used during the calibration must itself have full traceability, either by calibrating the complete force measuring system of transducer and instrumentation together, or by calibrating the instrumentation separately.

Primary standards are usually defined at a national or international level by a single authoritative measuring instrument known as a national standard or international standard. Traceability normally means that the calibrations have been undertaken by the national standards laboratory, by an accredited laboratory, or by a national or accredited laboratory in another country with which there is a reciprocal recognition agreement.

Most documentary standards in the area of force measurement were written to satisfy a need for traceability in materials testing. The procedures contained in these standards are also used for the calibration of force measurement systems in a wide range of other industries. The calibration, or verification, of materials testing machines is covered by ISO 7500 (12) and other national standards. The document dealing with the calibration and classification of transfer standards (or force-proving instruments) is ISO 376 (13).

The above standards have been developed for the calibration of systems to measure static forces acting along a single well-defined axis. Calibrations are also required for multiaxis situations and for systems that measure dynamic forces.

Multiaxis calibration is similar to single-axis calibration, but done once for each axis. The calibration of multicomponent force sensors is more demanding on the equipment, although the principles remain the same.

At the time of writing, dynamic force calibration is not yet an established procedure. The statically derived force transducer sensitivities are assumed to be applicable for dynamic force measurements. This can lead to significant errors, and work is ongoing to produce a dynamic calibration standard.

There are three main calibration options available for establishing the uncertainty of the force measurement system. The first is to leave the force transducer in its permanently installed position and use a transfer standard to carry out the calibrations. The second is to calibrate the force transducer prior to

installation and remove it as required for further calibrations. The final option is to calibrate the force transducer prior to its permanent installation in the force measurement system and then not to recalibrate during the life of the installation.

The user also needs to consider how often to calibrate the device, whether to calibrate the whole system or just the transducer, whether adjustment of the instrument is required, and what uncertainty level is required. The end-loading and temperature conditions during the calibration should be similar to those experienced in the application.

Before taking any calibration readings the transducer should be preloaded up to its rated force and back to zero several times. This is to ensure that any mechanical or electric connection, offsets, or mismatches have been allowed to settle in. When taking measurements, the applied force should always be approached from the same direction, and allowed to stabilize before a reading is taken. It is also important that zero force be a well-defined mechanical point at the same level and direction, taking account of backlash and the like.

Analysis of the calibration data will often be carried out by the calibration laboratory and a calibration certificate supplied to the user when the transducer is returned. There are other checks the user can make, such as checking that the worst-case error is within the process needs, checking for any anomalies or bias, checking that the linearity is within process needs, and reviewing the history of the device's calibrations.

QUALITY ASSURANCE OF FORCE AND MASS MEASUREMENTS

Many organizations are granted a recognized certification or accreditation for their activities, covering their overall quality management system. However, a generalized quality certification does not address the details of specialised technical practices. Accreditation, on the other hand, means that certain aspects of their business have been independently assessed, and that they comply with given criteria of competence and quality.

In the United Kingdom, for example, the United Kingdom Accreditation Service (UKAS) undertakes the National Accreditation of Measurement and Sampling (NAMAS). NAMAS accreditation of a calibration or testing laboratory provides assurance that measurements are carried out to the highest standards of technical competence, traceable to recognized national or international standards, using agreed methods, and with realistic statements of uncertainty. The NAMAS regulations are based on international standards for the operation and accreditation of laboratories, such as EN 45000 (14) and ISO Guide 25 (15). NAMAS certificates are widely recognised and accepted throughout the United Kingdom and also world-wide.

Counterparts of NAMAS exist in many other countries, and in many cases are recognized as equivalent. Formal agreements provide for the mutual recognition of certificates from different national accreditation schemes. The European Co-operation for Accreditation (EA) is the body that is the focus for multilateral recognition among national measurement accreditation schemes in Europe.

GRAVIMETERS

Gravity measurements reflect the earth's gravitational attraction, its centrifugal force, tidal accelerations due to the sun, moon, and planets, and other applied forces. They are invaluable to oil and mineral prospectors. They are used by physical scientists to determine the exact size and shape of the earth and they contribute to the gravity compensations applied to inertial navigation systems. If the earth was a sphere of uniform density, then its gravitational attraction on small bodies located on its surface would be constant everywhere. In fact, the earth's centrifugal forces of rotation have flattened it at the poles, making its polar radius approximately 21 km less than its equatorial radius. The outward centrifugal acceleration at the equator (which is nonexistent at the poles) decreases inward equatorial gravity accelerations by approximately 3400 mgal (1 mgal = 10^{-5} m/s² $\cong$ 1 μ g or 1 part per 10^6). Equatorial gravity measurements also reflect a greater attraction to the whole earth (owing

to the lower latitude bulge), and this results in an increase of approximately 4900 mgal. Polar gravity measurements reflect being closer to the center of mass which accounts for an increased measurement of approximately 6600 mgal. Taken collectively, polar gravity is roughly 5100 mgal stronger than equatorial gravity. Gravity measurements also decrease by about 1 mgal for every 3 m increase in height above mean sea level. Local and regional subterranean density variations also produce gravity changes as large as 200 to 300 mgal, although these tend to be smaller.

As explained by Einstein, the Equivalence Principle does not permit gravity to be measured at a point. What is measured is the *specific* force impressed on the instrument. The *gravitational* force is inferred from knowledge (and assumptions) of the acceleration of the instrument. Accelerometers and gravimeters are very similar devices because they are sensitive to the same types of inputs. They are, however, optimized for different measurement regimes in terms of dynamic range, frequency response, and operating environments.

The first gravity measurement device was the pendulum clock, invented by Huygens in 1656 (Newton's 14th year). The pendulum's period (T) and the acceleration of gravity (g) are inversely related by $T = 2\pi(I_m/mgh)^{1/2}$ where I_m is the pendulum's moment of inertia about its pivot axis, m is its mass, and h is the distance between its center of mass and its pivot point. French astronomers soon noticed such clocks lost time at the equator when compared to Paris-based observations. This was the first direct evidence that gravity lessens as latitude lessens. Pendulum measurements are time consuming and require elaborate executions and corrections. Moreover, neither I_m nor h can be measured with great precision. A pendulum's mechanical properties also change with time and transport. These mechanical changes create changes in the pendulum's period that are difficult to calibrate. Owing to these problems, pendulums have been completely replaced by two classes of high-precision, high-accuracy gravity measurement devices: (1) absolute gravity apparatuses (both portable and stationary) which use lasers and atomic clocks to measure and time freely falling body distances and (2) relative gravity meters (or gravimeters), which measure the force required to rebalance the gravity force acting on a leveled proof mass attached to a spring *against* the force exerted by the spring, as the meter is moved from one measurement point to the next.

ABSOLUTE GRAVITY MEASUREMENTS

Free-fall Acceleration Measurements

Neglecting air resistance, if a freely falling body is a distance x_0 from an overhead origin at time t_0 and moving with velocity v_0 m/s, then subsequent x_i distances occur t_i seconds after t_0 with time and distance related by (assuming g is constant from x_0 to x_i)

$$x_i = x_0 + v_0 t_i + \frac{1}{2} g t_i^2 \quad (1)$$

Designating t_1 as a starting time, t_2 an intermediate time, and t_3 a final time; and taking combinations of $x_i - x_j$ differences

Figure 1. Block diagram of the Joint Institute for Laboratory Astrophysics free-fall method, patterned after Niebauer et al. (2).

yields

$$g = 2 \left[\frac{\Delta x_3 - (\Delta t_3 / \Delta t_2) \Delta x_2}{\Delta t_3^2 - \Delta t_2 \Delta t_3} \right] \quad (2)$$

where $\Delta x_3 = x_3 - x_1$, $\Delta x_2 = x_2 - x_1$, $\Delta t_3 = t_3 - t_1$, $\Delta t_2 = t_2 - t_1$, and it's noted Eq. (2) is free of x_0 and v_0 . Precise and accurate measurements of distance *and* time are required to accurately measure the absolute value of g in this manner. Today's most sensitive free-fall measuring instruments are portable and rely on stabilized lasers and atomic (rubidium) clocks to provide length and time standards. The drifts in these standards are low enough that they can be used for months without drift errors contributing at the parts per 10^9 level. The standards also are minimally affected by transit vibrations and environmental temperature changes (1). Since a mass dropped from rest falls approximately 5 m in 1 s, time and distance measurements precise to 1 part per 10^9 yield absolute gravity measurements with precisions of a few μgal ($1 \mu\text{gal} = 10^{-8} \text{ m/s}^2 \cong 10^{-9} g$).

Figure 1 is a simplified diagram of the free-fall, absolute gravity meter at the Joint Institute for Laboratory Astrophysics (JILA) (2). A stabilized laser illuminates a Michelson interferometer formed between one light beam, reflected from a falling corner cube (a mirror that reflects the laser directly back, regardless of the cube's orientation) and a second light beam reflected from a stationary reference corner cube. The free-falling cube resides in a drag-free vacuum chamber to eliminate air resistance. The interference of the two reflected beams makes moving fringes (light or dark bands) sensed by an avalanche

photodiode, which activates the timing devices. An electronic scaler, linked to the atomic clock, determines the time between whole numbers of fringes to within a nanosecond (10^{-9} s). Since the wavelength of the laser is also accurately known, the distance traveled by the free-falling cube is accurately determined by counting the number of fringes passing during the time intervals Δt_3 and Δt_2 in Eq. (2). Because each fringe covers a distance of one-half the laser's wavelength (λ), the actual determination of g is from a modified version of Eq. (2), namely

$$g = \lambda \left[\frac{f_3 - (\Delta t_3 / \Delta t_2) f_2}{\Delta t_3^2 - \Delta t_2 \Delta t_3} \right] \quad (3)$$

where f_3 and f_2 are the counted fringes during Δt_3 and Δt_2 . The most accurate and precise free-fall absolute gravity measurements taken to date are discussed in Niebauer et al. (1). Accuracies of $2 \mu\text{gal}$ and repeatabilities of $1 \mu\text{gal}$ are claimed using a portable device weighing approximately 300 kg and possessing a 3 m^2 footprint.

Engineering challenges related to free-fall devices include making the vacuum chamber as free of electrostatic and magnetic effects as possible and ensuring that the laser beam reflected to the falling cube is accurately vertical. The latter is addressed by placing a dish of mercury under the point where gravity is measured. The optics base is then positioned and adjusted to make a vertical beam using the mercury as a reference. Another challenge is to optimally reduce microseismic motions. This is addressed by suspending the reference cube from the mass of a long-period vertical seismometer. Making the transmitted laser frequencies as stable as possible and improving the accuracies of the reference atomic clocks are ongoing challenges. Design of the release mechanism such that no impulse is applied is also a major challenge.

Symmetric Rise and Fall Absolute Gravity Measurements

Sakuma (3) has developed an up-and-down corner cube absolute gravity measuring system. The reflector is initially catapulted upward, and measurements are made of both the upward deceleration and the downward acceleration. Key advantages of the up-and-down approach are the cancellations of air resistance effects and systematic timing errors. Thus the cube need not reside in a vacuum chamber. Key disadvantages are the mechanical vibrations caused by the upward launching of the mass, its nonportability, and its overall mechanical complexity. The device is permanently mounted on a seismically stabilized platform in Paris.

If the distances x_1 and x_2 (from overhead origin) are passed by the catapulted cube at times t_1 and t_2 , and the free-falling cube later passes x_2 at t_3 and x_1 at t_4 , then the *mean* time values of the x_1 and x_2 passages are equal, that is, $(t_4 + t_1)/2 = (t_3 + t_2)/2$. Using this fact, letting $x_1 - x_2 = \Delta x$, and applying Eq. (1) gives the up-and-down calculation of g as

$$g = \frac{8\Delta x}{(t_4 - t_1)^2 - (t_3 - t_2)^2} \quad (4)$$

Sakuma's nonportable instrument also claims precision and accuracy levels of a few μgals .

RELATIVE GRAVITY MEASUREMENTS

Absolute gravity measurements give acceleration values in terms of the basic units of length and time. Such measurements are important to physicists, astronomers, and geodesists determining the dimensions of the earth. For most other purposes, such as oil and mineral prospecting, understanding the earth's deep structure, and inertial navigation gravity compensations; it is the relatively small variation in gravity from point to nearby point that is important. Such variations can be quickly measured with an easy-to-carry instrument called a gravimeter.

The majority of gravimeters in use today balance the gravity force acting on a so-called proof mass suspended from a metallic spring or quartz fiber *against* the force exerted by the spring. Such a gravimeter is illustrated in Fig. 2. At a starting point where the absolute value of gravity is often known, the gravimeter is leveled and the spring tension is adjusted until it is balanced against the gravitational force acting on the proof mass. The gravimeter is then moved to the next point, leveled, and balanced again. The change in spring tension required to bring the gravimeter back into balance is the actual measurement. This is equivalent to the change in the acceleration of gravity between the two points. Repeated rebalancing (nulling) of the instrument between closely spaced points yields two desirable by-products: (1) lower spring hysteresis (inability to return to its original tension standard after compensating for a tension change caused by an external gravity change) and (2) the gravimeter's beam (b in Fig. 2) is kept close to a horizontal position that reduces sensitivity to leveling errors.

Figure 2. Principles of force balance gravimeter.

Principles of Zero-length Spring, Rebalancing Force, Unstable Gravimeters

A spring is said to be zero-length if its tension is proportional to its actual length. Thus, if all external forces were removed, the spring would collapse to zero length. The key advantage of such a spring is that if its tension supports the beam b and mass m in Fig. 2 in the horizontal beam position, it will support them in any position. Referring to Fig. 2 and the above definition, the spring's tension T is given by

$$T = k(l - l_0) \quad (5)$$

where k is the spring constant, l is the spring's length, and l_0 is the very small length (see discussion below) at which the tension is zero. In a state of true equilibrium or balancing of the two forces, the moments of the weight of the mass (mg) and of the spring's tension (T) about the pivot point P are equal. That is

$$\rho T = mgb \cos \theta \quad (6)$$

where the perpendicular distances ρ and $b \cos \theta$ are shown on Fig. 2, θ being the small angle the beam b makes with the horizontal. Applying trigonometric laws to Fig. 2 and inserting Eq. (5) into Eq. (6) yields

$$l = \sqrt{h^2 + b^2 - 2hb \sin \theta} = \frac{kh l_0}{kh - mg} \quad (7)$$

where h is the distance between the beam pivot point P and the spring end attached to some micrometer screw apparatus (see Fig. 2). Since θ is nearly zero, it follows from Eq. (7) that

$$g \frac{d\theta}{dg} = \left(\frac{l - l_0}{l_0} \right) \left(\frac{h}{b} + \frac{b}{h} \right) \quad (8)$$

From Eq. (8) one sees the gravimeter's sensitivity $d\theta/dg$, that is the change of the beam's angle for a given change in gravity, is greater the smaller l_0 can be made. In practice l_0 is made very small (hence the zero-length name) by winding the coils of a helical spring such that the wire is twisted about an axis in its own length as it is wound (4). Such a gravimeter is classified *unstable* (or *astatic*) because it is a moving system that approaches a point of instability where very small changes in gravity produce relatively larger proof mass displacements.

In zero-length gravimeters the spring is attached to one end of the beam near the proof mass. The spring's other end is attached to the micrometer apparatus. By adjusting the micrometer, the force on the main beam is altered such that when a change in gravity occurs, the beam is returned to the same angle with the horizontal. The change in gravity is shown as an arbitrary scale division on the micrometer's dial, which is easily converted to gravity units. Current zero-length spring gravimeters typically detect changes in gravity at the 1 part/ 10^8 level (0.01 mgal or 10 μ gal). This level of sensitivity requires the spring constant k remain fixed at 1 part/ 10^8 and l_0 be held constant to an even higher degree. Unfortunately both k and l_0 vary with temperature, mainly through the change of the spring's elastic modulus. Therefore gravimeters require a constant temperature environment. This is achieved by housing them in sealed vacuum flasks or in electrically controlled

thermostats. Current gravimeter designs also minimize barometric pressure and magnetic effects.

Gravimeter Range, Accuracy, Precision, Calibration, Drift, and Tidal Effects

A single spring constant k value [see Eq. (5)] cannot give high accuracy measurements over the large range between equatorial and polar gravity. Moreover, if the spring is subjected to large differences in g between force rebalances, it suffers from increased hysteresis. Gravimeter calibration determines k for the specific gravity range to be surveyed. Readings at two or more stations where g is already known gives an average value of k over the range of these stations. The station range must be at least the range of the subsequent survey but not larger than the instrument's range. The latter can be between 5 mgal (geophysical prospecting gravimeters) to over 7000 mgal (global geodetic gravimeters). If the range to be surveyed is large, the calibration stations should be widely separated in latitude. Gravimeters can also be calibrated by tilting them to measure variable components of the g vector. This approach is much more time consuming than field calibrations (5).

There is an inevitable slow and regular change in the length of any gravimeter's spring. The rate of change or *drift* can be determined by returning to a local base as often as the desired accuracy requires (typically every 3 to 4 h). Repeated readings at the same base station over several days produces an oscillatory-shaped drift curve due to tidal effects. The latter result from changes in the gravitational attraction of the sun and moon as their positions change with respect to the earth. Depending on the solar and lunar positions, tidal effects can produce changes in gravity as large as 0.3 mgal over a period as short as 6 h (4). Tidal corrections can be calculated from knowledge of the positions of the sun and moon. However, these effects vary smoothly and slowly and they usually make up part of the gravimeter drift correction itself (unless the required accuracy dictates they be removed). The (tide-free) drift-rate of a fixed-site, specially modified, zero-length, LaCoste-Romberg gravimeter has been reduced to approximately 0.05 mgal/month. This instrument has measured relative gravity at precision and accuracy levels of 1 μ gal (6). Portable, mass produced geodetic gravimeters weigh approximately 2 kg and come with a heating battery to maintain constant temperature. These devices typically measure gravity differences at precision (repeatability) levels of 5 μ gal to 10 μ gal.

RESEARCH AND DEVELOPMENT AREAS

Superconducting Gravimeters

Ultrasensitive cryogenic gravimeters (accelerometers) are being developed wherein the mechanical spring is replaced by a magnetic field produced by current flow in superconducting coils. In the Goodkind (7) device, the field supports a small sphere whose position, determined by the balance between the gravity field and the magnetic field, is monitored electronically. The signal-to-noise ratios of these measurements remain high over a very broad frequency range, covering both the tidal spectrum and very-low-frequency seismic bands (as low as 1 cycle/annum). This instrument has determined major tide components to accuracies better than 0.01 μ gal. The nontidal signal along very low frequencies is mainly due to atmospheric

pressure variations (which can be independently recorded and removed) and the so-called Chandler component of the centrifugal force, a roughly 4 μ gal signal having a period of around 435 days. Superconducting gravimeters remain stable to a few μ gals over such periods and can lead to a better understanding of the Chandler phenomena. Paik et al. (8,9) are developing a superconducting six-axis accelerometer that senses the three translational and three rotational rigid body motions of a single levitated niobium proof mass. This device constitutes a complete inertial measurement unit that is free of drift-prone gyroscopes. Such an instrument could become the core of a passive, nonjammable, virtually drift-free inertial navigation system of the future.

Accurate Shipborne and Airborne Gravity Measurements

When a gravimeter is placed on a moving ship it measures (along its sensitivity axis) the resultant accelerations due to gravity as well as the ship's roll, pitch, and yaw motions. Assuming a velocity of 10 knots, a shipborne gravimeter is typically subjected to high frequency (>1 Hz) horizontal and vertical ship vibration accelerations as large as 0.01 g or 10,000 mgal, 0.01 Hz to 1 Hz ship heaves causing vertical accelerations as high as 0.1 g or 100,000 mgal, and 0.001 Hz to 0.01 Hz ship fishtail or swaying motions which mainly produce horizontal accelerations (4). Therefore only long-period mean gravity values (typically corresponding to frequencies <0.001 Hz) can be precisely and accurately extracted from shipborne gravimeter surveys (using low-pass filtering and averaging techniques over the applicable times and distances). All the motional accelerations cited above can be minimized by placing the gravimeter near the ship's metacenter and mounting it on a shock absorbent, gyroscopically stabilized platform, that is more or less kept level or perpendicular to the average vertical. The stabilized platform also controls cross couplings between the horizontal forces and the highly sensitive vertical response.

In addition to averaging out the ship motion accelerations, one must apply the so-called Eotvos correction to account for the east-west component of the ship's motion. The outward directed centrifugal force component at an earth surface point is given by $R_E \omega^2 \cos^2 \phi$, where R_E is the earth's radius, ω is its angular velocity, and ϕ is the geodetic latitude. At the equator this acceleration is approximately 3400 mgal. If the gravimeter itself has a velocity then the centrifugal force acting on it will be different than if it is stationary. An eastward component of gravimeter velocity numerically adds to the earth rotation effect. This increases the outward centrifugal force and decreases the gravity reading (dominated by the inward attraction of the earth's matter). A westward component of gravimeter velocity has the opposite effect. For an arbitrary gravimeter velocity vector of magnitude V , making a heading angle α with astromonic (true) north, the Eotvos correction is given by

$$E = 2\omega V \cos \phi \sin \alpha + \frac{V^2}{R_E} \quad (9)$$

An east-west velocity of 20 km/h along the equator produces an Eotvos correction of approximately 80 mgal. From Eq. (9) one sees that dE errors in the computed Eotvos corrections are related to dV velocity and $d\alpha$ heading errors by

$$dE = k_1 V \cos \phi \cos \alpha d\alpha + (k_2 \cos \phi \sin \alpha + k_3 V) dV \quad (10)$$

where the k_i are constants. Equation (10) implies an east-west course is most sensitive to velocity errors and a north-south course is most sensitive to heading errors. Therefore, in addition to minimizing the gravimeter's errors caused by the ship's motions and ocean waves, accurate estimates of the ship's positions, velocities, and orientations are required. A shipborne, multiple-antenna (attitude determining) global positioning system (GPS) receiver affordably provides such navigation data. For higher accuracy navigation, GPS data can be integrated with the gyroscopic and accelerometer outputs of an onboard inertial navigation system (INS). The potential of extracting vehicle-borne gravity vectors from integrated GPS/INS data has been examined (10). Therein one pursues the INS's insensitivity to gravity and the GPS's sensitivity to it.

Extraneous accelerations related to high-velocity airborne gravimeter surveys are much more problematic. In particular, large and rapid changes in altitude, linear acceleration, roll, and heading often occur. Even at a low flight speed of 100 km/h, the Eotvos correction in Eq. (9) is around 400 mgal. Thus a 1% error in the estimated speed or a 1 degree error in estimated azimuth introduce gravity errors of approximately 5 mgal. Since gravity decreases by about 1 mgal for every 3 m increase in altitude, and changes in elevation with time produce vertical accelerations, accurate vertical positioning is critical. A GPS or GPS/INS system can potentially meet these navigation requirements. Significant error sources coming from the aircraft's vertical and horizontal accelerations can be further minimized by using gyroscopically stabilized or gimbal suspended gravimeters, flying during periods of low atmospheric turbulence, and increasing the averaging time over which measurements are made (which reduces the resolution of the final mean gravity values). Brozena et al. (11) claimed 2 mgal to 3 mgal accuracies averaged over 20 km.

Gravitational Field Sensors

Jekeli (12) gives a semantically engaging explanation on how a single gravimeter *reacts* to the earth's centrifugal force and *applied* forces such as the one opposite and equal in magnitude to the gravitational attraction of the earth's matter; tidal accelerations caused by the sun, moon, and planets; atmospheric pressures; and any host vehicle accelerations. A gravimeter is insensitive however to a gravitational field (be it the earth's, sun's, moon's, etc.). A gravity gradiometer is a gravitational field sensor. The simplest gradiometer is made up of two closely spaced gravimeters (baseline lengths typically 15 cm to 30 cm) with sensitivity axes pointing in the same (or opposite) directions. By *differencing* (or adding) the two gravimeter outputs, the external forces cancel (at least to a first degree) and one is left *sensing* a gradient of the total gravitation of the solar system along the baseline. The earth's gravitational field clearly dominates those of other bodies and the measured gradient includes a centrifugal force effect. Short-baseline gravity gradient signals are very weak and reflect the higher spatial frequency components of the earth's gravitational spectrum. Engineering challenges abound in the design, fabrication, calibration and mobile operation of ultrasensitive, short-baseline gravity gradiometers. For an overview of these challenges see Jekeli (13). An omnidirectional gradiometer (or full-tensor gradiometer since it measures the full second-order tensor of the gravitational potential scalar) is an elaborate array of 12 or more gravimeters. Gravity gradient measurements interest oil and

mineral prospectors and their line integrals can become real-time gravity vector compensations applied to an accompanying inertial navigation system.

Another type of gravitational field sensor is a satellite-to-satellite electromagnetic ranging device. Like gravity gradients, intersatellite range-rate changes (or line-of-sight accelerations) are functionally related to the difference of the gravity vectors at the two satellite positions. Since satellites are in free-fall and are usually separated by significant distances, onboard gravimeters (accelerometers) can measure the nongravitational forces present at each satellite position (such as atmospheric drag and solar radiation pressure). These external effects can then be removed from the Doppler based satellite-to-satellite range-rate measurement.

VISCOMETERS

The commercial value of numerous fluids produced industrially depends strongly on their viscosity. That is the case when viscosity has a direct effect on how well the fluid performs in its intended application. For example, viscosity plays a significant role in how effectively paint adheres to a wall, and in

the uniformity of the coating. Viscosity also plays a key role in the effectiveness of a lubricant in reducing friction between surfaces, in the power required for pumping sludge from waste reclamation facilities, and so on. The quality of a number of products is specified in terms of well-defined values of viscosity. Such is the case for lubricants, where stringent viscosity specifications have been established since the early 1920s, and also for numerous industrial polymers, as well as inks, paints, and other coating materials.

Definition of Viscosity

When a force is applied to a fluid, the molecules of the fluid are displaced from their positions and move past each other. A velocity gradient is established because molecules located at various points develop different velocities in response to the applied force. This causes a deformation of the fluid: regions of high velocity can be easily imagined to cause a local stretching of the material with respect to regions of lower velocity. Clearly, the extent of the deformation can be quantified in terms of the observed variations of velocity at different locations, or more precisely, in terms of the developed velocity gradient. In some fluids the applied force causes only minor velocity changes, while for other fluids the same force may cause very large changes. The former are commonly referred to as *thin* fluids because they deform easily, posing little resistance to the applied force, while the latter are called *thick* because they are more difficult to deform. If the force is applied to a fluid surface parallel to the direction in which the material is flowing, it is known as a *shear force*, and the rate at which it causes the fluid to deform is called the *shear rate*. The shear rate produced by a given shear stress depends upon the *viscosity* of the fluid, which is a measure of its thickness. In qualitative terms, one may say that the viscosity of a fluid is the property that determines the extent to which the material resists deformation.

A quantitative definition of viscosity is more easily formulated in terms of the system shown in Fig. 1, where a fluid is contained between two parallel plates. A force F is applied to the upper plate, while the lower plate is kept stationary. As a result, the top plate and the fluid layer immediately next to the plate move with a velocity u , while the fluid layer next to the bottom plate remains at zero velocity. Clearly, the applied force has caused a deformation pattern in the fluid. If the surface area of the fluid is A , then the force per unit area, $\tau = F/A$, is called the *shear stress*. Furthermore, the gradient of the velocity field, $\dot{\gamma} = du/dy$, is called the *shear rate* (also called *shear strain rate*), and is interpreted as a measure of the rate of deformation of the fluid. The viscosity of a fluid is denoted

Figure 1. A fluid is sheared between two parallel plates separated by a distance L . While the lower plate is stationary, a force F is applied to the upper plate, causing a deformation in the velocity field such that the top fluid layer flows with velocity u while the bottom layer has velocity zero. The surface area of upper plate is A .

by the symbol η , and is defined as the ratio of the shear stress to the shear rate,

$$\eta = \frac{\tau}{\dot{\gamma}} \quad (1)$$

where in SI units the viscosity η is measured in pascal-seconds (Pa·s), the shear stress τ is measured in pascals (newtons per square meter), and the shear rate $\dot{\gamma}$ is measured in reciprocal seconds (s^{-1}). A common unit of viscosity is the *poise* (P), and $10 \text{ P} = 1 \text{ Pa}\cdot\text{s}$. In turn, the *centipoise* (cP) is defined so that $100 \text{ cP} = 1 \text{ P}$. The *kinematic viscosity* $\nu = \eta/\rho$ is defined as the ratio of the viscosity to the density of the fluid and is measured in units of m^2/s . For the velocity field shown in Fig. 1 it is clear that the shear rate is given by $\dot{\gamma} = u/L$, where L is the distance between the two parallel plates; therefore, application of the general definition (1) to this simple flow system yields that the viscosity is given by the expression $\eta = L\tau/u$. For more complicated shear flow systems, the viscosity is often determined by imposing a shear stress τ , measuring the resulting shear rate $\dot{\gamma}$, and then taking the ratio of these quantities to calculate the viscosity as prescribed by the general definition given by Eq. (1).

In general, the viscosity is a function of the temperature, pressure, and chemical composition of the fluid. The viscosity is also affected by the physical composition of the material, namely, the number and type of different thermodynamic phases present. For example, a multiphase system consisting of water (liquid) and air (gas) will have a very different viscosity from that of the homogeneous water system or the homogeneous gas system, depending upon the relative concentrations of air and water in the multiphase mixture. The viscosity of common fluids is available in tables of physical properties of materials. For example, at 20°C and 1 atm (10^5 Pa) of pressure the viscosity of air is approximately $1.8 \times 10^{-5} \text{ Pa}\cdot\text{s}$, while the viscosity of water is $1.0 \times 10^{-3} \text{ Pa}\cdot\text{s}$, and of ethyl alcohol is $1.8 \times 10^{-3} \text{ Pa}\cdot\text{s}$. Some materials have exceedingly high viscosities; for example, molten glass at 500°C has a viscosity of $1.0 \times 10^{40} \text{ Pa}\cdot\text{s}$. In practical applications fluids are exposed to a wide range of shear-rate values. For example, lubrication oils operating between rotating metal walls in an automobile axle can be exposed to shear rates as large as 10^7 s^{-1} , whereas the sedimentation of particles initially suspended in a fluid exposes the walls of the falling particles to shear rates as small as 10^{-6} s^{-1} .

Newtonian and Non-Newtonian Fluids

A fluid is said to be *Newtonian* if the viscosity remains constant for all shear rates at constant temperature, pressure, and chemical composition of the material. Many common fluids exhibit Newtonian behavior at room temperature. However, other fluids of interest, such as polymer melts, coatings, foods, and many multiphase mixtures, are non-Newtonian in that the viscosity is a function of shear rate. Non-Newtonian fluids can be time-independent or time-dependent, depending on whether the viscosity at constant shear rate remains constant or changes with respect to time. Time dependence of viscosity can be the result of chemical changes (e.g., polymer degradation) or structural changes in multiphase systems (e.g., ketchup, mayonnaise) that occur during shearing. Finally, some non-Newtonian fluids exhibit elastic shear properties, that is, part of the deformation produced by the stress can be recovered when the

Figure 2. Shape of four typical curves of shear stress versus shear rate for time-independent fluids. The viscosity, given by the ratio of shear stress to shear rate, is constant for Newtonian fluids. Bingham plastics show no deformation for shear-stress values below a minimal nonzero value called the yield stress. Dilatant and pseudoplastic fluids are strongly non-Newtonian materials.

stress is removed. Such materials are called *viscoelastic* fluids. The response of a viscoelastic fluid to shear is strongly dependent on the shear rate. Obviously, all viscoelastic fluids are non-Newtonian, and a complete description of their response is extremely complex. However, in general the viscous portion of the response can be characterized separately from the elastic component.

Figure 2 illustrates several relevant types of viscous responses normally encountered for time-independent fluids. The constant slope of the shear-stress versus shear-rate curve shown in the curve for a Newtonian fluid reflects the fact that the viscosity is constant for all shear rates. Simple homogeneous fluids and most lubricants are Newtonian. If the viscosity decreases with increasing shear rate, the fluid is described as *pseudoplastic*; if it increases, *dilatant*. Nearly all polymers and polymer solutions are pseudoplastic, while many multiphase materials are dilatant. For some fluids, a certain level of shear stress, called the *yield stress*, must be exceeded before the fluid begins to flow. After this stress is exceeded, the fluid may behave as a pseudoplastic or dilatant material, or may adopt a behavior similar to a Newtonian material (as is the case of the Bingham plastic behavior shown in Fig. 2). Many food products and pastes exhibit yield stress.

Measurement of Viscosity

A *viscometer* is an instrument used to measure the viscosity of a fluid. These instruments are also called *rheometers*, since rheology is the science that studies the flow of materials under stress. A viscometer can be used in a laboratory facility, or directly in the industrial production line where the fluid of interest is processed. The laboratory method is an *off-line* technique which often involves a time delay because the sample of the fluid must be transported from the production facilities to

an adjacent laboratory environment. The off-line measurement has the advantage that the viscosity can be determined under highly controlled temperature and pressure conditions, and for a wide range of shear rates, resulting in a more accurate characterization. The delay associated with off-line measurements, however, can result in poor process-control performance, and the production of large quantities of material of undesirable characteristics. Furthermore, factors such as corrosiveness and toxicity of the fluid often complicate the use of off-line methods. Also, for materials such as slurries, the rheology of which is important for many mineral processing operations, off-line measurements may be nonrepresentative of the actual sample in process, due to particle settling and the possible occurrence of irreversible particle interactions such as coalescence and agglomeration.

When measurement delays cannot be tolerated, the viscometer can be installed directly in the path of the fluid being processed (*in-line* installation) or in a bypass line that is directly connected to the main path of the fluid (*on-line* installation). Diagrams illustrating in-line and on-line deployment of a viscometer are shown in Fig. 3. Both in-line and on-line instruments aid in maintaining desired product quality. In-line viscometers measure the viscosity at the temperature, pressure, and flow rate of the flowing fluid. Furthermore, since the process conditions (temperature, pressure, concentration, etc.) are usually measured and values are available, no extra hardware and control effort in addition to the in-line viscometer is needed to characterize the sample being tested. However, the sensor is subject to harsh process conditions and disturbances in the process line may damage the sensor. Also, testing is limited to the process conditions. A good instrument must allow for the fact that process streams are often subject to perturbations in temperature, pressure, and flow rate, which can have a great influence on the viscosity measurement. An additional disadvantage of an in-line installation is that the process flow must be interrupted when the viscometer requires service, causing a discontinuity in the production rate and possibly affecting processing equipment located downstream.

In contrast, on-line installations have the advantages that instrument service and repairs can be done by isolating the bypass line without affecting the flow of the process fluid.

Figure 3. Viscometers deployed in an (a) in-line and (b) on-line fashion. In-line and on-line instruments are designed for use in the production environment and measure the viscosity of the fluid as it flows through its processing lines. The on-line configuration can include flow-control valves and heat transfer equipment to provide stable thermodynamic conditions on the bypass line. Viscometers designed for use in laboratory facilities are known as off-line instruments.

Furthermore, the temperature and flow rate of the sampled fluid can be more closely controlled with the installation of small heat exchangers and flow valves, which can improve the accuracy of the viscosity measurement. However, on-line installations often require a higher capital investment because of the additional cost involved in the installation of the bypass lines, flow valves, and heat exchangers.

In the food and dairy industries, where hygiene is a dominant concern, in-line installations are often avoided because they introduce an additional maintenance overhead due to the need for frequent cleaning and disinfection. However, in many applications in-line installations are necessary in order to maintain adequate measurement conditions, such as laminar flow.

The desirability for in-line or on-line measurement of viscosity, particularly for multiphase materials and for materials from natural sources, has been recognized for at least 20 years. Also, the economic incentives for in-line blending of fluids to reduce inventory and labor costs, for better control of product uniformity, and for increased rates of production have been recognized, and are expected to drive the continuous development of new viscometers and the identification of new applications for the instruments. Implementation has been retarded by the complexity and costs of the instruments, by the range of design modifications necessary for general application, and by the moderate resources available to most viscometer manufacturers, who are constrained by the fact that any particular design will address only a limited market segment. Nevertheless, several in-line and on-line instruments are currently available and are beginning to be used with increasing regularity.

Viscometers can be grouped into the following major types according to the principle used for measurement: (1) falling-element, (2) rotational, (3) pressure-flow, and (4) vibrational. Viscometers of these four types may be designed for use in off-line, in-line, or on-line deployment modes. Each measuring principle involves specific governing equations that relate the viscosity to measurable parameters. Other principles of measurement are possible, but they are less common and are therefore not discussed here. A viscometer must be designed and operated so that flow within the instrument is laminar. In all cases, the approach consists in subjecting the fluid to a known or controlled shear rate and measuring the shear stress, or vice versa.

For accurate viscosity measurements, most instruments require calibration against fluids of known viscosity. This is most often performed with commercially available standard oils that are Newtonian fluids of precisely known viscosity. The calibration procedure consists in measuring the viscosity of the standard fluid and then adjusting one or more parameters in the governing equations until the instrument readings match closely the viscosity of the standard.

Because of specific mechanical constraints, each instrument has limits on the shear rates and shear stresses that can be attained; hence, particular care must be taken in the selection of an instrument for a given application. This is most particularly important for non-Newtonian fluids, since the viscosity may be a strong function of shear rate. Furthermore, viscosity is a bulk transport property, and care must be exercised to ensure that measurements are free of artifacts introduced by the instrument geometry; this concern is particularly significant for the measurement of the viscosity of multiphase materials.

MAJOR TYPES OF VISCOMETERS

This section presents various types of viscometers grouped according to the principle of measurement used, and discusses the underlying physical relationships and governing equations associated with each instrument. For reference, Table 1 lists several commercial viscometers available for off-line use, and Table 2 lists instruments designed for in-line or on-line use. Table 3 gives contact information for several major viscometer manufacturers.

Falling-Element Viscometers

Falling-element viscometers involve dropping a solid weight inside a fluid contained in a vessel and measuring the terminal velocity of the weight as it falls. The viscosity is then determined from a governing equation that uses the terminal velocity as a primary input, and that also makes use of a number of known variables such as the weight and dimensions of the falling element, the densities of the element and of the sample fluid, and other geometric factors. The shear rate produced is the result of a combination of the drag force on the moving surface of the falling element and the

Table 1. List of Selected Off-Line Viscometers That Are Commercially Available

Viscometer Type	Manufacturers	Specific Features	Target Industries
Capillary	Goettfert Contraves Instron Shimidzu	Shear-stress control. Shear-stress control. Shear-rate control. Shear-rate control.	Polymer industry
Rotational	Bohlin Rheometrics Haake Contraves Brookfield Rheologica	Vary depending upon geometry of viscometer as well as fluid properties. Limited to lower shear rates.	Used in all industries covering a wide range of viscosities
Vibrational	Nametre	Newtonian fluids only limited to one frequency. Very broad viscosity range.	
Sliding element	Cambridge Stony Brook Scientific	Fluid need not be Newtonian; used mainly for quality control. Fluid must be particulate-free.	Petroleum, specialty chemicals

Table 2. List of Selected Viscometers Designed for In Line or Off Line Use

Viscometer Type	Manufacturers	Specific Features	Target Industries
Capillary	Rheometrics Seiscor Micro Motion Kayeness	Applicable to non-Newtonian and high-viscosity fluids. Pressure drop required.	Polymers, food, petroleum, pulp and paper
Rotational	Brookfield BTG		
Vibrational	Nametre Dynatrol BTG	Wide viscosity range. Large volume of fluid required for accurate measurement.	Broad applications
Sliding element	Cambridge	Relatively inexpensive. Only clean Newtonian fluids with low viscosity (<200 cP) for accurate measurement.	Petroleum and marine fuels, simple solutions

pressure flow due to the motion of the fluid as it is displaced by the falling element. Therefore, even though the shear rate is significant in one direction only, the flow pattern is nevertheless complex. The most common falling-element viscometers utilize a cylinder or a sphere as weights. The Gardener viscometer uses a perforated disk as the falling element, but although this instrument was widely used in the past, it is now obsolete (1).

Although falling-element viscometers are predominantly used as off-line instruments, several instruments are now available commercially for utilization in an on-line mode with clean, Newtonian fluids. In these instruments a sample from the flowing stream is drawn into the viscometer's vessel by pumping. Then the sample is isolated from the flowing stream by closing an inlet valve, and a measurement of the terminal velocity of the falling element is taken. When the measurement has been completed, the sample is discharged back into the flowing stream, a new sample is introduced, and the process is repeated. An example of such type of on-line falling-element viscometer is an instrument marketed by Cambridge Instruments.

Falling-element devices can be used to measure the viscosity of Newtonian fluids accurately, but are of limited value for non-Newtonian fluids. The problem is that these instruments operate at a fixed shear rate, and therefore cannot describe the shear-rate-dependent viscosity of non-Newtonian fluids. Moreover, the governing equations for the physics that describe the fall, including a situation where the falling element is off center, have not been solved successfully for non-Newtonian fluids. Therefore, use of these devices should be limited to measurements under conditions where the fluid exhibits Newtonian behavior.

Falling-Cylinder Viscometer. Falling-cylinder viscometers are the most commonly used falling-element viscometers. These devices consist of a solid cylinder that falls vertically through a hollow cylindrical vessel of larger radius (2). The sample fluid contained within the hollow vessel is sheared by the solid cylinder, which falls downward over a fixed vertical distance under the influence of gravity, or a combination of gravity and an externally applied force (3). The time required for this distance to be traversed is a function of the fluid's viscosity. As with all falling-element viscometers, the higher the viscosity of the fluid, the lower the velocity of the falling element. When the relative gap width, defined as $(r_0 - r_c)/r_0$, is very small, the vis-

cosity of the fluid can be calculated using the relationship (4)

$$\eta = \frac{F(r_0 - r_c)}{2\pi r_c h u} \quad (2)$$

where F is the force driving the fall of the element, r_0 is the radius of the cylindrical vessel, r_c is the radius of the falling cylinder, and u is the terminal velocity of falling cylinder. The terminal velocity u is easily determined by measuring the time the falling cylinder takes to travel between two reference points in the vessel separated by a known distance. This measurement can be made using optical or electrical detectors that sense the instant when the falling element passes through the reference points. When the cylindrical element falls under the influence of gravity alone, the force shown in Eq. (2) is given by the expression $F = \pi r_c^2 h(\rho_c - \rho_f)g$, where h is the length of the falling cylinder, u is its terminal velocity, ρ_c is its density, ρ_f is the density of sample fluid, and g is the gravitational acceleration. The cylinder's fall can also be driven by electromagnetic forces provided by an electrical coil wrapped around the outside wall of the vessel. In that case the force F used in Eq. (2) must include the prescribed electromagnetic force in addition to the gravitational force. Equation (2) is valid for non-Newtonian as well as Newtonian fluids, provided that the relative gap width is small.

The accuracy of the viscosity measurement determined by the falling-cylinder method may be degraded by several undesirable effects. In particular, the following potential problems are of relevance: (1) end effects in the flow pattern near the top or the bottom of the cylindrical vessel can lead to significant errors in the viscosity measured, and must be taken into account; (2) tumbling may occur while the cylinder is falling through the fluid; (3) a horizontal shifting of the solid cylinder may result in an off-center descent in the vessel. These problems can be alleviated to a certain extent by decreasing the radius of the falling cylinder while increasing its length (2). The net objective is to achieve a larger value of the length-to-diameter ratio (L/D) of the instrument, so that horizontal shifts and end effects are minimized.

Falling-Sphere Viscometer. Falling sphere viscometers operate on the principle of measuring the terminal velocity of a solid sphere as it falls through a sample fluid contained in a cylindrical vessel. As in the case of the falling cylinder, the terminal velocity is simply determined from the measurement of the

time taken by the sphere to traverse a fixed distance (5). The viscosity can be calculated from Stokes's equation (6)

$$\eta = \frac{2(\rho_s - \rho_f)r_s^2g}{9u} \quad (3)$$

where ρ_s is the density of the sphere, ρ_f is the density of the fluid, r_s is the radius of the sphere, u is the terminal velocity of the sphere, and g is the gravitational acceleration. Stokes's equation is applicable when (1) the sample fluid is Newtonian and (2) the radius of the sphere is much smaller than the radius of the cylindrical vessel.

Rotational Viscometers

Rotational viscometers utilize the principle of shearing a fluid between two walls (one moving in a rotational motion and one stationary) to create a velocity profile in the liquid as well as to impose a force on the stationary wall. The resulting type of flow is known as *drag flow*. The walls, or boundaries, are arranged with specific geometries that allow the viscosity of the liquid contained between them to be determined through measurement of the force applied on the stationary wall. The best-known drag-flow instruments are the cone-and-plate viscometer, the parallel-plate viscometer, and the coaxial-cylinder viscometers.

Cone-and-Plate Viscometer. The cone-and-plate viscometer is a rotational drag-flow device in which the sample fluid is sheared between a rotating cone and a fixed plate (Fig. 4) (2). The cone is usually situated above the plate, with a point of contact at the vertex of the cone and the midpoint of the plate (7). In order to achieve a shear rate that depends only on the direction of rotation (i.e., that is independent of the radial direction), the angle between the cone and the plate surfaces is small (usually smaller than 3°) (8).

At constant angular velocity, the shear stress in the fluid is proportional to the torque exerted by the fluid on the cone. For small angles between the cone and the plate surface, the shear rate within the fluid is constant. The viscosity of the sample at

a particular shear rate can be calculated as (3)

$$\eta = \frac{3\tau\alpha}{2\pi R^3\Omega} \quad (4)$$

where τ is the torque exerted on the cone, α is the angle between the cone and plate, Ω is the rotational velocity of the cone, and R is the radius of the cone. Equation (4) is valid for all incompressible fluids, provided there is no slip at the surface (2).

Cone-and-plate viscometers are easy to operate; however, there are several sources of error that can affect the measurement, including (1) fluid inertia and secondary flow, (2) edge effects, (3) nonuniformity of the shear field due to a large cone angle, (4) viscous dissipation, and (5) nonideal geometry.

Figure 4. Schematic of a cone-and-plate viscometer geometry where the plate rotates at a constant angular velocity while the cone is fixed. The angle between the cone and plate is typically smaller than 3° . The fluid is confined between the surfaces of the cone and the plate.

Collyer and Clegg (2) or other pertinent references should be consulted for information on appropriate procedures to avoid or minimize these errors. The operation of cone-and-plate viscometers is restricted to creeping flow conditions; therefore their use is limited to low shear rates, typically smaller than 20 s^{-1} .

Parallel-Plate Viscometer. A parallel-plate viscometer is simply a cone-and-plate viscometer in which the angle between the cone and the plate is zero and there is no longer a contact point between the two surfaces. This instrument is particularly useful for the measurement of the viscosity of multiphase materials; however, it is restricted to measurements at very low shear rates, and the shear rate is no longer constant throughout the fluid. In a given sample, the viscosity at a particular shear rate (the shear rate at the edge of the fluid) can be calculated as (3)

$$\eta = \frac{\tau h}{2\pi \Omega r^4} C_F \quad (5)$$

where τ is the torque exerted on the plate, Ω is the angular velocity of the moving plate, r is the plate radius, h is the distance of separation between plates, and C_F is a correction factor defined as

$$C_F = 3 + \frac{d \ln(\tau/2\pi r^3)}{d \ln(\Omega r/h)} \quad (6)$$

In general, the parallel-plate viscometer is subject to the same limitations as the cone-and-plate viscometer.

An instrument for on-line viscosity measurement using parallel-plate or cone-and-plate geometries is available through BTG. This instrument may yield relative viscosity values that are useful for process control purposes, but it is unlikely to yield accurate on-line measurements, since the flow does not have a free surface at the boundary between the plates. For measurement accuracy there must be virtually no flow through the gap between plates during a measurement; however, some flow is necessary to make measurements of viscosity periodically on fresh samples of the flowing fluid.

Rotating-Cup Viscometer. This viscometer consists of two coaxial cylinders that contain the fluid to be measured in the annular gap between them. One cylinder (called the *stator*) is held stationary while the other cylinder (called the *rotor*) is rotated. Two configurations are possible. In one configuration the cup rotates inside the hollow stator, and in the other the immobile stator is located inside the rotating cup. The fluid being measured is sheared in the annular gap. The shear stress can be directly determined by measuring the torque delivered by the motor that drives the rotating cup, or by measuring the torque required to hold the stator immobile. The shear rate can in turn be directly determined by the rotational speed of the cup. For the configuration that features the stator positioned inside the cup, the shear stress and shear rate are given by

$$\tau = \frac{1}{2\pi R_o^2 L_c} T \quad (7)$$

$$\gamma = \frac{4\pi C_F}{1 - (R_i/R_o)^2} N \quad (8)$$

where T is the measured motor torque, N is the rotational speed of the cup measured in revolutions per second, the geometrical parameters R_i and R_o are the inner and outer radii of the gap, and L_c is the effective length of the stator. The parameter C_F is an experimental curvature-flow-index correction factor that takes into account the fact that the curved walls of the gap are not exactly parallel plates and that the fluid may be non-Newtonian (9–12). Using the viscosity definition (1), the working equation for the rotating-cup viscometer reduces to

$$\eta = \frac{1 - (R_i/R_o)^2}{8\pi^2 R_o^2 L_c C_F N} T \quad (9)$$

When the correction factor is arbitrarily set equal to $C_F = 1$, ignoring the effects of curvature, then Eq. (7) yields the *apparent shear stress*, Eq. (8) gives the *apparent shear rate*, and Eq. (9) the *apparent viscosity*. For accurate viscosity determinations, the instrument is calibrated with standard fluids to determine effective length L_c for use in Eq. (9) (4,13).

A typical approach for determining viscosity using the governing Eq. (9) is to first fix the rotational speed N at a desired operating value, and then rewrite Eq. (9) in the form

$$\eta = \phi T \quad (10)$$

where ϕ is a parameter determined experimentally by measuring the torque attained when the instrument is loaded with a standard calibration oil of precisely known viscosity. Equation (10) is then used to calculate the viscosity of any fluid at the given rotational speed. Other specialized types of rotational instruments, such as the Stormer viscometer (1), were widely used in the past, but are now superseded by coaxial cylinder viscometers for laboratory use.

It must be emphasized that the flow induced within the gap by drag must be laminar. If the inner cylinder is the rotor, the curl in the fluid caused by the rotation of the inner cylinder can induce secondary rotational flows imposed on the laminar flow. This can introduce serious error. Finally, viscous dissipation within the fluid can introduce errors due to temperature changes if the fluid is sheared for extended periods. The useful shear-rate range varies with the instrument and fluid, but is generally limited to 600 s^{-1} to 800 s^{-1} if the inner cylinder is the rotor, and 1000 s^{-1} to 1300 s^{-1} if the outer cylinder is the rotor. Rotational viscometers are popular measurement devices because they require small sample sizes, are reasonably easy to use, deliver accurate measurements if used correctly, and can be used for non-Newtonian as well as Newtonian fluids. Their principal disadvantage is that in order to protect the motor and electronics from the fluid, the moving part uses a seal that may require regular check and maintenance.

A commercial rotating-cup viscometer produced by Brookfield Engineering is shown in Fig. 5. The schematic shown is for an in-line instrument that features a rotating cup and a stator mounted vertically inside the cup while the process fluid flows along a horizontal pipe. Most of the material flows around the external walls of the rotor, bypassing the instrument to reach the outlet port. A fraction of the fluid enters the sampling chamber from the bottom and flows upwards into the measuring gap, where it is sheared by the rotating cup. The measured fluid then leaves the measurement gap by flowing upwards and exiting through openings at the top of the rotor. The pressure flow through the gap superimposes an axial shear-rate component

Figure 5. Schematic of an in-line rotational viscometer. The torque required to maintain a specified rotational speed is related to the viscosity of the sample.

on the rotational component. Care must be exercised to ensure that the stress resulting from pressure flow through the instrument gap is negligible compared to the stress resulting from the drag flow. This can be controlled by varying the bypass area for flow, by varying the total flow rate, or by varying the instrument dimensions.

BTG has also marketed a coaxial cylinder viscometer for in-line or on-line measurements. In the proposed design the entering flow is directed through the gap, which leads to superimposing a large pressure flow stress, unless the flow is interrupted for measurement. With continuous flow, this instrument can give only relative values, even with constant flow rate.

Pressure-Flow Viscometers

Several methods for measuring viscosity are based on the properties of axial flow through a channel, where the flow is driven by the pressure difference between the ends of the channel. Ideally, the pressure difference should be measured for fully developed laminar flow through a channel of circular cross section (i.e., a tube); however, one-dimensional flows through a slit have also been used successfully. Usually, the pressure difference is measured over the entire channel length; nevertheless, this practice is not recommended, because it can introduce errors due to entry and exit effects. These adverse effects can be minimized by using tubes with large L/D ratios.

Pressure-flow viscometers are most often constructed using a *capillary*, which is simply a tube of small diameter. The pressure drop needed to maintain a sustained liquid flow rate can be supplied mechanically (using a pump or a plunger, for example), or simply by the fluid head due to gravity. In the latter case, pressure-flow viscometers allow the determination of only the kinematic viscosity, $\nu = \eta/\rho$, where ρ is the density of the fluid. The viscosity η of the fluid can be found from the

measured kinematic viscosity provided that the density of the material is known or is measured using a densitometer. The most common types of pressure-flow instruments include classical capillary viscometers capable of accurate measurements, glass capillary viscometers in widespread use for characterizing Newtonian fluids, and specialized capillary viscometers that have been standardized for use in selected fluids.

Classical Capillary Viscometers. A number of pressure-flow viscometers featuring a capillary tube are available for making accurate viscosity measurements for a wide range of fluids. The laboratory versions of these instruments can be configured in a stress-controlled or a shear-rate-controlled mode, depending on whether the instrument operates at a constant shear stress or at a constant shear rate. For reference, selected instrument manufacturers are listed in Table 1. In response to market demands, a large number of the instruments available commercially have been developed for the study of highly viscous materials. Generally, end effects are minimized by using long capillaries ($L/D > 50$), or by making measurements with capillaries of different lengths and the same diameter and using the results to make appropriate corrections for end effects (14–17). With such techniques accurate measurements of viscosity as a function of the shear rate at the wall of the capillary can be made. When the flow is laminar, the shear rate at the wall of the capillary is given by the expression (3,4,18)

$$\dot{\gamma}_w = \frac{Q}{\pi r^3} \left(\frac{3n+1}{n} \right) \quad (11)$$

with

$$n = \frac{d \ln \tau_w}{d \ln Q} \quad (12)$$

where Q is the volumetric flow rate through the capillary, r is the radius of the capillary, τ_w is shear stress at the wall, and $\dot{\gamma}_w$ is shear rate at the wall. The parameter n defined in Eq. (12) is known as the *flow index*, and for Newtonian fluids it takes the value $n = 1$. The shear stress at the wall of the capillary is in turn given by the expression (3,4,14)

$$\tau_w = \frac{r \Delta P}{2h + 4r C_F} \quad (13)$$

where ΔP is the pressure drop across the capillary, r and h are respectively the radius and the length of the capillary, and C_F is a correction factor that must be determined experimentally. From Eq. (1) it follows that the viscosity is given by the expression

$$\eta = \left(\frac{\pi r^4}{2h + 4r C_F} \frac{n}{3n+1} \right) \frac{\Delta P}{Q} \quad (14)$$

An experimental measurement of viscosity using a capillary viscometer consists of measuring the volumetric flow rate Q along with the pressure drop ΔP across the capillary, and then using Eq. (14) to compute the viscosity. The greater the L/D ratio of the capillary, the more accurate the measurement, due to decrease in end effects. In every case, the flow rate through the capillary must be adjusted to ensure laminar flow.

Figure 6. Schematic diagram of an on-line capillary-Coriolis viscometer geometry. The Coriolis sensor measures the mass flow rate m and the density ρ while the differential-pressure cell measures the pressure drop Δp . A signal processor combines the three measurements to produce the viscosity output η .

In general, off-line versions of classical capillary viscometers require relatively small volumes of fluid samples, and permit making measurements at shear rates of $30,000 \text{ s}^{-1}$ or higher. In most cases, the commercially available laboratory instruments of this type are designed for fluids with high viscosity (typically in excess of 600 cP). Furthermore, laboratory versions of these instruments are typically inexpensive; in contrast, in-line and on-line versions of pressure flow viscometers are expensive, and therefore have found applications in manufacturing operations where there are significant economic incentives to justify the higher capital expenditure, such as in the processing of polymer melts. On-line and in-line instruments are marketed by several providers, including Kayeness and Rheometrics, among others (Table 2).

A recent variation of a capillary viscometer that is being successfully used in a number of on-line applications consists of combination of two sensors, namely, (1) a Coriolis mass-flow meter that measures the density and the mass flow rate of the fluid, and (2) a differential pressure cell that measures the pressure drop across a capillary tube (19). Recognizing that the volumetric flow rate Q and the mass flow rate m are related by $Q = m/\rho$, where ρ is the density, it is possible to rewrite Eq. (14) in the form

$$\eta = \phi \frac{\rho \Delta P}{m} \quad (15)$$

where ϕ is an instrument constant that in principle is equal to the factor inside the parentheses on the right-hand side of Eq. (14). In practice, ϕ is determined experimentally for the specific fluid of interest, and may be a function of temperature. A capillary-Coriolis viscometer arrangement similar to that marketed by Micro Motion Inc. is shown in Fig. 6. It is preferred that the pressure drop be measured across a straight tube upstream or downstream of the Coriolis meter to minimize turbulence and end effects. For common combinations of Coriolis and pressure-cell sensor pairs, the instrument can operate in a range of viscosities differing by a factor of 6.

Glass Capillary Viscometers. Pressure-flow viscometers featuring a glass capillary, such as the Cannon, Ostwald, and Ubbelohde viscometers, have been used for many years in

off-line environments to measure the viscosity of Newtonian fluids. Since in these devices the pressure driving force is supplied by the fluid head, the instruments measure the kinematic viscosity. The principle of measurement consists of determining the time needed for a given volume of fluid to pass through the glass capillary. This lapse of time is known as the *time of efflux*, and can be used to calculate the kinematic viscosity via the equation

$$\nu = \phi_1 t + \frac{\phi_2}{t} \quad (16)$$

where ϕ is the kinematic viscosity, ρ is the density, t is the time of efflux, and ϕ_1 and ϕ_2 are constants determined by calibration against fluids of known viscosity. These glass capillary viscometers are useful for Newtonian fluids only. Usually, the instrument is used to measure viscosities of fluids for which the term ϕ_2/t is negligible.

Specialized Capillary Viscometers. Specialized pressure-flow viscometers that carry out measurements under conditions specified by standards organizations have been used for many years for specific materials. For example, the *Zahn cup*, a fluid-head device with an extremely short L/D ratio, has been used to control the viscosity of paints, inks, dyes and other materials as specified by ASTM D4212-93 (1990). Also, the *Saybolt viscometer*, a device with a short L/D ratio, incorporates a load-bearing plunger on the chamber containing the fluid to add a significant pressure difference to the fluid head. The time for a known volume of fluid to be forced through the capillary under the specified load is measured, and the viscosity is reported in arbitrary time units commonly referred to as *Saybolt viscosity units*. Specifications for the test are given in ASTM D1238-90b (1990). Saybolt viscometers have been used so extensively that tables for converting Saybolt viscosity measurements to poise and other conventional units have been developed for Newtonian fluids and can be found in standard references (20).

Another important specialized viscometer of pressure-flow type is the *melt indexer*, which is used extensively for polymer melts. The melt contained in the viscometer chamber is driven through a capillary of small L/D by a fixed load to give a constant pressure difference. The measured mass of polymer that flows through the capillary in a specified period of time is determined, and is reported in grams as the *melt index* (or *melt flow* for some polymers). Complete specifications for the use of this instrument are given in ASTM D445-88 (1990).

Vibrational Viscometers

Vibrating elements immersed in a fluid can be used to measure the viscosity, because the energy required to sustain a given frequency and amplitude of oscillation depends upon the viscosity of the fluid. A wide variety of vibrational viscometers, which differ primarily in the geometry of the vibrating element, have been developed. The most commonly used elements are spherical or cylindrical probes, as well as wires, rods, or plates. The vibrating element is fixed at one end, allowing motion about a pivotal point. Typically, the element is made to oscillate by an induced magnetic force. Vibrational viscometers are used in a variety of industries, due to their versatility.

The principle of operation of these instruments is based upon either controlling the amplitude or the frequency of oscillation

of the element. In an amplitude-controlled vibrational viscometer, a force is applied to the element in such a way as to make it oscillate at a high frequency but at constant amplitude. The power required to maintain a particular amplitude is directly related to the viscosity (21). For a given amplitude, the power required increases as the viscosity of the sample increases. Frequency-controlled viscometers operate using an analogous principle, but keep the frequency at a user-specified constant value.

The physics of oscillation of a spherical probe in a fluid medium at a constant amplitude is described by the equation (6)

$$\eta = \frac{1}{2} \delta^2 \omega^2 \rho^2 \quad (17)$$

where ω is the vibrational frequency that yields the required amplitude, ρ is the density of the fluid, and δ is the distance the oscillatory wave propagates through the sample medium until its amplitude falls to $1/e$ of its original level, where e is the base of natural logarithms. Therefore, there is a fundamental relationship between the viscosity and the frequency. The specific governing equation for a practical viscometer must take into account a number of additional factors, including the geometry of the vibrating elements as well as the compartment size in which the element vibrates. Note that for a spherical probe the mass of the vibrating element can be considered to be concentrated at a point, whereas for a vibrating rod the mass is distributed throughout the entire element.

A commercial vibrational viscometer for in-line or on-line use, produced by the Nametre Company, is shown in Fig. 7. The vibrating sensor is located inside the measuring chamber. The fluid flows past the instrument from the bottom, after colliding with a deflector plate that protects the sensor from direct fluid impact. The material flows through the chamber and exits

through the outlet port at the top of the instrument. The instrument can be fitted with a heating jacket in order to maintain a constant temperature. The Nametre Company viscometer operates on an controlled-amplitude mode; hence, under normal operation, the transducer that causes the sensor to vibrate is driven in such a way that the amplitude of motion of the sensor is held constant at approximately $1 \mu\text{m}$, and the average electrical power P required to accomplish this constant amplitude is measured. It can be shown that the product of the viscosity of the fluid times its density is given by the expression

$$\eta\rho = \frac{2}{\omega} \frac{P^2}{\phi} \quad (18)$$

where η is the viscosity, ρ is the density, ω is the frequency of vibration, P is the power, and ϕ is an experimental factor specified by the manufacturer and stored in the instrument's on-board electronics. Note that the viscosity of the fluid can be obtained from the viscosity-density product measured by the instrument if the density of the material is known or is measured using an on-line densitometer. The shear rate is given by $\dot{\gamma} = \omega$, where ω is measured in radians per second. Equation (18) gives accurate estimates of the viscosity-density product of fluids that do not show viscoelastic behavior, such as Newtonian fluids, for example. When the sample fluid is viscoelastic, the viscosity appearing on the left-hand side of Eq. (18) is interpreted as a *nominal viscosity* because it is affected by the energy-storage behavior of the elastic modes of the fluid.

Vibrational viscometers for on-line measurements are marketed by a number of companies. These devices can also be used for laboratory measurements. In particular, Nametre Company, BTG, and Dynatrol market vibrational viscometers. The measurements are fairly independent of the flow rate of the fluid being measured; in fact, the flow can even be moderately turbulent. Most instruments operate at a single frequency of oscillation, hence they operate at a single shear rate, a disadvantage when characterizing the flow of non-Newtonian fluids. During operation of the instrument, extreme care must be taken to keep the vibrating element free of deposits that could affect the total mass of the element and lead to biased measurements.

Challenges in On-Line Viscosity Measurement

On-line measurements using the traditional principles of operation introduce many technical challenges, and appropriate remedial measures are necessary to obtain reliable measurement and control. The problems and solutions depend on the particular process at hand. For example, if a rotational device is used, with a superimposed axial flow, a spiral flow within the instrument results, and this can introduce errors in measurement at high flow rates. If a capillary-Coriolis device is used, the flow rate must be high enough to produce an appreciable pressure drop between the points of measurement, but the flow regime must still be laminar. With a falling-element device, axial flow can force the falling element to hit the wall of the instrument, and this can result in malfunction of the instrument. There is also the possibility of corrosion of the equipment or deposits on elements of the instrument due to continued exposure to the process conditions. This can change critical dimensions or change the response of measuring elements.

These are problems of a general nature. In addition, every application gives rise to a unique set of challenges. For example,

Figure 7. Schematic of an in-line vibrational viscometer. The power required to maintain the vibration element at a constant amplitude is related to the viscosity.

preserving the phase distribution of the sample in a multiphase flow (as in suspensions, slurries, and pastes) during measurements is a major challenge.

Reported Applications of On-Line Viscometers

Many application studies have been reported in the literature on using in-line and on-line viscometers in process industries. The following abridged list gives an overview into the range of applications of on-line viscometers. See Table 2 for an overview of commercial in-line and on-line viscometers available in the market, and Table 3 for contact information. Kalotay (19) and Bates (22) discuss the principles and various applications of on-line capillary–Coriolis and on-line rotational viscometers, respectively, for measurement and control. See also De Laney et al. (23). Essegheir et al. (24) discuss the development of in-line and on-line sensors to monitor blend rheology and morphology for microstructure monitoring in compounding polymer blends. Baker et al. (25) discuss an on-line rheometer to monitor the change in melt index of polymer products. Broadhead et al. (26) used an in-line rheometer for closed-loop viscosity control of reactive extrusion. Kawatra et al. (27) studied the effect of slurry viscosity on hydroclone classification by installing an on-line viscometer on a hydroclone system. Shi and Napier-Munn (28) have developed a new procedure for obtaining a full shear-rate–shear-stress curve by using an on-line viscometer. Kawatra and Bakshi (29) have used vibrating-sphere and rotational on-line viscometers for measurements on mineral suspensions. Pillo et al. (30) describe using a viscometer in closed-loop control of recycled high-density polyethylenes during extrusion; the melt viscosity was measured with an on-line rheometer and used as the indicator of polymer quality. Speight et al. (31) use in-line process viscosity monitoring for injection molding control.

The advantages of using an on-line viscometer are also being realized in the food and the pulp and paper industries. For example, in the manufacture of skim milk powder, it is known that using an on-line viscometer to control the degree of evaporation leads to a significant reduction of steam consumption and stack losses, and to the minimization of fouling problems (32). Furthermore, maintaining a constant viscosity also results in a more consistent product, as the mean powder particle diameter is known to be directly proportional to the viscosity of the skim milk concentrate (33).

It is also known that using on-line viscometers in the pulp and paper industry can assist in obtaining enormous energy savings, and studies have been done to evaluate various principles of viscosity measurement (34,35) for this purpose.

Future Developments

There are continuing efforts to develop new types of on-line rheometers for various applications. For example, see Todd et al. (36) for a helical-barrel rheometer, and Arola et al. (37) for an NMR-based method in which nuclear magnetic resonance imaging and fundamental principles of capillary flow are combined.

Rapid advances in the development of viscometers have been made in the last two decades, and the pace of development and applications is accelerating, as is seen from the examples cited. However, much more is needed. The viscosity range that is of interest for industrial fluids varies by about five orders of magnitude. Also, the rheology of the fluid is an additional complication. Technology is available now for accurate on-line

measurement of Newtonian, single-phase fluids and for time-independent non-Newtonian single phase fluids. However, accurate measurements can be made now for only a limited number of multiphase fluids, and time-dependent viscosity is extremely difficult (virtually impossible) to measure on line at present. Corrosive process conditions add to the complexities.

On-line viscometers are moderately expensive devices. That they are nonetheless being adapted for measurement and control in such a diverse array of industries is the best indication of their potential value.

IMPORTANT ISSUES IN VISCOSITY MEASUREMENT AND CONTROL

Challenges Posed by Non-Newtonian Fluids

Incompressible Newtonian fluids at constant temperature are completely characterized by two *material constants*: density and viscosity. For non-Newtonian fluids the rheology leads to *material functions* that are dependent on shear rate, frequency, composition, and time (3). These complexities make it significantly more difficult to measure and control the rheological properties of non-Newtonian materials. However, a wide class of industrially important materials such as polymer solutions, polymer melts, motor oils, varnishes, adhesives, coatings, paints, and foods are non-Newtonian.

From an application viewpoint, the most important rheological property is the non-Newtonian viscosity. Viscosity has very significant effects on heat transfer, fluid transport, droplet and bubble formation and breakup, foaming, lubrication, coating and calendering, extrusion, mixing, and molding, just to mention a few commercially important operations. Proper measurement of viscosity on line can lead to major improvements in these operations and processes.

In addition, the viscosity of the fluid is an important performance specification for the final product. Direct on-line measurement can lead to vastly improved control of product uniformity. This possibility is particularly important for foods, coatings, and lubricants. It is, of course, complicated by the wide range of viscosity exhibited by industrially important fluids. Even a single fluid can exhibit very large variations in viscosity during processing due to temperature, concentration, and shear-rate changes. For example, Kraft black liquor obtained from pulping only one wood species can vary in viscosity by more than three orders of magnitude in the course of processing (38–41). At high concentration, the viscosity of such liquors can vary by more than an order of magnitude at the same temperature, concentration, and shear rate due to variations in composition and interaction of the constituents. This is not uncommon for concentrated solutions or suspensions derived from natural sources.

The phenomenological behavior of any one of these complex fluids is uniform, even though the viscosity varies widely. Various theories proposed to explain the rheological behavior of non-Newtonian fluids have led to models of varying complexity, ranging from generalized Newtonian models such as the power-law model (3), the Cross model (42), and the Carreau–Yasuda model (43,44), to more complex nonlinear viscoelastic models (3). These models yield the general response. For limited ranges of shear rate, two measurements in the shear-sensitive region can be used to define the viscosity

behavior. Thus, it is possible to control the viscosity of Newtonian and simple non-Newtonian time-independent fluids with one or two on-line measurements if the general rheological behavior of the fluid is known.

Challenges Posed by Multiphase Fluids

The problem of measuring viscosity is more challenging in the case of multiphase materials. The shear-rate-dependent viscosity and the flow behavior change markedly with phase distribution and particle size distribution. Many industrially important products are in this category. Examples include milk products, mayonnaise, peanut butter, unleavened dough, chocolate, cheese spreads, latex paints, and coating materials such as inks and paints. Measurement is usually difficult, and on-line control is virtually impossible. For example, see Kawatra and Bakshi (45) for an extensive discussion of various problems involved in the on-line measurement of slurry viscosity using rotational, capillary, and vibrational viscometers. However, if the slurry can be shown to behave as a bulk fluid by obtaining off-line measurements made in different viscometer geometries that are in agreement with each other, on-line measurement and control is possible.

Challenges Posed by Fluids with Time-Dependent Viscosity

A third major challenge is time dependence of the viscosity of materials. For example, the viscosity of tomato juice decreases with time of shearing, whereas that of egg white increases. The usual approach to this problem is to measure viscosity under identical and controlled conditions in the laboratory. On-line measurement and control is still an open issue.

COMPASSES

Modern life is unthinkable without extensive physical movement of humans and goods around the globe. Since the advent of Sputnik in 1957, extraterrestrial space has been added.

The general problem of developing instrumentation to aid in this transfer has been recognized for thousands of years. It has led from simple observation of geographic and astronomical features to use of magnetic compasses, global positioning systems with the aid of earth-bound satellites, and to inertial guidance systems. A qualitative step from the observation of external features like the stars to an internal device is the recognition by the Chinese and the Vikings in the eleventh century that pieces of magnetized iron point in the direction of the magnetic north when allowed to orient themselves freely.

As a result of these developments, the instruments became at the same time more precise and more accurate. For example, millimeter precision can now be achieved for differential changes of position on the earth's surface by using the global positioning system (GPS) with interferometric techniques, with accuracies in the meter range, and directions can be measured

with large ring lasers with precisions reaching subarcseconds, with accuracies in the arcsecond range. Here, *accuracy* means the usual sense of difference between measured value and true value, whereas *precision* means scattering of measured values around the measured average.

One notes that the angular accuracy and precision achievable through astronomical observations at optical wavelengths with instruments mounted at sea level is limited through air turbulence to 0.1 arcsec. It can only be further reduced by special techniques.

POSITION AND DIRECTION ON EARTH, COMPASSES AND GYROS

Position and direction are in principle two very different categories, and the instrumentation required is correspondingly different.

Positioning of a Fixed Point

In positioning a fixed point, the position is to be recorded with respect to a coordinate system that should satisfy the following requirements, among others:

- Realizable and easy interpretable coordinates
- Good time stability
- High resolution or precision
- High reliability and repeatability, or accuracy

Instruments need to be developed that are ideally capable of a resolution and accuracy commensurate with the level of accuracy that the coordinate system is able to afford. These requirements are not self-evident. A nonspherical earth in the large introduces systematic errors when a purely spherical coordinate system is applied. Also ultimately, effects like the continental drift introduce errors in a time-independent system.

A variety of phenomena is at present used with positional accuracies in the meter range. On the earth's surface, starting with well-established stable surveying fix points (geodetic positions), triangulation instruments used in geodetic surveys can establish millimeter accuracy over short distances, up to kilometer distances. For larger distances, astronomical references are used. A large variety of astronomical bodies have historically served as references, starting with the sun for navigational purposes. The moon, with positional data versus time (ephemerides) of centimeter accuracy, is capable of yet higher accuracy. Among the stars, Polaris (North Star or Pole Star, the super giant Ursae Minoris of stellar magnitude +2 in the constellation Ursa Minor) describes a circle around the celestial North Pole with a radius of only 49.5 arcmin and is thus well suited to locate latitude with arcsecond accuracy. It is a preferred reference for navigation, including extraterrestrial. One notes that 1 arcsec of latitude on the earth's surface corresponds to about 30 m.

Finally, for geodetic surveys requiring submillimeter accuracy over global distances, quasars are excellent fiducial radiation sources whose positions can be considered fixed for positioning purposes within our galaxy. For geodetic studies, their radio emission is monitored with a globally distributed set of radio antennas. By study of the correlation of the radio noise of the

receiving antenna dishes, submillimeter accuracy is achieved, allowing the measurement of even continental drift, which is generally on the scale of millimeters per century. Such observations require, however, considerable expense of equipment. Quasars are suitable references mainly on account of their luminosity and their large distances from earth, up to several gigaparsecs (1 parsec = 3×10^{16} m), with corresponding very good positional stability, whose radio emission can be detected with radio dishes of sufficient size. In terms of angular resolution, coordinated radio dishes with dish diameters in the 10 m range achieve milliarcsecond accuracy as opposed to positioning of visible astronomic sources.

Direction at a Point

The establishment of a direction in a given coordinate system is a fundamentally different problem. Mathematically, position is a scalar property at a point that can be established by measuring the three positional coordinates, while the direction is a vector with three vector components. It is, however, possible to evaluate a given direction, for example, the course (clockwise angle relative to the direction true north), by accurately measuring two successive positions of it and evaluating the vector connecting the two positions; this can be done with instruments of sufficient precision (not necessarily accuracy), for example, with GPS.

The time-honored process of dead reckoning used in navigation is roughly the inverse of the process just described: knowing the starting position, the instantaneous direction of the vessel, its instantaneous speed, and the time of travel for each leg, the position of the vessel can be evaluated at any future time by a vector sum where each vector represents the direction and distance traveled with a given speed and direction at each leg.

There are a variety of physical principles available that are able to provide a reference direction independent of the position at which the measurement is performed. Such instruments may either evaluate a direction locally by differential analysis, or else supply an internally generated reference direction that is independent of time and motion of the carrier on which this instrument is mounted. Naturally, great care has to be exercised to render such an instrument insensitive to any rotation of the carrier vessel.

The discussion of such instruments is the main concern of this article.

A variety of physical effects have been employed in directional devices.

Magnetic Compasses. These instruments use the ability of a magnetized needle to align itself in the earth's magnetic field. Since in the present era the horizontal components of the magnetic induction of this field point with reasonable accuracy to a north geomagnetic pole that is close to the (geographic) North Pole, the direction of such a needle is, at least at latitudes far away from the polar regions, reasonably aligned with a meridian on the earth surface, with deviations (declinations, see glossary at the end of this article) generally amounting to less than 10° .

Internally Defined Direction References. For instruments of this kind, any physical principle that establishes a direction in space that is constant is usable. A practically important class

of instruments employ mechanical gyros. They work with the principle that the rotation axis of a rotating massive body maintains its direction under any translation if no torque is applied to it.

Electronic and Nuclear References. Besides electronic interferometers, a recent version of nuclear interferometers is the use of nuclei that have an angular momentum or spin associated with them. When techniques are employed that overcome the randomizing thermal effect such that sufficient nuclei can be aligned in a probe, a readout mechanism will then show a constant direction of such an assembly. Such instruments are called *nuclear magnetic resonance gyroscopes*.

Ring Lasers. These lasers operate with two or more beams, that is, photons, that circulate in opposite directions around a given area defined by three or more mirrors or, more commonly, by an optical fiber. The thus defined area can be represented by an area vector that provide the desired reference direction. The mechanism of excitation of the beams is in principle irrelevant. Besides the classic excitation via inversion through dc current with internal electrodes, high-frequency excitation is used with external electrodes, but modern approaches employ Brillouin stimulation and other methods as well (1).

Any rotation around the area vector or axis results in an output frequency that is proportional to the rate of rotation or the angular velocity. This principle can be used to define directions in various ways. A direct way is its use as a north finder, where a ring laser mounted on the surface of the rotating earth is tilted until its area vector is parallel to the earth rotation axis, which is then verified by measuring a maximum output rate of the ring laser. This vector then points to the geographic North Pole.

In a "strapped-down" version, the ring laser is clamped on the carrier. It records then any rotational component of it. Thus, given the original direction of the ring-laser axis, the integrated output is then used to evaluate the new direction. Since one ring laser can only measure angular velocity components around its own axis, one needs three such rings to completely evaluate the direction vector. Commercial devices with one to three rings in one instrument are on the market, including tiny gyro sensors for image stabilization in binoculars (2), inertial navigation systems in modern airliners, submarines, and missiles, and for establishing stable platforms (3).

DIRECTION FINDING IN THE EARTH'S MAGNETIC FIELD, ERROR SOURCES, AND GYRO OPERATION

Direction Finding via the Earth's Magnetic Field

The Earth's Magnetic Field. The magnetic flux density $\mathbf{B}$ of the earth's field is a vector field whose flux lines define a direction anywhere within a few earth radii (the average earth radius is 6371 km). Its direction can be sensed by placing a freely movable compass needle into it. The torque exerted by the earth's field on the compass dipole becomes zero when the dipole is aligned with the field at that location. Observations show that the earth's field itself can be described to a good approximation by a dipole (Fig. 1) with magnetic moment $m_E = 8.0052 \times 10^{22}$ A·m² (4). This dipole is fixed at the earth's center and its axis is tilted by about 11° against the earth's axis (1996) (the number in parentheses is the year in which these

Figure 1. The earth's magnetic field. Dipole approximation. The vertical axis is the earth's kinematic axis, with poles P_N and P_S . [Source: Maloney, Ref. 7, p. 62.]

coordinates were observed). An aligned needle whose movement is restricted such that it only shows the component parallel to the earth's surface will then point to the coordinates 79° North, 105° West (1996), which is called the north magnetic pole. The magnetic poles, by virtue of the fact that the magnetic flux lines at these points are normal to the earth's surface, constitute also perfect portholes for entry of charged particles from space (5). The following comments qualify the statements above:

1. There is no theory of earth magnetism that is able to predict the field's magnitude, direction, or time evolution sufficiently for navigational purposes.
2. The dipole approximation is good but a closer description of the actual earth field in terms of associated Legendre polynomials has several hundred terms in addition to the basic dipole term (4). The justification of using the dipole approximation stems from the fact that the dipole term in such an expansion is at least an order of magnitude larger than any subsequent term. The actual field distribution on the earth's surface is shown in a Mercator projection in Fig. 2.
3. The south magnetic pole is not at the homologous point in the southern hemisphere; it is at 65° South, 138° East (1996).

4. The nature of the dipole-dipole interaction is such that opposite poles attract each other. In order to keep the notion that the magnetic pole closest to the geographic north pole is called north magnetic pole, the end of the compass needle that points north would have to be the needle's South Pole.
5. Local disturbances due to the presence of, man-made or other, magnetic depositions measurably distort the local field.
6. The field is slowly time dependent, both in magnitude and in direction. Daily changes exist. Figure 3 shows a measurement with a diurnal peak-to-peak excursion of 40 nT (6). These changes include a daily movement of the magnetic poles in elliptical paths with a major axis of about 50 miles (7).

The yearly change in magnitude is of the order of a few tens of nanoteslas depending on the location.

Paleomagnetic studies show that the field is known to have reversed itself approximately once per one million years (7a). The movement of the north magnetic pole during the last 430 years is shown in Fig. 4 (4). The data are, however, not as smooth as the figure implies, as an estimate of the position in 1360 is 66° N, 291° E (69° W) (8). In recognition of this movement, modern atlases indicate only a "North magnetic pole area" (1998: near Bathurst Island, Canada).

Figure 2. Deviation of horizontal compass directions from geographic South–North directions, or Variation. The poles in northern Canada and in Antarctica are clearly visible. [Source: Maloney, Ref. 7, p. 65.]

7. Magnetic storms add additional time dependence. Their magnitudes may range up to $5 \mu\text{T}$ (6).

From detailed studies of the earth's magnetic field it can be concluded that the accuracy of compasses is limited to about $\pm 0.5^\circ$, due to the lack of stability of the earth's field, local disturbances, and due to the difficulty of eliminating man-made fields in the vessel. This error is achievable with a compass whose vicinity has small residual stray fields that are properly compensated for, and whose declination is updated at regular intervals (at least annually).

It follows that a compass mounted in precision instruments, such as surveyor's instruments, that are capable of ± 20 arcsec resolution can only give cursory initial guidance. Also, since

0.5° corresponds to about 55 km on the earth's surface, it is impossible to direct, for example, a vessel with subkilometer accuracy on the globe using compasses alone. Meter accuracy of positioning can be achieved with GPS, and arcsecond accuracy of direction is achieved with inertial guidance systems, for example, with ring-laser gyros (RLG).

Analysis and Reduction of Disturbing Fields from Sources other than the Earth's Field. Given that the earth's field has at present an average magnitude of $53 \mu\text{T}$, but man-made saturation fields of permanent magnets reach magnitudes of 1 T, the necessity of elimination of or compensation for fields other than the earth's field is an important consideration during installation and use of compasses.

Any extraneous ac fields can easily be removed by enclosure in a nonmagnetic metallic screen. This problem is, however, of lesser importance because the compass that is to sense the dc earth field is usually made with a large time constant of several seconds, thereby integrating to zero any ac fields with frequencies well above 1 Hz, for example, 50 Hz or 60 Hz fields generated by nearby power lines.

Time Constant. The large time constant for the needle is usually obtained by immersion in a liquid. While this method is very convenient, it is nevertheless not optimal from the point of view of minimizing the mechanical fluctuations or the mechanical noise. The latter is achieved by introducing feedback via a lossless mechanism, which, however, introduces an effective damping into the needle movement and thus lowers the noise temperature of the needle. Approaches of this kind are well known in electrical engineering but not in connection with magnetic compasses. The reason for this lack of development is probably the inherent, much larger limitation of precision due to the fluctuations of the earth's field that make further development of the precision of magnetic compasses redundant for any but the shortest observation times.

Figure 3. A measurement of a daily variation of the earth's magnetic field strength measured by nuclear magnetic resonance at Jussy, Switzerland, on 11 March 1959. A peak-to-peak change of 40 nT is apparent. [Source: Hochstrasser, Ref. 6, p. 232.]

Figure 4. Movement of the geomagnetic North Pole between 1550 and 1980. The movement covers about 7 degrees of latitude and 50 degrees of longitude. Corresponding yearly variations depend on the location on earth. [Source: Reprinted from Ref. 4, p. 389, by permission of the publisher Academic Press Limited, London.]

Magnetic Stray Fields. The compensation of extraneous dc fields can become a formidable problem. There are two simple rules used to assess such fields' magnitudes.

***B* field produced by an electric dc current:** "One ampère produces 200 nT at one meter distance." This rule is derived from a current flowing in an infinite straight line. This field decreases with distance R as R^{-2} .

***B* field produced by ferromagnetic material in the earth's field:** "One gram of iron produces 1 nT at 1 m distance." This rule is derived from the dipole field of a ferromagnet induced by the earth's field. The strength of a dipole field decreases with distance R as R^{-3} . The basis of this rule was first espoused in Ref. 9, p. 139.

The disturbances are such that the field due to the iron mass of a typical automobile or a ship needs to be carefully compensated for if a magnetic compass is to be used in such an environment.

The two rules are heeded to the extreme in high-resolution nuclear magnetic spectra in the earth's field. This method to obtain an accurate mapping of the earth's local magnetic field vector requires a housing of the apparatus that has to be set up at least 100 m away from power lines, and all ferromagnetic materials, including glass and bronze nails with traces of iron in them, have to be avoided in the construction of such sites (6).

Conversely, these rules require careful selection of the site of a compass on a vessel with a typical iron mass of the order of 10,000 tons. The second rule previously given suggests 10 μ T at 10 m distance, of the same order as the horizontal field component (15 μ T). Furthermore, the induced dipole moment of a ship depends not only on the ship's position on the globe but also on its alignment with the local field. Additionally, many types of ferromagnetic material may be present with vastly different nonlinearities, saturation, and remanences. This is dealt

with approximately by distinguishing between a permanent part and a variable part of the disturbing field.

Methods of Compensation

Helmholtz Coils. A rigorous approach is to set up three orthogonal pairs of Helmholtz coils (10) whose currents are controlled by sensors of the three spatial components of the stray field. A pair of Helmholtz coils, with an axial separation equal to the coil radius, produces a rather homogeneous **B** field in the symmetry center with a drop-off at the fringes varying with the fourth power of the distance and is therefore an excellent, precisely adjustable tool. As such it is the preferred tool where compensation down to picoteslas or less are required as in the production of magnetoencephalograms, where the fields to be measured themselves are at the picotesla level. For regular compass applications in the field, this solution is too spacious and too expensive.

Compensating Permanent Magnets (11). The horizontal component of the disturbing field can be split into two orthogonal components. A straightforward method of compensation is therefore to place two small permanent magnets at 90° off the needle such that after any rotation of the vehicle with respect to the direction North, the needle shows in the same direction, that is, North plus the proper declination. The installation and adjustment of such compensating magnets require a proper empirical approach, since the direction and magnitude of the stray field are generally not known.

Flinders Bars (12). This is an ingenious method to compensate for the induced variable component of the magnetic dipole moment of a large vessel. One or more pieces of soft iron (with low remanence) are placed near the compass, such that their induced moment compensates the ship's magnetic moment. Since the field of the ship decreases with R^{-3} , relatively small pieces

Figure 5. Schematic of a magnetic compass for a ship. The compass card (B) is immersed in a bowl (C) filled with liquid (D) and an airbubble (E). The bowl is centered on a vertical axis, a pivot, which lets the card's magnets stay oriented toward North when the ship changes direction. There is an expansion bellows (F), and a bezel ring (G) to secure the cover. See also text.

in close vicinity of the compass suffice; furthermore, any rotation of the ship or positioning of it at a different magnitude of the earth's field induces a proportional amount into ship and Flinders bars, and thus keeps the compensation valid.

Details for the use and adjustment of compasses are given in the excellent book by Maloney (7).

Degaussing Coils. These coils are used to neutralize the external field of the vessel, for example, to avoid detection by an adversary. Typically, however, the internal field increases as a consequence, and therefore the compensation has to be adjusted depending on whether the degaussing field is switched on or off.

Description of a Practical Magnetic Compass

A widely used instrument is the US Navy Standard No. 1 7.5 inch compass; see Fig. 5 (Ref. 7, p. 67). The housing (C) is made from nonmagnetic material. Two bar magnets (A) of a nickel-cobalt-iron alloy are fixed and aligned with magnetic north on a compass card (B). A ring magnet may also be used. The card is in a bowl filled with alcohol or varsol (D) to provide a passive dampening with a time constant of a few seconds. A mark, the lubber's line, at the compass rim indicates the ship's direction. The graduation on the compass card opposite to the lubber's line indicates the ship's course. Correction pieces of soft iron with negligible remanence and hard iron with a permanent dipole moment are placed in certain configurations outside the compass. The goal of initial correction is to compensate not only for the ship's horizontal dipole moment at various headings of the ship but also to an extent for the vertical magnetic moment of the ship and the earth's magnetic field, since generally only the horizontal component is used for navigation.

Astronomical Direction Finding

A very convenient fact is the position of Polaris close to the celestial north pole, which is equivalent to the direction of the kinematic earth axis. Although Polaris is by no means fixed (13), its motion is known to better than arcsecond accuracy, and for determination of positions or directions of such accuracy, the *American Ephemeris and Nautical Almanac* (14) can be used to correct the observation. The Almanac is updated every year.

An obvious disadvantage of this mode of direction finding is the restriction to nights and cloudless skies.

Gyros

A radical departure from the use of external aids is the use of instruments based on phenomena that provide a stable reference direction independent of external parameters. Gyros can be mechanical, based on nuclear spin, electron spin, or macroscopic quantum systems with an angular momentum given by circulating photons (ring lasers) (15), electrons (16) including superconducting rings, atoms (atomic ring interferometers) (17), or in particular helium atoms (superfluid rings) (18). All gyros possess an internally defined direction, given either by the direction of the angular momentum or spin $\mathbf{M}$ of the spinning particle or quantum fluid, or by the area vector that is circumscribed by the moving particle. For spinning massive particles the time evolution in the absence of a torque $\mathbf{T}$ is described by

$$d\mathbf{M}/dt = \mathbf{T} = \mathbf{0} \quad (1)$$

that is, the vector $\mathbf{M}$ has then a constant direction. In particular, its direction stays constant under any movement of the vessel on which this system is placed if one ensures that the movement does not impart any torque to the system. For mechanical gyros, a Cardan suspension or similar gimbaling structures are designed to effect the decoupling of motions of the carrier from the gyro system; see Fig. 6.

Readout. There must be an engineering solution to the readout problem. For gyros the position of the rotation axis has to be read out with an accuracy that the particular gyro system is capable of. The interaction of the readout and gyro has to be minimized to avoid any backlash that affects the gyro axis. An equivalent problem exists in optical gyros where the required interference of the optical beams at the output may produce backscattering into the cavity, which in severe cases synchronizes the sensing beams inside and thus renders the device useless for interrogation of its rotation status or as a compass.

Figure 6. Schematic of an inertial navigation system with mechanical gyros and acceleration sensors on a navigational platform which is placed in a Cardan suspension. The platform keeps its attitude in space while the vessel on which it is mounted rotates freely in all directions. [Source: Der Spiegel, No. 10, 1984, p. 214.]

In modern gyros, a viable system has to have a resolution of 1 arcsec or better. A submarine, to get to its berth after a long time of inertial navigation without external references, needs arcsecond accuracy.

Of the many possible internal directional references, mechanical gyros with various types of suspension and readout capabilities as well as ring-laser gyros and fiber-optic gyros have been developed to engineering standards. These devices are all capable of arcsecond resolution, as far as the principle of operation and the resolution of the readout is concerned. In mechanical gyros, the rotor of a motor constitutes the spinning part; in this case, the coupling to the outside world is basically through the stator's rotating magnetic field, with no friction except for the bearing of the rotor itself. High accuracy gyros employ air bearings.

Superconducting Mechanical Gyro (19). An extreme case of development is the Gravity Probe B where a satellite houses a mechanical gyro which is to measure a secular change of 44 marcsec per year with an error of ± 1 marcsec per year. The superconducting rotor is electrostatically suspended in a vacuum, and the readout is optical. The development of this gyro has so far lasted for about three decades, but the previous specifications are now secured (1997).

Superfluid Gyros. They are based on the rotation of superfluid ^3He or ^4He in a closed circuit. They are in the development stage. Their basic resolution is theoretically far superior to ring lasers, and more so to classical mechanical gyros, but laboratory results (1997), while encouraging, show nevertheless that much work needs to be done to approach the anticipated performance limits.

Ring-Laser Gyros and Fiber-Optic Gyros. The counterrotating beams in an optical cavity form typically a triangle or a square

Figure 7. Schematic of a plane square ring-laser gyro with dc excitation. The interferometric readout is visible on the right of the figure. The mirror on top is moved in and out by a piezoelectric device, to compensate for pathlength changes. A dithering motor is mounted in the center to prevent the beams from locking at small rotation rates. [Source: G. T. Martin, *IEEE Spectrum*, Feb. 1986, p. 50. © 1986 IEEE.]

(Fig. 7). The beams develop a phase difference as soon as the cavity is rotated around its area vector in absolute space. If the rotation in three dimensions needs to be known, a three-gyro system as in Fig. 8 is employed. In interferometer fiber-optic gyros (IFOGs, Fig. 9), this phase difference is measured by special readout techniques (20).

In self-oscillating loops, the requirement of phase closure forces a shift of the optical oscillation frequency, which is opposite for beams in opposite directions. The corresponding frequency difference Δf between the beams is then given by the Sagnac formula (15)

$$\Delta f = (1/2\pi)d\phi_o/dt = (4/\lambda L)\mathbf{A} \cdot \boldsymbol{\Omega} = (4/\lambda L)A(d\phi_r/dt) \cos \alpha \quad (2)$$

Figure 8. Three-gyro mount to sense three-dimensional rotation. [Source: G. T. Martin, *IEEE Spectrum*, Feb. 1986, p. 49. © 1986 IEEE.]

Figure 9. Principle of an interferometer fiber-optic gyro (IFOG). The fiber-optic loops on the right are excited by an external laser on the left whose beam is split into the two counterrotating beams by the coupler. A second coupler, immediately at the laser output, picks up the returning beams and feeds them into the detector where a phase difference is detected. [Source: Hotate, Ref. 3, p. 108.]

where $\mathbf{A} = (1/2)\oint \mathbf{r} \times d\mathbf{l}$ is the area enclosed by the beam path, represented by its normal vector, Ω is the angular velocity vector to which the device is subjected, α is the angle between the two vectors, λ is the vacuum wavelength of the laser light, and L is the perimeter $L = \oint dl$, or the length of the cavity. This general definition of $\mathbf{A}$ and of L includes also nonplanar RLG configurations as in the quadrilateral Raytheon device (21), for example. After integration of Eq. (2), the optical phase ϕ_o of the RLG output becomes proportional to the mechanical angle of rotation, ϕ_r , if the direction of Ω stays constant.

Certain gyros (21) work with four beams, with pairs of counterrotating beams. In those cases, the beat frequency doubles.

Scale Factor. This denotes the sensitivity of the transduction from the mechanical rotation rate to the optical frequency, or conversely the ratio of equivalent electronic phase change of the ring-laser output frequency to the mechanical rotation angle of the device. It is defined as (22)

$$S = 4A/(\lambda L)[\text{Hz}/(\text{rad/s})] \quad (3)$$

In normal usage, the scale factor is, however, given as

$$S' = [4A/(\lambda L)](\pi/180)(1/3600) \quad (\text{counts}/\text{arcsec}) \quad (4)$$

A typical RLG operating at $\lambda = 633 \text{ nm}$, with an area $A = 1 \text{ dm}^2$ and a length $L = 40 \text{ cm}$ then has a scale factor $S' = 0.76 \text{ counts}/\text{arcsec}$.

Sensitivity to Attitude. The scalar product $\mathbf{A} \cdot \Omega = A\Omega \cos \alpha$ in the Sagnac Eq. (2) gives rise to a sensitivity to the tilt angle α ,

$$|d\Delta f/d\alpha| = S \frac{d\phi_r}{dt} \sin \alpha \quad (5)$$

Equation (5) is important for North-finding ring-laser gyros, where the device is oriented on the rotating earth until the output is maximized, or with equivalent strategies. The uncertainty $d\alpha$ is a measure of the achievable error of the RLG as an indicator of the direction North, that is, the direction of the kinetic axis of earth rotation. Since $d\alpha \propto 1/\sin \alpha$, better sensitivity is basically obtained by finding the direction(s) orthogonal to North.

Limits of Accuracy of Ring-Laser Gyros. Contrary to mechanical gyros, ring-laser gyros possess no rotating mass. Errors due to torque, Eq. (1), that give rise to a variety of effects in

mechanical gyros are therefore absent. Absent also are basic time constants when the ring laser changes its rotation rate or its attitude. Equally, no spin-up time is required to initialize the sensor. In practice, the electronics surrounding the gyro cause warm-up times that are typically in the millisecond range.

Basic quantum limits have been reached, which allow, for example, one to measure a rotation as slow as the earth's with very high precision.

Quantum Noise and Optical $1/f$ Noise. The photon statistics in a laser beam produce a frequency fluctuation whose white one-sided power spectral density $S_{\Delta f}$ is given by

$$S_{\Delta f} = hf_0^3/(PQ^2) \quad (6)$$

where h is Planck's constant, $= 6.6 \times 10^{-34} \text{ W}\cdot\text{s}^2$, f_0 is the average optical oscillation frequency (Hz), P is the optical power lost by the beam in the cavity, including the output (W), and Q is the passive quality factor of the cavity in which the beam is created.

For a standard RLG operating with two independent counterrotating light beams, the beat frequency Δf has twice this noise power density, provided that the beams are uncorrelated and each has the same optical power P . In a four-frequency gyro, the noise power quadruples, but there is a net gain in the signal-to-noise ratio of the latter, because the doubled output frequency [see Eq. (2)] is accompanied by a root-mean-square frequency fluctuation that is only $\sqrt{2}$ times larger.

In ring-laser systems a $1/f$ noise component has also been observed empirically (23). Its power spectral density is

$$S_{\Delta f, 1/\nu} \cong 4(f_0^2/Q^4)(1/\nu) \quad (7)$$

where ν is the Fourier frequency of the oscillator. The inverse quartic power dependence of Q suggests, however, only a small contribution to optical cavities with large Q 's as in RLGs.

Time Averaging. When averaging the beat frequency between two beams over a time duration T , the average has an rms error (24)

$$\overline{\Delta f}_{rms} = [hf_0^3/(PQ^2)]^{1/2}(1/T)^{1/2} \quad (8)$$

The error of the average frequency is thus reduced proportional to $1/\sqrt{T}$. The stability of the system with time sets a useful upper limit of measuring time and with it the ultimate limit of accuracy.

An RLG as mentioned before, with a quality factor $Q = 1 \times 10^9$, a power output of $100 \mu\text{W}$, and a measurement time of 1 min has an rms frequency fluctuation of 3.4 mHz from Eq. (8). The equivalent mechanical phase excursion due to rotation follows from S' above as 4.5 marcsec in 1 min of observation time.

As a North finder [Eq. (5)] the compass error of the same device, again with 1 min of observation, is about 6 arcsec on the earth, if measured with $\alpha = 90^\circ$.

RLGs are so far superior to IFOGs on account of their larger quality factors achievable.

Optical Frequency. The beat frequency versus rotation rate, or the scale factor, can be increased by increasing the optical frequency, that is, lowering the wavelength. Gas-ring lasers are using a helium-neon mixture, approximately 7:1, whereby the helium may be actually the isotope ^3He , which achieves a better conversion of input power to optical power than the naturally occurring ^4He , and an approximately equal mixture

Figure 10. Schematic of a high-resolution research ring laser for detection of fluctuations of the earth rotation. The main differences to RLGs are the large size with a 1 m² area mounted in a stiff 600 kg Zerodur block, a very-high-*Q* cavity, and RF excitation.

of the two naturally occurring neon isotopes ²⁰Ne and ²²Ne to minimize the cross coupling between the two counterrotating beams. Other lasing gases with larger optical frequencies have been found to be inadequate for RLGs.

The optical cavity needs to be excited in one and only one mode clockwise (CW) as well as counterclockwise (CCW). This limits the power, whose upper limit is given by the onset of multimode excitation. Fiber-optic rings are operated at wavelengths in the infrared. The preferred wavelength is 1.55 μm with a fortuitous coincidence of minimum absorption in the fused silica fiber used and europium-doped fibers that can be used as in-line amplifiers.

Area and Path Length. For a given geometry of the ring the area is proportional to L^2 , and it follows from Eq. (2) that larger-area rings are more sensitive. For usual navigational applications decimeter-sized rings are quite sufficient, mainly due to the large quality factor [Eq. (2)] that can be achieved with high-quality mirrors. The latter have reflection losses approaching 1 ppm (1997).

Fiber-optic rings have quality factors that are several orders of magnitude smaller. The effective area is therefore increased by making spools of many turns. With n complete turns the effective area is increased n -fold. The output frequency (or the equivalent phase shift) is then also increased n -fold.

Optimum RLG Geometry. Of all possible planar and nonplanar polygons, plane regular polygons have the largest area to perimeter ratio and therefore the largest scale factor [see Eq. (3)]. Furthermore, given a fixed circumscribed circle for them and employing mirrors with a fixed finesse, the optimum geometry of a gas-ring laser is a square. With this geometry, the gain in the area to perimeter ratio overcompensates the additional loss when going from an equilateral triangle to a square. Square rings also have additional advantages (15). However, in practice triangular-shaped as well as square-shaped RLGs are used.

These geometric considerations do not apply to fiber-optic rings. There the loss mechanisms are distributed in the fiber, and the total loss and therefore the noise power are roughly proportional to the total length L of the fiber. The signal is also proportional to the length; thus the beat frequency to rms frequency fluctuation ratio generally increases in fiber-optic rings with $\sqrt{L}$.

Practical RLG. See Fig. 8. The beam path is encased in a material with a very low coefficient of thermal expansion; at this time (1997) the two materials ultralow expansion (ULE) quartz and Zerodur, with thermal expansion coefficients approaching 0.01 ppm/K, are used. Compared to these artificial materials,

the best-known naturally occurring low-expansion material is fused silica with 0.55 ppm/K, which is, however, inadequate, since the amount of electronics required to keep a single optical cavity mode tuned to the laser gain medium at even modest ambient temperature changes becomes prohibitive.

The maturity of these devices is underlined by the fact that as early as in the mid-1970s a “laser navigation system” was planned for the Sojourner that landed on Mars on 4 July 1997 (25).

Figure 10 shows a high-resolution ring laser specifically constructed for geodetic research (26). The beams circumscribe a plane square area of 1 m². It is designed to resolve the earth’s rotation rate to about one part in 10⁸, which comes close to the known fluctuations of the earth’s rotation vector Ω . Recent developments (June 2000) include a 4 m × 4 m RLG on a Zerodur base with a diameter of 4.2 m, to be housed underground at Wettzell, Germany, for geodetic research.

MORE DETAILED ANALYSIS OF THE EARTH’S MAGNETIC FIELD, COORDINATE SYSTEMS, AND NEW DEVELOPMENTS

Some Details about the Earth Magnetic Field

Units. The SI system is used here as it is throughout this encyclopedia. In order to facilitate the reading of older literature, three hard-to-eradicate non-SI units are translated.

$$\text{One gauss} = 1 \text{ G} = 0.0001 \text{ T} = 100 \mu\text{T}$$

$$\text{One gamma} = 1 \gamma = 1 \text{ nT}$$

$$\text{One oersted} = 1 \text{ Oe} = 1000/4\pi \text{ A/m} = 79.6 \text{ A/m}$$

The Magnetic Dipole Approximation. The magnetic flux density $\mathbf{B}$ of a dipole at far field is given in coordinate-free form by (10)

$$\mathbf{B} = [\mu_0/(4\pi R^3)] \left(3 \frac{\mathbf{R} \cdot \mathbf{m}}{R^2} \mathbf{R} - \mathbf{m} \right) \quad (9)$$

whereby the dipole with magnetic dipole moment $\mathbf{m}$ is placed at $\mathbf{R} = 0$. The far field of $\mathbf{B}$ is then given at the vector distance $\mathbf{R}$.

With the equivalent magnetic moment at the earth’s center pointing in the direction of magnetic north, the far field at the earth surface is given by

$$\mathbf{B} = [\mu_0 m/(4\pi R_E^3)] (\mathbf{a}_R 2 \sin \phi_m - \mathbf{a}_{\phi_m} \cos \phi_m) \quad (10)$$

and its magnitude by

$$B = [\mu_0 m / (4\pi R_E^2)] \sqrt{1 + 3 \sin^2 \phi_m} \quad (11)$$

Here, R_E is the average earth radius, $m = m_E$ is the magnitude of the equivalent dipole approximating the earth's field, ϕ_m is the magnetic latitude (positive for northern latitudes, negative for southern latitudes), $\mathbf{a}_R$ is a unit vector at the field point normal to and pointing away from the earth surface, and $\mathbf{a}_{\theta m}$ is a unit vector pointing to magnetic north. The magnitude near the north magnetic pole ($\phi_m = 90^\circ$) is $62 \mu\text{T}$, whereas at the magnetic equator ($\phi_m = 0^\circ$) it is $31 \mu\text{T}$. The average field at the earth surface is $53 \mu\text{T}$ but the average horizontal component of it is only $15 \mu\text{T}$.

The curl of any $\mathbf{B}$ field is always 0.

Coordinate Systems. In the literature, generally three coordinate systems are in use.

Right-Handed Spherical Coordinate System r, θ, ϕ . Here the radius r_s is measured from the earth's center, the polar angle is measured starting at the (geographic) North Pole with $\theta_s = 0^\circ$ and ending at the (geographic) South Pole with $\theta_s = 180^\circ$, and the azimuth ϕ_s is measured from a reference meridian (Greenwich) onwards east for a full circle, or 360° .

Geographic-Navigational Coordinate System for the Earth Surface ϕ, λ . Here the latitude ϕ is counted from the equator on, positive towards North, negative towards South. The longitude (meridian) λ is counted from Greenwich on positive towards West and negative towards East, so that the meridian opposite the Greenwich meridian has both assignments, $\pm 180^\circ$. For most purposes of navigation, the earth's surface can be considered as a perfect sphere except for local features like mountains and valleys. This coordinate system is not right-handed.

Coordinate Transformations. The piecewise linear transformations between the geographic-navigational and spherical coordinate systems can be written with the aid of the signum function $\text{sgn}(x)$ [$\text{sgn}(x = 0) = 0$, $\text{sgn}(x > 0) = 1$, $\text{sgn}(x < 0) = -1$] as

$$\begin{aligned} \phi_s &= -\lambda + \text{sgn}(\lambda)[\text{sgn}(\lambda) + 1]180^\circ \\ \lambda &= -\phi_s + \text{sgn}(\phi_s - 180^\circ)[\text{sgn}(\phi_s - 180^\circ) + 1]180^\circ \\ \theta_s &= 90^\circ - \phi \\ \phi &= 90^\circ - \theta_s \end{aligned} \quad (12)$$

Magnetic Coordinate System ϕ_m, λ_m . This system is similar to the geographic-navigational system except that the magnetic latitudes $\phi_m = \pm 90^\circ$ are defined by the geomagnetic poles.

The local angle between a magnetic meridian and the corresponding local geographic meridian is the declination D (degrees).

Because of local and temporal changes of the direction of the magnetic field that may amount up to about 0.5° even for observations over one day and/or over short distances (6), the magnetic coordinates, including the most important declination, are not reliable when better accuracies are required. The compass mounted on a level or theodolite for surveying purposes is exclusively used for cursory orientation in the field, not for measurements, considering that these instruments are generally capable of performing at the subarcminute level for civil engineering tasks.

Calculation of Declination. Given the spherical coordinates of the north geomagnetic pole $\theta_{s,Nm}$ and $\phi_{s,Nm}$, a location X with coordinates $\theta_{s,X}$ and $\phi_{s,X}$, and the dipole approximation of the earth's field, the declination D at X becomes, through application of spherical-trigonometric equations,

$$D = \cos^{-1} \left[\frac{\cos \theta_{s,X} - \cos \theta_{s,Nm} \cos \phi_{m,X}}{\sin \theta_{s,Nm} \sin \phi_{m,X}} \right] \quad (13)$$

$$\begin{aligned} \phi_{m,X} &= \cos^{-1} [\cos \theta_{s,Nm} \cos \theta_{s,X} \\ &\quad + \sin \theta_{s,Nm} \sin \theta_{s,X} \cos(\phi_{s,X} - \phi_{s,Nm})] \end{aligned}$$

where $\phi_{m,X}$ is the great circle distance from the north geomagnetic pole to the location X expressed as an arc, in degrees, as seen from earth's center. Care has to be exercised in applications of these formulas, as the relation of the spherical coordinates to the navigational coordinates is only piecewise linear.

Distortion of the Earth's Magnetic Field by Ferromagnetic Materials. The magnetic dipole moment $\mathbf{m}$ of a piece of material with relative permeability μ_r and volume V that is placed in a field $\mathbf{H}$ is estimated by

$$\mathbf{m} = (\mu_r - 1)V\mathbf{H} \quad (14)$$

One kilogram of iron with a mass density of 8580 kg/m^3 placed in a magnetic field $H = 50 \mu\text{T}/(\mu_0) = 40 \text{ A/m}$ with a relative permeability of about 2000 satisfies the rule for distortion by magnetic dipoles given previously.

Size of Torque. Given the magnetic dipole moment $\mathbf{m}$, the torque exerted on this moment in a field $\mathbf{B}$ is

$$\mathbf{T} = \mathbf{m} \times \mathbf{B} \quad (15)$$

The torque on a compass needle is small. With the magnetic moment of a needle of $2 \text{ A}\cdot\text{m}^2$, the torque corresponds to that of a 10 mW electric motor running at 1000 rpm . Here the relation $P = T\omega$ is used, where P is the power generated (W), and ω is the angular frequency (rad/s).

Some Details about Ring Lasers and Other Gyros. A ring laser is an example of an ordered spin system with correlation lengths that may extend to megameters depending on the quality factor of the optical cavity in which the light beam is generated and on the power output. It is one of a very few macroscopic quantum systems. This one uses photons; others are superfluid systems using liquid ^3He or ^4He and electronic superconductors using electrons (Cooper pairs), and magnetic systems (quantum Hall effect). Gyros with low-noise electronic beams are also under active investigation. Of these novel principles, only the RLG and fiber-optic gyros are at this time engineered into mature systems. A recent addition to these tools are atomic interferometers in ring arrangements.

All these systems have in common a closed path enclosing a finite area around which the quantum fluid is circulating. In ring lasers this circulation is internally generated. In other systems the quantum fluid is injected by an external source whereby with specific devices (beam splitters or generally flux splitters), two different paths are created. At the point of

rejoining there is a detection system that detects the phase difference, which is then a measure of the rotation rate.

Frequency Difference and Phase Difference in Optical Gyros; Sense of Rotation. The general problem of obtaining an output signal that is linearly related to the rotation of the device is solved as follows. Given a frequency split of the counterrotating beams $f_{1,2} = f_0 \pm \Delta f/2$ during a rotation, with a corresponding split in the wave numbers $k_{1,2} = k_0 \mp \Delta k/2$, and phase splits after rotation of $\phi_{0,1,2} = \phi_{00} \pm \Delta\phi_0/2$. The split may have a slow time dependence. The two optical beams are overlaid to each other, say in the x direction. The rapidly oscillating electric fields of the beams, with frequencies on the order of 10^{14} Hz to 10^{15} Hz and splits ranging up to 10^6 Hz, having equal amplitudes E_0 , are then

$$E_{1,2} = E_0 \exp[j(2\pi f_{1,2}t - k_{1,2}x)] \quad (16)$$

The observed output power of the combined beams is then

$$P_{out} \propto |E_1 + E_2|^2 = 2E_0^2[\cos(2\pi\Delta f t - 2\pi\Delta kx + \Delta\phi_0) + 1] \quad (17)$$

Observation at $x = 0$ results in a cosinusoidal pattern with frequency Δf (ring lasers) and phase $\Delta\phi$ (nonoscillating Sagnac interferometers) superimposed on a background of constant power. The time dependence is then detected by a low-frequency optical ac detector, typically by a silicon junction device. If the direction of rotation is desired, the beams are slightly misaligned to produce a moving interferometric fringe pattern. Two detectors are then placed a quarter-fringe apart. Their phase differences versus time determine the direction of rotation uniquely.

It also follows from the extreme smallness of the Sagnac frequency relative to the optical frequency that the beam path must be extraordinarily symmetric in clockwise and anticlockwise direction. Any nonreciprocity will lead to an additional non-Sagnac effect, either an additional phase or a frequency bias depending on the nature of the nonreciprocity.

Modifications of Optical Beams. Two new types of optical beams are investigated: One investigation centers on the possibility of correlated emission of the amplifying plasma with the goal of creating beams whose quantum noise is correlated, so that the noise of the interfering beams can be greatly reduced (27). Another approach is to use squeezed light (28), where the quantum noise of the amplitude fluctuations is greatly increased in order to substantially reduce the frequency fluctuation, which keeps the Heisenberg uncertainty relation intact, but affords RLGs with much lower (frequency) noise.

Polarization-Preserving Fiber. When the beams are guided by optical fibers, the original polarization may not be maintained if irregularities are present along the fiber. Special fibers have been manufactured with a slightly elliptical cross section that enforces the same polarization throughout. This is necessary for several reasons, one of the most important is the necessity to have the polarizations of the two beams aligned when they are brought to interference.

Quality Factor Q . This factor enters with its inverse square in the noise and is therefore an important factor in the sensitivity of a gyro, whether as an interferometer or as a self-oscillating device.

In ring lasers with an amplifying gas at low pressure of the order of 1 torr, the overall quality factor Q of the optical

cavity is mainly determined by the losses of the mirrors (29). Given a square cavity with four mirrors, each with a relative power loss $1 - R$, where R is the power reflectivity of a mirror, $Q = (\pi L/2\lambda)/(1 - R)$. In a square research ring laser (Fig. 10) with good mirrors approaching $1 - R = 1$ ppm each, $L = 4$ m, and $\lambda = 633$ nm, a quality factor of 9.9×10^{12} can be achieved (26). Q increases linearly with the perimeter of the cavity, as the losses are localized.

In fiber-optic gyros, the losses are distributed along the fiber. With a total loss of α dB/m (1000α dB/km), the quality factor becomes independent of the path length and is $Q = (2\pi/\lambda)(10/\ln 10)(1/\alpha)$. A good fiber with $\alpha = 0.001$ dB/m (1 dB/km) at $\lambda = 1.55$ μ m gives rise to $Q = 1.8 \times 10^{10}$, almost three orders of magnitude less and independent of the length of the cavity.

GLOSSARY

Agonic line. A line on the earth's surface that connects points with zero magnetic variation.

Cardinal directions. North, East, South, and West.

Compass error. Algebraic sum of variation and deviation.

Declination. Variation.

Deviation. Errors caused in the compass direction by local effects.

Dip. Inclination of a perfectly balanced compass needle (inclination or dip circle) with respect to the local horizontal.

Isogonic line. A line on the earth's surface that connects points with equal magnetic variation.

Point. Subdivision of the compass circle into 32 points. 1 point = 11.25° .

Variation. Angle, in degrees, between the magnetic meridian and the corresponding geographic meridian. It is the direction of the horizontal component of the magnetic field with respect to the geographic coordinate system.

GONIOMETERS

Goniometry is the science of measuring angles. The instruments used to perform this task are called goniometers. They provide an accurate reference system for angular-dependent measurements in a wide field of applications. In their most elementary form, goniometers have existed for many hundreds of years. Recently, they have assumed an extra role as powerful high-precision and computer-controlled systems capable of positioning an infinite variety of emitters, detectors, and targets in any combination and permutation of geometrical configurations. Their field of application has widened as the need for more precise information from an ever-increasing number of high-precision emitters and detectors has grown and, above all, because the large amount of information generated in the process can now be rapidly and automatically acquired, stored, processed, and analyzed. From a simple hand-held device for the measurement of angles, the goniometer has also become the heart of many of the most sophisticated and intelligent analytical tools available to mankind. Goniometers today find

numerous new applications in research and industry, from the traditional fields of medicine and materials analyses to the more recent fields of remote sensing and space applications. At the same time, they remain the basic element in a large number of precise mechanical positioning systems.

HISTORICAL BACKGROUND

Considering the fact that traditional navigational instruments such as astrolabes, quadrants, octants, and sextants are all examples of goniometers, we can see that the goniometer is one of the oldest scientific instruments known to mankind. The original astrolabe was a hand-held astronomical instrument used by ancient Greeks and others to measure the height above the horizon of celestial bodies. Another version of this was the marine astrolabe, a simple wooden or brass graduated disk used for measuring the angle of the sun or a star from the horizon in order to obtain one's position in terms of degrees of latitude above the equator. The quadrant, a graduated quarter circle with a suspended plumb bob, was another example of a goniometer used to assist in determining latitude by alignment with the sun or a star, typically the Pole Star.

An improved version of the quadrant was Hadley's octant in 1731, which incorporated the use of a mirror to bring the object viewed into coincidence with another. From the inclination of the mirror, a measurement of the angle between the two objects could be obtained. The octant was in time superseded by an improved goniometric instrument, the sextant, which along with the compass has remained the basis of marine navigation until recent times.

In other sciences, such as mineralogy, improvements were also being made to the goniometer. One of the first references to be found on the subject is that of Carangeot's contact goniometer (1), which was used by mineralogists to compare large crystals of different development by measuring the interfacial angles. It consisted of two flat steel bars pivoted together like a pair of scissors. The angle between the bars was read from a graduated semicircle with a precision of about a half degree. The contact goniometer was mainly used for large dull crystals that did not yield reflections. For the study of the morphology of smaller crystals, Wollaston's reflecting goniometer in 1809 was a considerable improvement on the contact goniometer, enabling more precise measurements to be taken. This was a simple, cheap, and portable instrument that affected the interpretation of the structure of crystals and had a great influence on the science of mineralogy.

This type of goniometer was followed by the two-circle or theodolite goniometer in 1876, which was a combination of the vertical- and horizontal-circle types. This eliminated the need to mount and readjust the crystal for each series of measurements.

Another important event in the history of goniometers and their role in crystallography took place in 1912 when von Laue showed that diffraction of X rays occurred when they were passed through a suitably oriented crystal. At the same time, he effectively established that X rays have very short wavelengths and that crystals have their atoms arranged in a regular structure. This was followed shortly by the experiments of Bragg in 1912, which gave further important insights into the nature of X rays. These pioneering experiments led to the development of the X-ray goniometer, which used X rays instead of visible light

as the source and an ionization chamber instead of a telescope as the detector and which was designed to measure angles between the atomic planes within crystals.

Reflectivity measurements of different kinds of surfaces have been made for various purposes in the field of astronomy from the turn of the nineteenth century using goniometric systems. The earlier studies mainly concerned the overall photometric behavior of materials. These measurements are still important today because they were made usually in a more systematic way than more recent ones.

As a result of satellite navigation systems, the role of one type of goniometer—the sextant—has lost some importance, although it still remains an essential marine navigational instrument. Thanks to earth-observation satellites, a new type of goniometer has been developed for remote sensing applications during the last few decades because of the need for a more complete characterization on the angular reflectance characteristics of natural and man-made surfaces. This is partially achieved today with the help of custom-built and generally large-scale goniometers capable of observing relatively large target areas, covering one to several tens of square meters.

APPLICATION FIELDS

Today, goniometers are found in a large number of traditional and new application fields. In navigation they are intensively used for direction finding. The direction of a radio transmitter can be rapidly and precisely obtained by measuring the angle of maximum intensity of the transmitted signal with respect to a fixed point. This technique is used in the electronic goniometer or direction-finding receiver, which can be mounted in a fixed or mobile station and is used to measure the direction of propagation of electromagnetic waves. The electronic goniometer can take a variety of forms but is a basic element in most direction-finding antenna array systems in navigation.

In surveying, the theodolite, a very accurate goniometric instrument, allows the precise measurement of angles, both vertically and horizontally. It is usually mounted on an accurately graduated horizontal circle and consists of a telescope and an alidade with a graduated vertical circle. The optical theodolite uses horizontal and vertical circles graduated on glass. Another version of the instrument used in terrestrial photogrammetry is the photo-theodolite consisting of a combined theodolite and camera. The electronic tachymeter or tacheometer is another example of a goniometer mainly used in large-scale topographic surveys and designed for the rapid determination from a single observation of horizontal angles and zenith distances. Trigonometric heighting, electronic distance measurement, traversing, contouring, and detail surveys are just some of the applications of electronic tacheometry.

Goniometers have also many medical uses. In anthropology and surgery, goniometric devices are used to measure the various angles of the skull and other bones. These are often in the form of hand-held goniometers used to measure the range of motion and the angle of joints in the human body (e.g., to monitor knee joint angle or movements of fingers about knuckle joints). Measurements of these angles also provide important information for analysis of changes in posture and movement of the human body during space flight. In certain eye diseases, it is necessary to measure the anterior chamber angle formed by the iris with respect to the rear face of the cornea.

This is performed by means of another goniometric device—the gonioscope.

In industry, goniometers have innumerable applications. To analyze the light distributions of different compact fluorescent lamps, for example, goniophotometers with automated control and data acquisition systems are used. These measure the angular distribution of light emanating from various lighting fixtures. Goniometers have been used in projection photometry where the angular characteristics of search lights and projectors (e.g., cone angles) are measured and analyzed and for the photometric calibration of light sources including the infrared region (2). Goniophotometric measurements are used to quantify light interactions with coated surfaces (e.g., to study the reflectance of metallic finishes in the automobile industry and to improve colorant formulation and shading). In the paper industry, goniometers have been used to provide the necessary scattering characteristics of cellulose fibers and pigments used in papers. Goniometers are also used in the test and calibration of angular dividing equipment. In general, they have helped to develop a better physical understanding of the complex problem of color and the appearance of coatings in industry.

In military use, goniometric compasses have been extensively employed for topographic measurements and for aiming artillery fire.

In science, goniometer systems play a vital role in a large number of disciplines. Three representative examples (advanced material science, astronomy, and remote sensing) are presented in some detail here.

ADVANCED MATERIAL SCIENCE

X-ray diffraction is probably the best known and most appropriate method of determining the crystalline structure of solid materials. It is used for a variety of structures, and even though it is particularly simple in the case of well-crystallized inorganic solids as a “fingerprinting” method for phase analysis, it can also be applied to a wide variety of more complicated organic molecules and to nanocrystalline or amorphous materials. In addition to the crystalline structure, X-ray diffraction can reveal information on stress, crystallite size distribution, preferred orientation, and texture.

Highly accurate goniometers are an essential part of X-ray diffraction systems (Fig. 1). The most common experimental

configuration for polycrystalline materials consists of an X ray beam passing precisely over the axis of a perfectly concentric dual goniometer system, each goniometer having a precision of better than 0.001° , and in many cases, especially in research, some orders of magnitude better than this. The sample is then moved by an angle θ , and the detector by precisely 2θ . The Bragg condition for diffraction peaks to appear is

$$n\lambda = 2d \sin \theta$$

where n is an integer and d is an interplanar spacing present in the material. The intensity of the peaks depends on several factors and in some cases may be zero. The diffracted intensity plotted against 2θ in a *diffractogram* may then be analyzed either by reference to a database of fingerprint spectra or, in the case of new crystalline structures, by comparison to simulated spectra generated by appropriate computer programs using postulated structures. Of course, there are many other experimental arrangements (e.g., for single-crystal analysis or for stress determination) and methods of analyzing or treating diffraction spectra to extract the appropriate information.

At the Institute for Advanced Materials of the Joint Research Centre, Ispra, Italy, a special system has been constructed for the structural analysis of very thin films. Instead of both goniometers being scanned during a measurement, the incident beam impinges on the sample at a very low incident angle, typically from 0.2° to 1.0° . Only the detector (2θ) goniometer is scanned, and special optics ensure that a good angular resolution is maintained. This glancing angle geometry renders the diffraction measurement much more sensitive to the surface of the specimen under examination. Additionally, in order to optimize the signal-to-noise ratio, the distances from x ray source to sample and from sample to detector have been minimized, a high-precision variable slit system to define the incident beam dimensions is used, and a solid-state detector is employed to isolate the desired wavelength without the use of filters or a monochromator and to reduce the background count rate to a minimum. The system may also be used for x ray reflectivity measurements, which can provide highly accurate information about the thickness of thin films, as well as their density and interfacial roughness, by monitoring the specularly reflected X ray intensity as a function of angle of incidence (3).

Many versions of horizontal and vertical goniometers with microprocessor control units have been designed for X ray powder diffraction measurements, phase analysis, and stress and texture analysis. Stand-alone operation of the diffractometers is often possible, thereby reducing the risk of human error. Automated sample spinning is also implemented in some systems to compensate for surface effects and nonrandom crystal orientations.

ASTRONOMY

Various kinds of goniometers have been devised by astronomers mainly for the measurement of the angular reflectance of planetary surfaces. Reflectance measurements of natural surfaces were not started in earnest until the 1960s with the advent of space exploration. Toward the end of the 19th century, however, Kononoviz (4) had started to measure the *surface reflectance* (i.e., the ratio of the light scattered from a surface to the light incident on the surface) of various surfaces on the Earth using

Figure 1. An X-ray diffraction goniometer at Joint Research Centre, Ispra, Italy.

a large range of angles. Ångström (5) also made a series of measurements on natural surfaces with various angles of incidence and reflectance. The measured surface materials were mainly different surface types of water, sand, and vegetation.

Albedo measurements were also accomplished later by Kulebakin (6) and Kimball and Hand (7). The main purpose of the studies was to establish a measure (usually the reflectivity) for different kinds of scattering media. Kulebakin made systematic measurements of natural and artificial surfaces using a rudimentary form of goniometer. His study focused on the simulation of the overall roughness of natural surfaces such as snow, sand, and vegetation, and some man-made surfaces, which were made from cardboard. Kulebakin's work was the first attempt to accomplish the parametrization of the scattering phenomena of surface materials from laboratory measurements. In addition, Kimball and Hand demonstrated for the first time the importance of surface roughness on the backscattering of light properties. They also included in their study natural surfaces such as water and snow. Measurements were made with the help of an airplane and the sun was used as the illumination source.

The most important studies of light scattering by surface materials were accomplished by Oetking (8) and Hapke and van Horn (9), who made extensive goniometric measurements of snow, rocks, and different kinds of powders. These works were the basis of the theoretical explanation of the scattering properties of the surface of the Moon. The study of Hapke and van Horn concentrated mainly on the Moon's photometric properties, whereas Oetking made systematic photometry of various kinds of powders with a selection of particle sizes. Oetking focused on the comparison of laboratory measurements and the reflectance of different parts of the Moon. His goniometer was capable of measuring phase angles of less than 1° , but operated in the principal plane only. The device was table mounted, with a constantly positioned 75 W Zenon arc lamp as light source and the detector, a photomultiplier, at the end of a rod. At the other end was a corotating sample tray with a mirror above it inclined at 45° . Because the detector was placed under another semitransparent mirror at 45° , it was also possible to measure samples at zero phase angle. Oetking measured extensively phase curves of different types of rocks, aluminum oxide, magnesium oxide, magnesium carbonate, small spheres, and even granulated sugar. The particle sizes were accurately measured, making this set of measurements an excellent example of a controlled and repeatable experiment.

The measurements of snow surfaces by Knowles Middleton and Mungall (10) have been important in explaining the photometric results of the bright and icy objects of the solar system. The aim of this study was to investigate the specular reflection of different kinds of snow surfaces. The smallest detectable angle was 5° . Thus the opposition spike could not be detected. They concluded that below an angle of incidence of 45° diffuse reflection dominates for most of the snow surface. With angles greater than that, the specular reflection is more profound.

Instruments for these types of goniometric measurements were usually made according to the purpose of the study so there was no standard way to build the instrumentation. This is still the case, as we shall see later in the section dealing with the remote sensing applications of goniometers. Sometimes, the instruments were portable [e.g., Knowles Middleton and Mungall, (10)], whereas others were fixed in the

laboratory. The original aim of the studies may have been rather restricted, and so the instruments are far from multipurpose. Also for most instruments, the financing seems to have been rather low, and therefore they were generally suited only for restricted purposes in a limited time.

Goniometric measurements by van Diggelen (11) were of great importance in understanding the reflection of the particulate surface of the Moon. The aim of the measurements was to compare the reflectivity of the Moon to terrestrial volcanic ash samples.

Egan (12) made extensive goniometric measurements of porous materials. The main purpose of his study was to understand the polarimetric properties of materials, particularly from Mars. The importance of his work is in establishing the albedo-polarization rule of the dark particulate surfaces, which is a useful tool in determining the radiometric sizes of atmosphereless objects. The method is based on the dependence of a negative polarization of the surface porosity of the object. This relationship is one of the major methods to determine the albedos of asteroids. The goniometer designed by Egan used two fixed photometers at viewing angles of 0° and 60° . The collimated light source could be rotated. The phase angles were limited to a range of 40° to 130° . Egan used tilted mirrors to produce polarization of light.

Other researchers have measured the polarization of a variety of targets in the principal plane using a goniometer with 1.2 m arm and a rotating Glan-prism to have an effective way to measure the degree of polarization (13). These basic studies of planetary materials have been successfully continued using a goniometer designed at Deutsche Forschungsanstalt für Luft- und Raumfahrt (DLR) of Berlin, Germany (14), which was used mainly to support space missions such as NASA's *Mars Pathfinder*.

Another interesting device used to measure the backscattering range of small phase angles is a type of microscopic goniometer (15). The measurements were used as a reference during the introduction of the coherent backscattering mechanism. The goniometer applied can reach all possible angles including the backscattering direction. This device has been deployed for the comparison of the scattering of bright materials with the observations of bright (icy) solar system moons. Recently, Piironen et al. (16) have published a series of goniometric measurements of snow at very small phase angles. The results show that the degree of backscattering depends on the type and amount of impurities in the snow.

Small particle goniometers have been widely used for basic research in the Free University of Amsterdam (17). Their instrument is based in the flowing particle stream and can measure the full Muller matrix (18). The Muller matrix explains the conditions of light scattering including polarization and directional information and is an extension of the Stokes four-element vector to a 4×4 matrix. Stokes parameters are used to describe the polarization of electromagnetic radiation. The activity has been recently concentrated on the study of micron- and submicron-sized particles of silt and algae in water. Another ingenious goniometer for small particle scattering measurements is designed by Sasse in DLR, Stuttgart, Germany (Fig. 2). The device uses fiber optics to measure the full half circle of scattering angles at the same time of a single particle inside an electrostatic levitator (19). This instrument has been used for scattering measurements of fluidized bed particles for improved solar power plants and meteoritic

Figure 2. A small particle goniometer at DLR, Stuttgart, Germany.

particles in the size range from a few tens to a few hundreds of micrometers.

REMOTE SENSING

Most of the earth's surfaces reflect varying amounts of electromagnetic radiation in different directions. Unless a surface is reflecting isotropically, any change of the viewing or illumination directions has an impact on the spectral reflectance signature in remote sensing imagery. Varying illumination angles are caused by changes in the latitudinal coordinates in a global remote sensing data set or by seasonal and diurnal effects in a multitemporal approach. Viewing angle geometry is influenced by topographical effects, by the extent of the sensor's field-of-view, or by actively changing the view direction in pointable sensors. To make correct measurements of the total reflected flux, the earth's surface must be observed from many directions using air- or satellite-borne detectors. The directional reflectance characteristics or the amount of solar radiation scattered from a surface in a given direction provides important information about the surface characteristics. Many earth-observation satellite instruments today look only vertically downward at the earth's surface, but in the near future a highly increased amount of data from sensors with off-nadir capability will become available primarily from NASA's spaceborne sensor MISR (20). In order to apply remote sensing data to land use change and ecologically relevant studies within NASA's Earth Science Enterprise and other programs, bidirectional ground reference data must be widely available. A wide variety of bidirectional reflectance models have already been designed to use the multidirectional information effectively with these remote sensing data. However, there is still a lack of bidirectional ground reference data to adequately validate the remotely sensed data and the various models.

Reflectance, BRF, and BRDF

Bidirectional reflectance factor (BRF) and bidirectional reflectance distribution function (BRDF) are the key parameters addressed in goniometric measurements of reflected radiance. The bidirectional reflectance factor R is the ratio of radiant flux $d\Phi_r$ reflected from a target to the flux $d\Phi_{rid}$ reflected from a lossless isotropic (Lambertian) surface for a given

Figure 3. Concept and parameters of BRDF.

illumination-viewing geometry $(\theta_i, \phi_i; \theta_r, \phi_r)$ and wavelength (λ) :

$$R(\theta_i, \phi_i; \theta_r, \phi_r; \lambda) = d\Phi_r / d\Phi_{rid} \quad (\text{dimensionless})$$

The bidirectional reflectance distribution function f_r as defined by Nicodemus et al. (21) is the fraction of the radiance $L[W \cdot m^{-2} \cdot sr^{-1} \cdot nm^{-1}]$ of the incident irradiance $E_i[W \cdot m^{-2} \cdot nm^{-1}]$ from direction θ_i, ϕ_i reflected into a specific direction θ_r, ϕ_r (Fig. 3):

$$f_r(\theta_i, \phi_i; \theta_r, \phi_r; \lambda) = \frac{dL_r(\theta_i, \phi_i; \theta_r, \phi_r; \lambda)}{dE_i(\theta_i, \phi_i; \lambda)} \quad (sr^{-1})$$

Assuming isotropic irradiance and BRDF within designated solid angles, R and f_r are interrelated by

$$f_r(\theta_i, \phi_i; \theta_r, \phi_r; \lambda) = \frac{R(\theta_i, \phi_i; \theta_r, \phi_r; \lambda)}{\pi}$$

It might be confusing that BRDF is not defined as a ratio of equal units although dL_r and dE_i are both clearly directional quantities. The reason is found in the diffuse reflection that causes the small, but finite incident radiant flux to be reflected in infinitesimally small parts in all directions over the hemisphere. It seems appropriate therefore to produce a dimensionless quantity only when all "parts" of dL_r reflected over the hemisphere have been integrated before taking the ratio of dL_r to dE_i . This however contradicts the bidirectional concept of the BRDF.

Both R and f_r are intrinsic properties of the reflecting surface and are mainly driven by the reflection properties of the material, the surface structure, multiple scattering, and mutual shadowing effects. Because of the directionality, BRF and BRDF expose values between 0 and infinity. Values over 1 are achieved in peak reflectance directions such as the specular spot of a metallic surface, where the reflected flux in a single direction is much higher than the flux reflected from a corresponding ideal diffuse (Lambertian) reflector. Hemispherical reflectance ρ , however, only exposes values between 0 and 1, as a result of the conservation of energy. ρ is defined as the ratio of total hemispherical incident Φ_i and reflected Φ_r radiant flux:

$$\rho = \frac{\Phi_r}{\Phi_i}$$

Figure 4. BRDF of a grass lawn at 675 nm wavelength acquired with the FIGOS field goniometer under 35° sun zenith angle.

For most natural and man-made surfaces bidirectional reflectance factors vary significantly for different view and illumination angles. Only very few, highly homogeneous and fine-structured objects like gypsum sand or reference panel material expose nearly lambertian (i.e., completely diffuse reflectance characteristics). Vegetation surfaces for example show a strong backscatter component with a peak reflectance in the direction of illumination, called hot spot (Fig. 4). Mirroring surfaces like metals and some natural surfaces, such as ice and weathered snow, expose distinctive high-reflectance values in the forward scatter direction related to the specular spot. Other materials like concrete exhibit a mixture of forward and backscattering components (Fig. 5). In general, BRDF effects are most prominent in the principal plane where the source of illumination, sensor, and target surface are aligned in one plane. In the plane perpendicular to the principal plane, bidirectional effects are least pronounced.

BRF and BRDF can only be approximated and not actually measured because by definition an infinitesimally small sensor

Figure 5. BRDF of a concrete slab at 675 nm wavelength acquired with the EGO laboratory goniometer under 35° illumination zenith angle.

field-of-view would be required. In practice, BRDF values are derived from goniometric measurements by dividing radiances L measured with a small aperture radiometer by the hemispherical irradiance E_i determined from calibrated reference panels. BRF values are likewise obtained by the ratio of fluxes $d\Phi_r$ and $d\Phi_{id}$ measured in small solid angles with a goniometer-mounted radiometer. For a full characterization of a BRDF, an infinite number of measurements would be required. For practical reasons, only a limited number of sample points are measured over the hemisphere, which in most cases are regularly spaced with the help of a goniometer. The BRDF is then derived from these sample points using various modeling techniques.

Spectral Ranges

Most of the goniometric measurements in the optical domain have been performed in the reflecting part of the spectrum between 300 and 2500 nm (e.g., EGO, FIGOS, and PARABOLA, which are described later). In the thermal infrared region relatively few data have been acquired using goniometric devices for remote-sensing applications. Thermal infrared studies revealed a rather high dependence of measured infrared temperatures on view zenith angles. Sun-illuminated parts of a plant canopy were found to be considerably warmer than the shaded components. Kimes et al. (22) found temperature differences as great as 13°C when changing the view zenith angle from 0° to 80° which were a function of canopy structure and vertical temperature distribution. Leaf temperature measurements by infrared emission at different detection angles have also been made using the FEBO spectrogoniometer (2). Goniometers have also been used in the past with Light Detection and Ranging (LIDAR) systems at the Joint Research Centre, Ispra, for the remote sensing of air pollution and in particular for the mapping of smoke plumes (23). Another unique goniometer system installed at the Joint Research Centre, Ispra, is the EMSL facility, which operates in the Radio Detection and Ranging (RADAR) domain and is described in more detail later.

Goniospectroscopy

With the tremendous increase of spectral bands in remote sensing devices in recent years, a need for hyperspectral ground reference data has arisen. Most of the BRDF data sets available today however lack a high spectral resolution. Only recently have hyperspectral BRDF data, acquired with the EGO and FIGOS goniometers, been analyzed (24). In these studies, a strong wavelength dependence of BRDF effects was found for vegetation canopies, mainly caused by multiple scattering effects as a function of leaf optical properties. The wavelength dependency is best observed in an erectophile (i.e., vertically structured vegetation surface such as a grass lawn), which exposes strong BRDF effects resulting from the gap structure of the canopy. Multiple scattering is particularly strong in the highly reflecting near-infrared range, and to a certain degree in the green part of the spectrum, and equalizes effectively the hard contrast between shaded and sunlit canopy particles. In the blue and red chlorophyll absorption bands, however, multiple scattering is low, and the canopy heterogeneity becomes dominant. As a consequence, the BRDF characteristics of a vegetation canopy are more isotropic in the near-infrared and the green range than in the blue and red range. Similar effects can also be observed in the mid-infrared range.

EXAMPLES OF GONIOMETERS USED IN REMOTE SENSING

Both laboratory (25) and field goniometers (26) have been developed and deployed for remote sensing applications, mainly addressing the reflecting range of the electromagnetic spectrum between 300 nm and 2500 nm. Out of the many goniometric systems recently developed, four significant state-of-the-art examples (EGO, FIGOS, PARABOLA, and EMSL) are described here.

EGO

The European Goniometric Facility (EGO) is operated by the Space Applications Institute of the Joint Research Centre, Ispra, Italy. It was constructed and assembled under custom design in a specialized workshop equipped with machinery to build and work large circular rails and arcs with a precision of 0.1 mm (27). The laboratory-based system allows the independent positioning of a light source and a detector anywhere on a 2 m radius hemisphere centered on a target, allowing bidirectional reflectance measurements under controlled laboratory conditions. To reduce light scattering, the goniometer is painted black, and accommodated in a special black laboratory featuring light-absorbing rubber floor material. The main support structure is made from a strong 10 cm double T angle iron. It consists of two horizontal circular rails of 4.4 m and 4.8 m diameter on which two vertical arcs, mounted on motorized sleds, rotate (Fig. 6). The outer arc supports the light source, and the inner arc holds the detector. In its most recent configuration, both arcs cover 90° on the vertical plane. The system is mechanically centered on the ceiling and the floor of the laboratory and weighs about 700 kg. Each arc supports a mobile sled that can displace a detector and a light source of up to 15 kg weight each. The vertical arcs are mounted 240 mm out of axis in such a way that both the source and the detector can reach the zenithal position and that a minimal distance between the source and the detector can be achieved. Another important characteristic is that the origin of the arcs, corresponding to the horizontal plane crossing the center of the hemisphere, is 280 mm above the mechanical plate on which the target is placed, thus allowing measurements at grazing angles. Microswitches and user-set software limits prevent rotation of the arcs beyond certain points, thus reducing the risk of mechanical damage resulting from collision.

Figure 6. The EGO goniometer installed at JRC, Ispra, Italy.

The EGO goniometer is equipped with an automated high-precision target tilt and rotation platform that can tilt and rotate targets with a precision better than 0.001°. The target can be rotated on a full circle, whereas the tilting is limited to an arc of 60° at a velocity of ~0.2°/s. This capability, although exceeding most remote sensing requirements, can be used for instance for targets with a row structure or for those where the specular reflecting component is of particular interest. The targets, which can be up to 1 m × 1 m in dimensions and can weigh up to 7 kg to 8 kg, are precisely positioned by means of small HeNe lasers. The four angular movements of the detector and the light source are realized by precision stepping motors with a resolution of 0.01° and an angular positioning accuracy of ±0.1°. Each stepping motor is equipped with an encoder. The angular velocity on the azimuth rail is 1°/s and on the zenith arcs 0.5°/s. All movements of detector, light source, and platform are controlled by a PC-based custom designed EGO monitoring system software, which is able to handle all experimental and measurement data. The control unit can be operated in manual or batch modes, allowing automated performance of bidirectional reflectance measurements. Two color charge-coupled device (CCD) TV cameras help to capture the experiment set up for future reference. Some of the currently available spectroradiometers used as detectors are the GER IRIS, Spectron Engineering SE590, and the ASD FieldSpec-FR. The system is also equipped with a high-resolution CCD camera. A series of calibrated polytetrafluorethylene (PTFE) panels are available as reference standards being very close to the ideal white diffuse lambertian reflector. Depending on the experiment purpose, various lasers and voltage-stabilized halogen lamps can be used as light sources. It is also planned to use natural light as an illumination source in the future thus enhancing the potential of the EGO goniometer. This versatile facility is currently being used by several European research groups involved in remote sensing applications.

FIGOS

The RSL Field-Goniometer System (FIGOS) was built by Willy Sandmeier at Fa. Lehner & Co AG, Gränichen, Switzerland, in cooperation with the Remote Sensing Laboratories (RSL) at the University of Zurich, Switzerland (28). The planning and construction required about 700 working hours. FIGOS is a transportable field goniometer that is operated with a PC-controlled GER-3700 spectroradiometer covering the spectrum between 400 nm and 2500 nm in 704 bands with a resolution of 1.5 nm (400 nm to 1050 nm) and 8.4 nm (1050 nm to 2500 nm), respectively. FIGOS consists of three major parts: a zenith arc, an azimuth rail of 2 m radius each, and a motorized sled with the spectroradiometer mounted (Fig. 7). FIGOS allows the acquisition of hyperspectral BRDF data under natural light conditions for a wide field of applications such as providing ground reference data for pointable remote sensing devices and BRDF model validation efforts. The technical design and the dimensions are similar to the EGO goniometer, but all parts are made of black-coated aluminum resulting in a total weight of only 230 kg. The complete goniometer system is stored and transported on a trailer with a specifically designed interior, allowing fast and convenient access to a field site. The construction of the zenith arc follows the technique used for cranes providing a high stability in spite of the rather small weight of 48 kg.

Figure 7. The FIGOS field goniometer in action in Zurich, Switzerland.

If transported, the zenith arc is separated into two parts. The azimuth rail is mounted on sockets forming a circle. It weighs about 150 kg altogether. For transportation, the rail and its base are split into four quarters. Mounting of the zenith arc is provided by sleds interconnected on the azimuth rail and allowing a full 360° rotation. The ball-bearing of the wagons embrace the azimuth rail in a way that the zenith arc is tightly fixed even on sloped terrain. A support linking the center of the zenith arc with the azimuth rail serves as a further stabilization and helps to guide the cables. Similar to the EGO goniometer, the zenith arc is mounted eccentrically on the azimuth rail to prevent it from shadowing the target when measuring in the solar principal plane. Freely placable labels on the zenith arc allow for an automated positioning of the spectroradiometer.

The sled with the spectroradiometer mounted is driven by a 24 V dc braking motor, and a precision chain serves as a guide-way for the $\frac{3}{8}$ in. cogwheel. The motor velocity is set to 2.5°/s. By default the labels are set every 15° resulting in 11 measurements with zenith angles ranging from -75° to +75°. It is also possible to drive the sled-motor manually from a remote control unit to any desired position on the zenith arc. The positioning precision on the zenith arc is within $\pm 0.2^\circ$. The geometric precision of the zenith arc is referenced with the help of a laser moving over the zenith arc on plane ground. The deviation of the laser spot, representing the center of the sensor's field-of-view, shows values within ± 3.5 cm. It is introduced by mechanical problems in bending the aluminum profiles. The roundness of the zenith arc is nearly perfect showing deviations of the laser spot from the center within ± 1 cm between -60° and +60°. The azimuth view angle is given by a scale engraved in the azimuth basement. In its current configuration, the zenith arc is positioned manually with the help of a pointer and a brake fixing the position of the zenith arc. The azimuth arc is almost perfectly round. A laser spot pointing vertically from the center of the zenith arc on the ground moves less than ± 1 cm when the zenith arc is rotated. By default, an increment of 30° is set on the azimuth arc resulting in 6 measurement profiles, each containing 11 measurements on the zenith arc. Thus to cover the full hemisphere, 66 measurements of the target surface are needed. In addition, a Spectralon reference panel is used to determine irradiance conditions during data acquisition. A full hemisphere is covered in approximately 15 min. About 90 min are needed for the set-up of the goniometer with a team of two people.

PARABOLA

The Portable Apparatus for Rapid Acquisition of Bidirectional Observations of Land and Atmosphere (PARABOLA) is a rotating head radiometer consisting of three primary units—the sensor head, data recording unit, and a power pack. It was designed and constructed by NASA to enable fast and effective in situ measurements of bidirectional reflectance (29). The original instrument features three spectral bands (0.65 μm to 0.67 μm , 0.81 μm to 0.84 μm , 1.62 μm to 1.69 μm), and an upgraded, commercially available version (Sensit Technologies, Portland, ND) consists of seven channels in the visible and near-infrared range. The sensor elements are mounted within a motorized two-axis rotating head, which scans almost the complete sky- and ground hemispheres in 15° instantaneous field-of-view sectors (respectively 5° for the upgraded PARABOLA version) in only 11 s (Fig. 8). To document the target observed, a nadir-looking camera with a wide field-of-view lens is mounted next to the radiometer head. The roll axis scan rate provides contiguous swaths at the nadir/zenith positions, and progressively increasing overlap at other elevation angles away from the nadir/zenith position. A timing wheel optical sensor triggers concurrent electronic sampling of the voltage outputs from the detectors along the roll axis. The angular positioning accuracy is estimated to be $\pm 0.5^\circ$ as a result of wind and other factors. Unlike EGO and FIGOS, targets are scanned in a continuous helical pattern rather than focusing on a specific spot. To reduce effects of spatial inhomogeneity, the system can be moved within a site, acquiring multiple replicates which are subsequently averaged. The height of the radiometer above the canopy surface is adjusted to accommodate the heterogeneity of the target and provide representative sampling. The primary mounting device for the 4 kg radiometer head is a lightweight, collapsible boom apparatus consisting of an aluminum triangular truss that decouples as four 2 m long sections. It can be deployed using a variety of mounting platforms including tripods, large van booms,

Figure 8. The PARABOLA instrument deployed in the field.

pick-up trucks, and even tower trams and hot-air balloons. All operations of the PARABOLA system are remotely controlled by PC-based software. Data have been collected over a wide variety of surfaces and have been intensively used in the BRDF community.

EMSL

In the microwave range of the electromagnetic spectrum, the European Microwave Signature Laboratory (EMSL), also installed at the Joint Research Centre at Ispra, Italy, is another example of a state-of-the-art goniometric facility that provides unique opportunities in terms of measurement capabilities and data processing (30). The laboratory is mainly devoted to polarimetric radar measurements aimed at complementing air- and spaceborne remote sensing experiments by providing stable and reproducible environmental conditions and flexible operational modes for well-controlled experiments. Although designed to serve researchers and users in the field of land-oriented remote sensing tasks, the laboratory can be efficiently used in many different research fields as well as for industrial applications. The overall structure is formed by the conjunction of a hemispherical and a cylindrical part, both with a radius of 10 m. The height of the chamber is 15 m so that the center of the hemisphere is located 5 m above the chamber floor. In the gap between the two parts, a circular rail is mounted where two sleds carrying the radar antennas can move independently. The object under test is transported inside the chamber through a large door (5 m wide and 8 m high) by means of a target positioner moving on a linear rail. The same system allows the rotational positioning of the object inside the chamber before and during the microwave measurements with a precision of $\pm 0.05^\circ$. Both the electromechanical components and the microwave measurement system are remotely controlled by a computer.

Field Versus Laboratory Measurements

Laboratory goniometers such as EGO and field instruments such as FIGOS and PARABOLA have nearly complementary advantages and disadvantages. Field measurements suffer from an instable irradiance resulting from changing atmospheric conditions and sun positions. But they allow us to measure targets in situ and in vivo under natural light conditions and are therefore generally better suited for remote-sensing applications than indoor measurements. In a laboratory, targets are either man-made or separated from their natural habitat and can suffer from water and temperature stress introduced by the intense laboratory irradiance. Additionally, the light intensity is usually lower than in the field leading to lower signal-to-noise ratios than in the field. Compared to sun light, laboratory irradiance is often highly heterogeneous and non-parallel and may suffer from voltage variations too. Furthermore, the spectral characteristics of the irradiance differ significantly from the solar spectrum. Major advantages of laboratory measurements, however, are the control over the light source position, the nearly complete lack of diffuse irradiance, and the ability to produce data sets in very high angular resolutions. Because of their application in an indoor environment, they are constructed much more sturdily and therefore are more precise than the lightweight field instruments. Thus, calibration procedures, sensitivity analysis, and controlled model validation efforts are generally easier to perform in a laboratory, and

remote-sensing ground reference data are more adequately acquired in goniometric field campaigns. The complete calibration of a large-scale goniometer is usually a very time consuming and tedious task however, and the results are rarely entirely satisfactory (31).

CONCLUSIONS

Geometrical optics have been of great interest during the last two millennia since visual phenomena have been man's most important contact with the physical world. Goniometers, in various forms, have played a very important role in the study of these phenomena. This has recently expanded with the development of sophisticated sensors operating in other regions of the electromagnetic spectrum and by the addition of powerful computerized control systems. Intelligent robots with goniometric positioning capabilities may become commonplace in the near future and replace many of the traditional forms of goniometers. In remote sensing, goniometric measurements and modeling of bidirectional reflectance data will become increasingly important with the advent of NASA's Earth Observing System (EOS) platforms and other satellites with multidirectional viewing capability. The potential of multangular data to derive biogeophysical parameters from remotely sensed imagery is still under study. Spectral libraries of bidirectional reflectance measurements of natural and man-made surfaces are only recently being set up and will become of significant importance for remote sensing and other applications. There is considerable hope that goniometric measurements from ground, air and space will contribute to a better understanding of the earth's biosphere and give insight into global change issues such as the global carbon balance issue. In astronomy, goniometric measurements of particles and particulate surfaces also have been essential in developing models and theories of light scattering from the planetary bodies and will continue to play an important role in the years to come.

GYROSCOPES

A gyroscope, sometimes called a *gyro*, is conventionally a rigid body or wheel, spinning around an axis of rotation mounted in a movable frame. This movable frame permits the spinning wheel to tilt freely in any direction and rotate about any axis (Fig. 1).

One of the basic modes of operation and functionality of such a gyroscope can be understood by considering an airplane in which the gyroscope is mounted. In this mode of operation, the gyroscope is used as an instrument that measures the tilt and orientation of the plane. Associated with any spinning object is a quantity known as the *angular momentum*. The angular momentum is the product of the spinning body's *angular velocity* and *rotational inertia*. The angular velocity is measured in radians per second. The rotational inertia, also known as the moment of inertia, depends on the mass and geometry of the body. Conservation of angular momentum is one of the basic principles of classical mechanics. According to this principle, any body upon which no net external torque is applied maintains its angular momentum. For a rigid body under appropriate conditions, this means not only that the angular velocity remains constant, but also that the axis of rotation does not change. The function of the movable frame is to suspend the rotor in such a way that no external net torque acts on it. Thus,

Figure 1. Parts of a two-axis flywheel gyroscope. The rigid body or wheel is referred to as the *rotor*. The two rings are referred to as *gimbals*, and constitute the movable frame.

if the airplane changes its orientation by tilting in one or more possible ways, the rotor will nevertheless keep spinning with the same velocity and with its axis pointing in the same direction. The frame, which is secured to the body of the airplane, will move around the rotor freely. By measuring this motion, it is possible to determine how much the plane has tilted with respect to its original orientation.

One of the most familiar example of a gyroscope is a toy spinning top. Such toy tops are usually set in motion by wrapping a string around the axle and pulling the string. They can perform amazing tricks such as balancing at an angle on the end of a finger or pencil even if the finger or pencil is moved randomly. If a spinning top is pushed gently in one direction, it seems to prefer another, and it moves obstinately in a direction perpendicular to the original force. As another familiar example of the gyroscopic principle in action, we might mention footballs and bullets, which are given a spin while setting them in motion, to keep them stable in flight and send them straight to the target. The same principles that govern the action of gyroscopes are also observed in nature. For example, the earth behaves as a giant gyroscope as it revolves around the sun.

Most modern gyroscopes can be broadly classified into two kinds:

- Mechanical gyroscopes
- Optical gyroscopes

Mechanical gyroscopes are based on the conservation of angular or linear momentum (1). The best-known example of a mechanical gyroscope is the *flywheel gyroscope* discussed above. Some more recent mechanical gyroscopes are based on vibrating, rather than rotating, structures. These vibrating structures are in the form of a tuning fork or a membrane or some other geometry.

Although optical gyroscopes do not contain rotating or vibrating masses, they serve the same purpose as mechanical gyroscopes. Optical gyroscopes have been under development as replacements for mechanical ones for over three decades. The operation of optical gyroscopes is often based on analyzing the interference pattern of two beams of light counterpropagating around a closed path. The interference pattern is an indicator of the direction of rotation. Having very few or no moving parts, these devices are easier to maintain. They also have no gravitational sensitivity, eliminating the need for gimbals.

Whether optical or mechanical in nature, gyroscopes can be further classified into two kinds as (1) *rate gyros*, which provide a voltage or frequency output signal proportional to the turning rate, and (2) *rate-integrating gyros*, which provide the actual turn angle (2). Fundamentally, gyroscopes provide angular rate information. It is important to note that rate-integrating gyros only detect relative angular position, and not absolute angular position like a magnetic compass. Thus, they must be initially referenced to a known orientation by some other means.

Although the rate information can be reliable over long periods of time, when integrated to provide orientation output, even very small rate errors can cause an unbounded growth in the error of integrated measurements. As a consequence, a gyroscope by itself is characterized by *drift* or position errors that grow with time. One way of overcoming this problem is to periodically reset the gyro output with other absolute location-sensing mechanisms and so eliminate the accumulated error.

Gyroscopes have a wide spectrum of applications. The most important use of gyroscopes is in navigation and stabilization instruments for aircraft, spacecraft, guided satellites, missiles, large ships, submarines and other underwater vehicles, cars and other land vehicles, and robots. Some of the specific gyroscopic instruments used are high-performance attitude and heading reference systems, compasses, stabilizers (antiroll equipment), autopilots, and inertial navigation systems (INSs).

An attitude and heading reference system determines the tilts of the vehicle in different directions, so as to aid stabilization, maneuvering, and navigation. Many other gyroscopic instruments, such as the rate-of-turn indicators and the gyro horizons, help aircraft pilots know the position and motion of their plane in the air. Ordinary magnetic compasses are affected by magnetic forces caused by the rolling and pitching of a ship. Gyroscopes are used to regulate such compasses so that navigators know more accurately in what direction their craft are headed. Gyrostabilizers compensate for the rolling of ships at sea, helping restore them to an erect position. Autopilots guide vehicles towards a destination with minimum or no human intervention. The purpose of INSs is to provide position and attitude information.

Gyros find other applications in mining and surveying, the automotive industry, medicine, motion measurement systems, and pointing technology for computers.

Gyroscopes with different accuracies are demanded in different application areas. High-accuracy gyros are required for aircraft, ships, and land vehicles. Medium-accuracy gyros are suitable for less-demanding applications such as vehicles with short flight times (e.g. some missiles) and land navigation systems. Accuracy is often measured in degrees per hour (deg/h). An accuracy of 1 deg/h means that the system makes an angular drift error of one degree over one hour of operation (3). Medium accuracy is defined as a bearing drift in the range 0.1 to 1.0 deg/h; high accuracy, a drift less than 0.01 deg/h (4). For instance, a drift of 1 deg/h would be acceptable in a warhead seeker or flight control system, but would only be tolerable for a short time for standalone navigation.

The *scale factor* of a gyroscope is defined as the ratio of the desired angle or rate information to the physical output (e.g. a voltage or a frequency) of the gyro. The scale factor can be asymmetric for positive and negative rates in mechanical gyroscopes and can be a source of error. This is much less of a problem for certain optical gyroscopes.

Gyro bias is the deviation between the ideal output of the gyro and its actual output. *Gyro bias error* is defined as the difference between the true low-frequency gyro bias (with period greater than the mission time) and the calibrated gyro bias value loaded in the computer to compensate for this error. As long as this quantity remains stable and the calibrated value is subtracted from the gyro output, the compensated gyro output will be correct. One-year stability of this error to better than 0.004 deg/h is achievable (5).

Thermal gradients in the environment affect all types of gyros. Unless adequate error models are built and incorporated in the system model, such errors will also drift the output. Current systems are able to compensate for thermal drift so that the residual thermal drift rate remains under 0.004 deg/h over a wide range of temperatures (5).

Magnetic sensitivity to the earth's magnetic field or to fields created by other instrumentation nearby is another source of

error. Proper shielding enables reduction of magnetic sensitivity by a factor of 60 (5).

HISTORY

The first written record of a gyroscope is found in Gilbert's *Annalen* of 1818. In that report, a flywheel gyroscope constructed in 1810 by a German scientist named G. C. Bohnenberger is described. Instead of a wheel at the center, it had a heavy rotor that was almost spherical, supported by three gimbals. The nineteenth-century French physicist J. B. L. Foucault first used the word gyroscope in 1852 to describe a device he had built to further confirm the rotation of the earth (6). Foucault had earlier demonstrated the rotation of the earth with the pendulum known by his name. However, his gyroscope failed due to the limited technical capabilities of his time. The device was basically a wheel, or rotor, mounted on a long axle within a framework composed of gimbal rings suspended on a ligament. The Foucault gyroscope with the framework suspended on a ligament is considered the original form of the north-seeking gyro. Foucault demonstrated that the spinning wheel maintained its original orientation in space regardless of the earth's rotation. He named this instrument a *gyroscope*, from the Greek words *gyros* (revolution) and *skopein* (to view). Thus, gyroscope means *to view a rotating body*.

A Scot, R. Whitehead, first used the gyroscope in military equipment by perfecting a gyroscopically controlled torpedo in 1896. Although the ability of a gyroscope to maintain its orientation suggested its use as a direction indicator, practical applications of the gyroscope were few before the twentieth century. This was because the equipment needed to keep the rotor of large gyroscopes spinning smoothly, such as electric motors and ball bearings, had not yet been developed. At that time, also, machining techniques were not sufficiently advanced to produce precision instruments.

About 1900, more ships were being built of steel instead of wood. The magnetic compasses that had been satisfactory in wooden ships were less reliable in steel hulls. To overcome this problem, the first gyrocompass for ships was invented and patented by a German scientist and engineer H. Anschütz-Kämpfe in 1903 (6). His colleague Schuler solved the problem of filtering external disturbing motions for the first time.

One of the leading figures in the development of the gyroscope was a US scientist and inventor, Elmer A. Sperry (1860–1930), who became interested in the instrument after seeing Foucault's historic gyroscope in France. In 1909, Sperry built the first automatic pilot using the direction-keeping properties of a gyroscope to keep an aircraft on route. In 1911, he successfully demonstrated a gyrocompass on a US battleship named Delaware. The same year, he patented and marketed a gyrocompass in the United States, and one was produced in Britain soon after. The Germany navy had also introduced gyrocompasses into its fleets by 1911. Sperry continued to extend the range of instruments based on the gyroscope.

The first autopilot for ships was produced by the Anschütz Company in Kiel, Germany, and installed in a Danish passenger ship in 1916. A three-frame gyroscope was used in the same year in the design of the first artificial horizon for aircraft. This instrument indicates roll (side to side) and pitch (fore and aft) attitude to the pilot and is especially useful in the absence of a visible horizon.

In 1912, Sperry's son Lawrence Sperry invented and flight-tested an automatic pilot that used four gyroscopes to stabilize an airplane. He competed with 53 others in a competition in Paris in 1914 and won a prize for the most stable airplane. In 1918, he developed the gyroscopically controlled turn indicator for airplanes.

The British fleet made use of a Sperry gyrocompass in World War I. The Sperry Gyroscope Company (now Sperry Marine, Inc.) devised a quite effective gyrostabilizer that reduced the rolling of ships in 1915. This not only minimized damage to cargo and increased passenger comfort, it also reduced stress in the hull of the ship. This gyrostabilizer fell out of favor because of its large weight, size, and cost. It was replaced by an underwater fin-type ship stabilizer developed by Japanese shipbuilders in 1925.

The directional gyroscope and the gyro horizon, which enable aircraft to fly safely at night and in bad weather, were developed by the Sperry Gyroscope Company in 1928. The same company developed its first gyropilot flight control for modern planes in 1932. This automatic pilot was installed on Wiley Post's airplane, the Winnie Mae. The automatic pilot helped Post make the first solo flight around the world in 1933 in a little more than 7 days, 18 hours. Sperry Gyroscope Company also led the development of several other gyroscopic instruments.

The principle of operation of the optical gyroscope was first discussed by Sagnac in 1913 (7). Sagnac's interferometer experiment produced a sensitivity of 2 rad/s. However, several technological developments had to be made before it could be put into practical use. Two years after the demonstration of the helium–neon laser at Bell Laboratories in 1960, the first operational ring-laser gyroscope (RLG) was developed by Warren Macek of Sperry Corporation (8). It took about two decades to achieve accuracies of 0.01 deg/h. In the early 1980s, smaller, lighter, more reliable RLGs quickly replaced the traditional spinning-wheel gyroscopes for applications such as commercial aircraft or automobile navigation. Navigational-quality RLGs (Fig. 2) have been employed in INSS for Boeing 757 and 767 airplanes since then.

As a result of the advances in the telecommunications industry, in particular optical fiber technology, fiber-optic gyroscopes (FOGs) have emerged as a low-cost alternative to RLGs (9). A FOG was first demonstrated by Stanford University researchers Vaili and Shorthill (10) in 1976. As with RLGs, it took about two decades to develop the technology in order to achieve better accuracies (11). More mature FOG technology emerged in the early 1990s. More than half a million navigation systems utilizing FOGs have been installed in Japanese automobiles since 1987 (12).

Mechanical Gyroscopes

Gyroscopic Forces. It is well known that spinning changes the properties of a body such as a cone-shaped toy top. For instance, while the top cannot stand on its pointed end when not spinning, it can easily be balanced on its pointed end when it is rapidly spinning. Why does the spinning motion give the system stability? Most simply, because the top is "confused" about which way to tip. If it starts to tip in one way, the rotation quickly reorients the tipping motion, and a new tipping process begins. The net result of this continuing process of tipping and reorientation is that the axis of the spinning top moves

Figure 2. MK-49 ring laser gyro navigator by Sperry Marine Inc. This is a navigational quality gyroscope. (Photo courtesy of Sperry Marine Inc., Charlottesville, VA.)

uniformly about a vertical line; this is the motion known as *precession*.

The operation of a bicycle depends on gyroscopic effects. The rider must control the gyroscopic forces in order to ride the bicycle successfully. To keep the bicycle standing upright, the wheels must be kept spinning. If the rider leans slightly to one side, the bicycle does not fall over, but turns in the same direction. Bicycles show two gyroscopic effects: (1) gyroscopic inertia, and (2) precession.

Gyroscopic inertia is the ability of the spinning axle of the gyroscope to maintain the same direction, no matter how the support of the gyroscope changes. The spin axis possesses inertia in the sense that it will maintain its direction as long as the gyroscope is undisturbed and continues to spin. The inertia of a body is its resistance to any change in its state of motion. Gyroscopic inertia plays an important role in determining a gyroscope's behavior. It is gyroscopic inertia that keeps the bicycle upright as long as the wheels keep spinning. If the speed of the wheel decreases, the gyroscopic inertia gradually disappears; the axle begins to wobble and ultimately becomes unstable.

Rotors with a high speed and a concentration of mass toward the rim of the wheel display the strongest gyroscopic inertia.

The consequence of gyroscopic inertia is that if a motor-driven gyroscope is observed for several days, its axis will appear to change its direction slowly, returning to its original position every 24 hours. For instance, if the spin axis of a rotating gyroscope is pointed at the sun, the end of the axis will seem to follow the sun as it crosses the sky. This is because the gyroscope holds its original position in an inertial frame of reference while the earth turns under it, causing the apparent motion. One exception is when the spin axis points toward the polar star. Then, there is no movement of the spin axis with respect to the observer's surroundings, as the axis is parallel to the earth's axis and points towards the poles.

The second interesting property of the gyroscope is its precession capability. Precession is the tendency of the gyroscope to move at right angles to the direction of any perpendicular force applied to it. If a force is applied to the gyroscope which has a component perpendicular to its rotational axis, the gyroscope does not move in the direction of the force. It starts to rotate, or *precess*, in a direction at right angles to the applied force. When the applied force is removed, the gyroscope stops its precessing motion. Precession makes the bicycle turn a corner when the rider leans to one side. This property can be illustrated using a bicycle wheel, mounted on an axle on which it is free to rotate. At first, the axle is supported at both ends while the wheel is made to rotate rapidly. If one support is removed, the wheel and the axle will tend to fall down. In addition, a reaction will be created which opposes the falling motion of the wheel, and instead causes the axle to appear to move horizontally about the remaining support. The removal of one support actually applies a torque to the axle. If a torque is applied to a rotating body that is not along the body's axis of rotation, then the rotational axis moves in a direction at right angles to the direction of the applied force. Hence, when a downward force is applied at one end of the rotational axis of a spinning gyroscope lying horizontally, the resulting torque will cause the gyroscope to precess. During precession, the rotational axis will be moving horizontally about the point of support. The rate of precession, Ω , is proportional to the applied torque τ and perpendicular in direction (13):

$$\tau = \Omega \times I\omega \quad (1)$$

where I is the rotational inertia of the rotor and ω is the rotor spin rate. Gyroscopic precession is the key factor in the operation of the north-seeking gyrocompass discussed below.

When the spinning top is acted upon by a gravity-induced torque, the original rotational motion tries to align itself with the added rotational motion of the torque. In other words, the spin vector tries to align itself with the torque vector by chasing the torque vector.

Flywheel Gyroscopes. The main part of the flywheel gyroscope is the wheel, or *rotor*, illustrated in Fig. 1. Typical rotors employed in aircraft instruments may be smaller than 5 cm and make 35,000 rpm, and are usually made of metal or fluid. In the latter case, the fluid is enclosed within a hollow sphere inside the gyroscope and is rotated at high speed to produce the gyroscopic action.

An *axle* passes at right angles through the center of the rotor. Usually, the rotor is heavily weighted around the rim to

increase its rotational inertia. One of the most important aspects of constructing a gyroscope is to mount the rotating wheel so that it is free of all unwanted torques. If this can be achieved, the spin vector of the gyroscope does not change from its initial value and always points in the same direction with respect to an inertial frame. This way, the gyroscope can function as a good reference direction system.

If the instrument is to be used in the gravitational fields of other bodies, the torques caused by the weight of the gyroscope must be eliminated. A gyroscope used on the earth, for example, is subject to the forces and torques due to gravity. To eliminate the torques, it is necessary to hold the gyroscope with a force applied at its center of mass, which is usually somewhere near the geometrical center of its rotor. It is very difficult to mount the gyroscope at this point. Thus, in order to be free of gravity, gyroscopes are placed in a *Cardan mount*, illustrated in Fig. 1. In the Cardan mount, the ends of the axle are mounted on ball bearings in a movable frame, or ring, called an *inner gimbal*. This inner frame is supported by bearings in an *outer gimbal*. The outer gimbal is mounted on bearings in a supporting frame, or *yoke*, by bearings along a diameter at right angles to the axis of the inner gimbal. Each of these three axes passes through the center of gravity of the entire system.

The number of gimbals determines the number of degrees of freedom of the gyroscope: If two gimbals are used, the gyroscope rotor is free to move in any direction without having to move the frame. If only one gimbal is used, the motion of the rotor is restricted, and it cannot assume certain positions without moving the frame. The center point of the rotor always remains at a fixed position within the gimbals no matter what the orientation of the axle is. The difference between two and three degrees of freedom can be observed in Fig. 3.

Three-Frame Gyroscopes. Unrestrained three-frame gyroscopes have little practical use, since their spin axes are subject to tilting and drifting due to the rotation of the earth. Three-frame gyroscopes are used in the *controlled state*, where the spin axis, by small continuous or intermittent applications of torque, is made to precess so that it oscillates around a mark fixed in relation to coordinates on the earth rather than in relation to space.

While the rotor of a three-frame gyroscope is spinning, if a slight vertical downward or upward pressure is applied to the horizontal gimbal ring at the two ends of the axle, the rotor axle will move at right angles in a horizontal plane. No movement will take place in the vertical plane. Similarly, if a sideways pressure is applied at the same point, the rotor axis will tilt upward or downward. A precession or angular velocity in the horizontal plane is caused by the application of a *couple* in the vertical plane perpendicular to that of the rotor wheel. A couple is a pair of equal and opposite parallel forces.

Controlled gyroscopes fall into three categories: north-seeking (meridian), directional, and gyrovertical (horizon indicator). The north-seeking gyroscope is used for marine gyrocompasses. In the settling (or normal) position, the spin axis is kept horizontal in the plane of a meridian as described later in the section on gyrocompasses. The directional gyroscope is used in aircraft and is sometimes called a self-leveling free gyroscope corrected for drift. Its spin axis is horizontal with directional properties, but the gyroscope does not seek the meridian plane automatically. The gyrovertical has its spin axis vertical and is used to detect and measure angles of roll and pitch. All these three-frame gyroscopes are *displacement gyroscopes*

Figure 3. Three-frame gyroscope (top) and two-frame gyroscope (bottom). The number of frames determines the number of degrees of freedom of the gyroscope.

in that they can measure angular displacements between the framework in which they are mounted and a fixed reference direction, which is the rotor axis.

Two-Frame Gyroscopes. Suppose that with the rotor spinning with the spin axis in a horizontal plane, the base of the gyroscope is rotated uniformly in the horizontal plane (Fig. 3, bottom). A resistance due to the gyroscopic inertia will be felt. At the same time, the spin axis will begin to precess in the vertical plane and will continue to do so until the axis is vertical and all gyroscopic inertia disappears. If the same experiment is repeated, except that while the base is being turned in the horizontal plane, the precessional movement of the spin axis is stopped by the application of a force on the end of the shaft where it joins the gimbal ring, then the resistance to the turning motion of the hand due to gyroscopic inertia will cease to exist. The faster the base is turned, the greater the vertical downward force that must be exerted on the shaft to stop the precession. This force can be exerted by a spring arrangement [Fig. 4 (top)] or a U-shaped tube containing mercury fastened to the axis supports. This gyroscope measures the rate of change of azimuth and is used in aircraft and ships as a rate-of-turn indicator. Angular rate of roll in ships can be measured by applying the same principle. In this case, the spin axis is positioned at right angles to the fore-and-aft line and the rate of roll is measured about this line. This is illustrated in Fig. 4 (bottom).

These are velocity or *rate gyroscopes*, which must be distinguished from *displacement gyroscopes* described above. The sensitive or input axis of a rate gyroscope is at right angles to

Figure 4. Rate gyroscopes for measuring rate of turn (top) and rate of roll (bottom). In the top figure, a spring arrangement is used to exert a force on the shaft to stop the precession. The amount of force exerted is a measure of rate of turn. In the bottom figure, the spin axis is positioned at right angles to the fore-and-aft line and the rate of roll is measured about this line.

its spin axis, while with a displacement gyroscope the spin axis is directly along the input axis. For example, a north rate gyroscope and a north displacement gyroscope have their spin axes perpendicular to each other.

If the bearing mounts of the gyroscope were frictionless, no external torque would be transmitted to the rotating wheel, irrespective of the orientation in space. In practice, the bearings on which the gyroscope rotates are made with care to minimize friction. They must be assembled in windowless, air-conditioned rooms so as to eliminate dust inside the bearings, which can cause a gyroscope to fail. As an alternative to ball bearings, rotors can also be supported (floated) by a fluid or electrostatic or magnetic fields in so-called *flotation gyroscopes*. In the first case, the airtight inner gimbal is suspended in an inert fluid. Gimbal bearing friction is reduced because the buoyancy of the inner gimbal is neutral in the fluid. Flotation also increases resistance to shock and vibration. There is a diaphragm that seals the product and allows for fluid expansion as the outside temperature and/or pressure changes. Alternatively, the rotor is suspended with the aid of electrostatic fields in a vacuum to prevent any mechanical contact between the spinning ball and the outside case. In some cases, a beam of light reflected from reference marks on the surface of the rotor measures changes in orientation. Moving charges, however, produce magnetic fields and currents that interact with each other and with the earth's magnetic field, thus producing torques just as frictional forces do. Many missiles are guided by electrically suspended gyroscopes.

Since very little friction is produced in the bearings, only a small amount of power is required to keep the rotor turning.

In most instrumental gyroscopes, the rotor is driven by a small self-contained electric motor or a small stream or jet of air that blows on the rotor.

The friction between the spinning wheel and the surrounding atmosphere also produces unwanted torques on the system. Such gaseous friction can be reduced by placing the gyroscope in hydrogen or in a vacuum. Over long periods of time, these combined torques, no matter how small, change the angular momentum of the gyroscope, causing it to drift.

After frictional torques have been minimized, a gyroscope can be used to measure applied torques resulting from forced angular motion. The applied torque, acting over a time interval, affects the original angular momentum by changing either the direction of the spin axis or the magnitude of the spin. Measurement of the change in angular momentum thereby provides information about the applied torque.

Modern Spinning Gyroscopes. A number of precision-machined gyroscopes are available on the market, costing between \$10,000 and \$100,000, depending on the accuracy. There have been recent developments and updates in mechanical gyroscope technology with the advent of solid-state electronics. A miniature gyro named GyroEngine (Gyrations, Inc.) uses a conventional spin gyroscope in which motion is sensed around two independent axes using an optical sensor technique (14). The use of this technology greatly reduces the gyro's size and weight. An injection-molded, clear polycarbonate plastic is used for the housing and structural parts. Polycarbonate was selected because of its lower cost, high strength, ability to withstand a wide range of temperatures, and very good optical properties. Optical properties are important, since the optics needed for the sensor system are molded into the structure to reduce cost.

GyroEngine is a flotation-type, free-spinning, low-cost, low-power, two-degree-of-freedom gyroscope, about the size of a 35 mm film roll weighing only 40 g, that provides data in serial packets. The device is available as either a vertical gyroscope for measuring pitch and roll or a directional gyroscope for measuring yaw.

In a conventional gyroscope, rate data signals are passed in and out of the device through a series of precision slip rings. In the GyroEngine, a light-emitting diode is mounted inside the gimbal assembly and shines through a ring on the inner gimbal, which has a precision grating pattern mounted on it. A set of clear decals with printed optical diffraction gratings (moiré patterns) are mounted at four different places throughout the gimbal system. As the inner gimbal rotates, the light beam passing through the pattern on the ring is modulated in such a way that the motion of the gimbal is detected and tracked. The modulated light beam passes through the center of the gimbal bearing, where it is detected by a photoelectric diode sensor that is outside the gimbal system. The outer gimbal employs a similar optical sensing mechanism. The device reports gimbal position data digitally, eliminating the need for analog-to-digital conversion (ADC) and simplifying the electronics. The open collector outputs can readily be interfaced with digital circuits. The resulting digital signals are transmitted to a microcontroller for processing and output. The control electronics is included in the plastic housing rather than being external. The motor electronics is within the inner gimbal. Since much less signal processing is necessary, the output can be reported without delay (15).

Figure 5. The block diagram of a quartz rate sensor. An oscillating tuning fork senses angular velocity by using the Coriolis effect. The linear motion of the tines is translated into an oscillating torque. After demodulation, a dc voltage is produced, which is proportional to the rate of rotation. (Courtesy of Systron Donner Inertial Division, Concord, CA.)

The resolution of the device is 0.1 deg/rev. A typical drift rate is about 0.15 deg/s. The device costs a few hundred US dollars. Some of its advantages include reduction of the number of slip rings from six or more to two, output being digital rather than analog, data providing absolute position and direction of gimbals, and ability to report motion in real time.

Vibrating Gyroscopes

Quartz Gyroscopes. The concept of using a vibrating element to measure rotational velocity by employing the Coriolis principle has been used for more than 50 years. In fact, the idea developed long ago from the observation that a certain species of fly uses a pair of vibrating antennas to stabilize its flight.

Recently, vibrating quartz tuning fork technology has emerged for the production of microminiature, solid-state gyroscopes on a chip (16). These are similar to the mechanisms used in digital wristwatches to provide the frequency or time reference.

A basic quartz rate sensor (QRS) has essentially two components: drive and pickup as shown in the block diagram in Fig. 5. The drive portion functions exactly like a simple tuning fork: Exploiting the piezoelectric properties of quartz, an electrical signal applied to the tuning fork causes it to vibrate at a fixed amplitude. Drive tines are the active portion of the sensor, and are driven by an oscillator circuit. Each fork tine has a mass and an instantaneous radial velocity that changes sinusoidally as the tine moves back and forth. As long as the fork's base is stationary, only the drive fork vibrates as it responds to signals from an oscillator. The momenta of the two fork tines exactly cancel each other and there is no net energy transfer from the tines to the base. The amount of power required to keep the fork ringing is only about 6 μ W (17).

Another similar fork is employed as a pickup element to produce the output signal. The passive pickup tines of this fork are the sensing portion of the sensor that vibrate only when the device rotates. When the tuning fork is rotated around its axis of symmetry, the Coriolis effect causes the pickup fork to vibrate. According to the Coriolis principle, a linear motion within a rotating framework will have some component of velocity that is perpendicular to that linear motion. Thus, each tine will

generate a force perpendicular to the instantaneous radial velocity of each of the other tines according to the following equation:

$$\mathbf{F}_c = 2m\mathbf{w} \times \mathbf{v}_r \quad (2)$$

where m is the tine mass, $\mathbf{w}$ is the rotation rate, and $\mathbf{v}_r$ is the radial velocity of the tines. Since the radial velocity of the tines is sinusoidal, the resultant force on each tine is also sinusoidal, equal and opposite in direction and in phase with $\mathbf{v}_r$. Hence, the oscillating torque created at the base of the drive tine fork is directly proportional to the input angular rate. The sinusoidal torque variation causes the pickup tines to begin moving tangentially to the rotation and at the same frequency as the drive vibration. The output reverses sign with the reversal of the input rate since the oscillating torque produced by the Coriolis effect reverses phase when the direction of rotation reverses. If there is no rotation, the pickup tines will not move, indicating a zero-rotation input.

The resulting vibration (pickup signal) from this second fork can be electronically analyzed to measure the angle and intensity of movement. The signal is first amplified and then demodulated using the drive frequency as a reference. After further amplification and signal shaping, a dc signal output is produced that is directly proportional to the input angular rate. Signal-processing electronics are fairly simple and usually custom developed on chip, and included within the same package as the sensing element.

QRSs are fabricated chemically from a wafer of single-crystal, synthetically grown piezoelectric quartz material using photolithographic and chemical etching processes characteristic of the microelectronics industry and micromachining techniques (18). Hence, several thousand of these items can be mass-produced in a single batch. Dual tuning forks on a QRS are pure crystal and nearly transparent. An example quartz gyro, Gyrochip II by Systron and Donner Inertial Division, is illustrated in Fig. 6. In another device by the same manufacturer, called MotionPak (see Fig. 7), three QRSs are used in conjunction with three linear accelerometers in order to realize a six degree of freedom inertial sensor cluster.

Figure 6. The GyroChip II solid-state gyro which employs a quartz tuning fork. Several thousand of these items can be mass-produced in a single batch. (Photo courtesy of Systron Donner Inertial Division, Concord, CA.)

The main advantage of quartz gyros is expected to be lower cost of manufacturing and maintenance, which is one-third to one-half the cost of fiber-optical equivalents. Other advantages include superior reliability, design simplicity, low power consumption, small size, low weight, ruggedness, and long operating life. A conventional flywheel rate gyroscope may have 100 to 300 separate precision parts, and a fiber-optic gyro (FOG) may have 10 to 20 parts and many meters of fiber, but a quartz gyroscope has only a single part in its sensing portion. These can withstand high shocks and accelerations of up to 10,000 times the force of gravity resulting from gun or projectile launching. A typical quartz gyroscope has a 2 cm diameter, whereas a comparable fiber-optic gyro would measure 4 to 8 cm.

The typical accuracy of quartz gyroscopes is around 1 to 2 deg/min, which is comparable to that of conventional medium-accuracy rate or rate-integrating gyros. The target markets for FOGs and QRSs differ according to performance capability. FOGs have much higher accuracy than QRSs, in the range of 1 to 10 deg/h. As microelectronic gyros develop further, they will be challenging FOGs for lower-accuracy applications,

Figure 7. The MotionPak inertial sensor, comprising three quartz rate sensors and three linear accelerometers with a total of six degrees of freedom. (Photo courtesy of Systron Donner Inertial Division, Concord, CA.)

especially in single-axis configurations. However, three-axis FOGs will remain cost-competitive because in multiplexed FOG configurations, one set of electronics is shared by all three axes. On the other hand, in three-axis quartz gyros, three sets of electronics are used, so a three-axis quartz gyroscope costs as much as three times what a single axis gyro costs.

QRSs have several disadvantages compared to FOGs. Key performance parameters such as bias drift and scale factor are unstable over the long term (19). The scale factor is a measure of how accurate and stable a signal is over time. Secondly, the turn-on to turn-on bias may be large. A large turn-on to turn-on bias means that gyroscope drift has different values on one day and the next. The vibration and shock performance is usually uncertain. Part of the ongoing research is focused on improving the accuracy of quartz gyroscopes.

Hemispherical Resonator Gyroscope. The solid-state hemispherical resonator gyro (HRG) is based on the rotation-sensing properties of a ringing wine glass, first noticed by the British physicist G. H. Bryan in 1890. The modern implementation of this principle involves a gyro comprising three fused-quartz parts, a wine-glass-shaped resonator, an external forcer housing, and a pickoff housing on the unit's base. These are joined by indium solder and employ metalized thin-film electrodes and conductors. When voltage is applied to the resonator, it flexes up to 0.00025 cm and creates a low-amplitude wave that can be sensed by the pickoffs. The precession of this wave is correlated with the rotation angle. There are no bearings or surfaces in the HRG subject to wear, and the interior of the device is maintained in a high vacuum. A typical service time is expected to be 20 years with mean time between failures (MTBF) of more than 150,000 h. Precision manufacturing is critical in the operation of this gyroscope.

Murata Gyrostar. Another type of vibrating gyroscope is the Gyrostar, which is a small relatively inexpensive single-axis piezoelectric rate gyroscope originally developed for the automobile market and active suspension systems by Murata Manufacturing Company in 1991 (20). A picture of the device is provided in Fig. 8.

The principle of operation is again based on the fact that a proportionate Coriolis force results if angular velocity is applied to a vibrating object. The sensor element unit comprises a 40 mm long triangular prism made of a special substance called *elinvar* (elastic invariable metal), which is a nickel-chromium-steel alloy with a very small coefficient of thermal expansion to ensure good dimensional stability (21).

Both the excitation and the detection units employ piezoelectric ceramics. On each of the three vertical faces of the bar, a PZT-6 ceramic piezoelectric transducer is placed as illustrated in Fig. 9. The flexural resonance frequency of a triangular prism is given by (22):

$$f_n = \frac{ka}{4\pi l^2} \sqrt{\frac{E}{6\rho}} \quad (3)$$

where k is a constant, a and l are the width and length of the bar respectively, E is Young's modulus of elasticity, and ρ is the density of the bar material.

Excitation of the prism by the left and right transducers at the resonant frequency $f_n = 7.85$ kHz of the bar, perpendicular to its face, causes vibrations to be picked up by the third transducer, which provides feedback to the drive oscillator (22). The

Figure 8. The Gyrostar manufactured by Murata Electronics. This is a small, relatively inexpensive, single-axis piezoelectric rate gyroscope originally developed for the automobile market and active suspension systems. (See B. Barshan and H. F. Durrant-Whyte, *IEEE Trans. Robot. Autom.* **11** (3), 328–342, June 1995. Copyright IEEE, 1995.)

equilateral triangular prism allows the driving transducers to be configured in the direction of the compound vibration mode. The same elements can be used for both excitation of the bar and detection of the resulting Coriolis forces (23,24).

The gyroscope detects the angular rotation by measuring the differential output of the left and right transducers. If the sensor remains still, or moves in a straight line, the signals produced by the pickup transducers are exactly equal. If the prism is rotated around its principal axis, a Coriolis force proportional to the rate of rotation w about the z axis is created according to the equation

$$F_c = 2mw \times v_y \quad (4)$$

where F_c is the Coriolis force, m is the equivalent mass of the prism, and v_y is the rate of change of position of the element in the y direction. The actual rotation rate w can be determined by measuring the amplitude of the vibration at the pickup

Figure 9. The triangular prism of Gyrostar with a piezoelectric ceramic transducer placed on each of the three faces of the bar. Excitation of the prism at its resonant frequency by two of the transducers causes vibrations to be picked up by the third transducer.

transducer. As the bar distorts due to the Coriolis forces, one detector output increases while the other decreases. The differential output is amplified to yield an analog voltage proportional to the angular velocity of the vehicle around the principal axis of the device. A block diagram of the device is provided in Fig. 10. The maximum rate that can be measured with Gyrostar is ± 90 deg/s within its linear range, with a response time of 0.02 s.

The unique geometry of the Gyrostar provides better performance than tuning-fork gyros at a significantly lower price (23). On the other hand, there is still thermally induced drift due to thermal gradients within the element and the mismatches in the material thermal expansion rates at the elinvar–ceramic interfaces. An evaluation of this gyroscope and modeling of its drift error is provided in Ref. 25.

The main application of the Gyrostar has been directional control in car navigation systems by keeping track of turns for short durations when the vehicle is out of contact with reference points derived from the additional sensors. Other target applications include video camera stabilizers, position and posture control of moving objects, robotics, and controlling the direction of satellite antennas on moving objects. The cost of the device is several thousand Japanese yen.

Optical Gyroscopes

Active Ring-Laser Gyroscopes. The operating principle of the active ring-laser gyro (ARLG), which is an angular-rate sensor, is based on the Sagnac (interferometer) effect. The basic device consists of two laser beams traveling in opposite directions around a closed-loop path. In 1966, Schulz-DuBois idealized the RLG as a hollow doughnut-shaped mirror in which the closed-loop path has circular shape (26).

Conventional RLGs include a source of lasing and optical mirrors. A circulant cavity or waveguide is made out of a low-expansion, quartzlike glass–ceramic material, and is filled with a gas such as helium–neon, which acts as the lasing medium. When the gas is excited, photons are emitted and begin to circle around in the cavity in both directions. In effect, this creates two counterrotating beams of coherent laser light, which create a stationary standing wave with intensity nulls and peaks as shown in Fig. 11, regardless of whether the gyroscope is rotating or not. The interference pattern tends to stay fixed in inertial space, and the path of the light varies with the rotational motion of the gyroscope. If the gyroscope cavity rotates in the counterclockwise (CCW) direction, then the CCW-propagating beam will traverse a slightly longer path than under stationary conditions. The path of the clockwise (CW) traveling beam will be shortened by the same amount. Consequently, a phase shift results between the two laser beams, which can be monitored. The magnitude of the change in the path length ΔL is given by

$$\Delta L = \frac{4\pi r^2 w}{c} \quad (5)$$

where r is the radius of the circular beam path, w is the angular velocity of rotation, and c is the speed of light in the medium. Since the change in path length is directly proportional to w , rotational rate measurement relies on accurate measurement of the change in the path length. The invention of the laser provided the means of accomplishing this measurement. A major portion of the light impinging upon the surfaces

Figure 10. Block diagram of the Gyrostar. The differential output is amplified and phase compensated to yield an analog dc voltage proportional to the rate of rotation around the principal axis of the device.

of the mirrors is reflected by the mirrors, and a minor portion is transmitted through at least one of the mirrors. The light transmitted through is measured by a system that includes optical sensors and a data processor to permit the device to detect changes in rotational motion.

In order for lasing to occur, the round-trip beam path must be precisely equal in length to an integral number of wavelengths at the resonant frequency. Thus, the wavelengths of the two counterrotating beams must change when rotation occurs. The resulting frequency difference or beat frequency Δf , between the two beams is given by (26)

$$\Delta f = \frac{2f r w}{c} = \frac{2r w}{\lambda} \quad (6)$$

where f is the frequency and $\lambda = c/f$ is the wavelength of the beam.

A doughnut-shaped resonator cavity would be practically difficult to realize. For an arbitrary cavity, the equation becomes

$$\Delta f = \frac{4Aw}{P\lambda} \quad (7)$$

where A is the area enclosed by the closed-loop beam path and P is the perimeter of the beam path. For single-axis gyros, the closed-loop path is most often formed by aligning three highly reflective mirrors to create a triangular path as shown

in Fig. 12. Systems similar to Macek's early prototype employ four mirrors to create a square path. The mirrors are usually mounted on a monolithic glass-ceramic block with machined ports for the cavity bores and holes (27).

A modern triaxial design employs six mirrors, centrally mounted on the faces of a cube. Within the enclosed volume of the glass-ceramic block, three mutually orthogonal and independent RLGs are placed such that each employs four of the mirrors. Hence, each mirror is shared by two of the axes (28). A picture of an example triaxial gyroscope is given in Fig. 13. To avoid magnetic sensitivities, the most stable systems employ linearly polarized light and minimize circular polarization (8).

Reliability and robustness are among the advantages of ARLGs. The main disadvantage of the ARLG is a phenomenon called *frequency lock-in*, which occurs at low angular rates when the two beams "lock" together in frequency (29). As in any physical system that sustains two modes of oscillation, problems occur when the two frequencies approach each other. Energy is exchanged between the two modes and the frequencies tend to lock and become one, violating Eq. (7). This trading of energy or coupling is mainly caused by periodic modulation of the gain medium or other effects due to a very small amount of backscattered radiation from the imperfect mirror surfaces (2). The result is a small deadband region for low rotational rates, within which no output signal is observed. Above the lock-in threshold, the output converges to the ideal linear response curve in a parabolic fashion.

Figure 11. Standing wave pattern created by two counter-rotating laser beams in an idealized RLG. The interference pattern tends to stay fixed in inertial space, and the path length of the light varies with the rotational motion of the gyroscope.

Figure 12. A triangular configuration for a single-axis RLG employing dual anodes. Three highly reflective mirrors have been used to create the triangular path. (Courtesy of John Wiley & Sons, Inc., New York; adapted from Ref. 2.)

One way to solve the frequency lock-in problem is by improving the quality of the mirrors in order to reduce backscattering. A more practical technique for reducing lock-in is to use a biasing scheme to shift the operating point away from the deadband zone. This is commonly accomplished by *mechanical dithering*, where the gyroscope assembly is oscillated back and forth about the principal axis (typically ± 100 arcseconds at 400 Hz)

Figure 13. An example triaxial monolithic RLG operating at 632.8 nm. (Photo courtesy of Kearfott Guidance & Navigation Corporation, Inc., Wayne, NJ.)

by using a stiff dither flexure suspension acting like a rotary spring. Piezoelectric transducers provide the force to rotate the laser cavity block. Disadvantages of this method include increased system complexity, increased failure rate due to moving parts, and crosstalk between axes. In addition, it introduces a random-walk error increasing as the square root of the time. After the application of randomized dither, residual lock-in falls just under 0.002 deg/h and random-walk error remains between 0.001 and 0.003 deg/h^{1/2}. Hence, dithering is not suitable for high-performance systems such as those used for flight control.

Other methods of reducing the frequency lock-in include the use of extremely short-duration laser pulses (30–33), the use of techniques based on nonlinear optics (8), or removing the lasing medium and using a passive resonator as described below.

The RLG is limited by the quantum noise level due to spontaneous emission in the gain medium (34). Other sources of error include stability of the mirror's optical axis, mirror surface erosion, outgassing of epoxy material within the laser cavity, precision of path length, current, and dither control, all of which affect the gyro bias error. Yet, the ARLG provides the highest sensitivity and is perhaps the most accurate implementation to date. The main problem with the ARLG is its high cost. If the cost can be lowered, the device will be more widely used.

Aronowitz (35), Menegozzi and Lamb (36), Chow et al. (27), Wilkinson (37), and Udd (2) discuss the theory of RLG and its fiber-optic derivatives in detail. Ezekiel and Arditty provide a tutorial review of the technologies, and an extensive bibliography on earlier work (34).

Passive Ring-Laser Gyroscopes. In the passive ring-laser gyroscope (PRLG), the laser source is external to the ring cavity,

Figure 14. Block diagram of passive cavity ring-laser gyro. The laser source is external to the ring cavity, providing a solution to the frequency lock-in problem. (Courtesy of John Wiley & Sons, Inc., New York; adapted from Ref. 2.)

Figure 15. Simplified block diagram of an open-loop IFOG. A single beam of light is split, with the two parts propagating in opposite directions through the optical fiber coil. After demodulation, an analog output is produced which is proportional to the rate of rotation.

ity as in Fig. 14, providing a solution to the frequency lock-in problem. This configuration also eliminates the problems caused by changes in the optical path length within the interferometer due to variation in the index of refraction of the gain medium (27). One problem, however, is that the theoretical limit for the photon shot noise level is higher than that of the ARLG (34).

The main disadvantage of both active and passive RLGs is the bulky packaging compared to those gyroscopes based on fiber-optic technology. In addition, production of RLGs requires high-tolerance machining and clean-room assembly. As a result, the *resonant fiber-optic gyroscope* (RFOG) has emerged as the most popular of the resonator configurations (38).

Like RLGs, FOGs are angular-rate sensors based on the Sagnac effect. Basically, a long fiber-optic pathway is created and wound into coils. A single beam of light is split, with the two parts being sent in opposite directions through the optical fiber. A low-coherence source, such as a superluminescent diode, is typically employed to reduce the effects of noise (39). The primary source of noise is backscattering within the fiber and at any interfaces. Consequently, in addition to the primary mode, there are also a number of parasitic secondary modes that yield secondary interferometers (40). The limited temporal coherence of the broadband light source causes any interference due to backscattering to average out to zero, making the system sensitive only to the interference due to the primary mode (34,40). A simplified block diagram is provided in Fig. 15.

The glass fiber forms an internally reflective waveguide for the beams of light. In essence, it replaces the bulky doughnut-shaped cavity first suggested by Schulz-DuBois. A *step-index multimode fiber* comprises a core region with a high index of refraction surrounded by a protective cladding with a lower index of refraction to keep the light in the core region through total internal reflection (41). If the core diameter is much larger than the wavelength of the light, a number of rays following different-length paths can simultaneously propagate down the fiber. Such multimode operation is clearly not desirable in gyro applications. If the diameter of the core is sufficiently reduced to approach the operating wavelength, only a single mode can propagate (41). *Single-mode fiber* is employed to ensure that the two counterrotating beams follow identical paths when the gyro is stationary. The fiber is also chosen to be of the *polarization-maintaining* type, since light of different polarization states travels through an optical fiber at different speeds (9,41).

Mainly, two types of FOG exist: interferometric (IFOG) and resonator (RFOG). When the two counterrotating laser beams meet at the end of the pathway, the two beams are compared. If rotation has taken place, the two beams will differ in some way, and the difference can be detected. If this is done interferometrically, the device is called an IFOG. More than 95% of existing FOG applications employ the IFOG, although the RFOG has been becoming more widespread recently. IFOGs can be further classified as open-loop and closed-loop gyroscopes as described below.

Open-Loop Interferometric Fiber-Optic Gyroscopes. The number of fringes of phase shift introduced by gyro rotation is given by (2)

$$Z_R = \frac{LD}{\lambda c} w \quad (8)$$

where L is the length of optical fiber in the loop, D the diameter of the loop, λ the wavelength of light, c the speed of light in vacuum, and w the rotational rate. The stability of the scale factor relating the phase shift to rotational rate is dependent on the stability of L , D , and λ (34). Typically, an IFOG operates over $\pm\pi/2$ phase shift with a theoretical sensitivity of $1 \mu\text{rad}$ or less (42). Increasing L by the use of multiple turns of fiber enhances resolution by effectively multiplying the change in the path length due to the Sagnac effect by a factor N equal to the integer number of turns (2). The optimal length is of the order of several kilometers, after which the fiber attenuation (typically 1 dB/km) begins to degrade performance (34). This large amount of fiber required represents a significant percentage of the overall system cost.

For FOGs the main accuracy limit is not optics but noise in the electronic control loops. The accuracy of FOGs depends on fiber length and coil diameter used as implied by Eq. (8) above. FOGs typically operate at one of three wavelengths: 0.86 , 1.33 , or $1.55 \mu\text{m}$ (42). The shortest wavelength is optimum for a precision FOG, since it offers the greatest sensitivity. In contrast, longer wavelengths are preferable for telecommunication systems because of lower signal attenuation.

A minimum-configuration open-loop FOG consists of an optical source (such as a semiconductor diode light source), source-detector directional coupler, polarizer, coil directional coupler, and an optical-fiber coil (Sagnac ring). The source-detector coupler is not part of the Sagnac interferometer and serves mainly to provide isolation between the broadband optical source and

Figure 16. Detected intensity versus phase shift (a) and output of demodulator (b) for the analog open-loop IFOG. The symmetry of the original intensity pattern, shown in (a), does not allow distinguishing the direction of rotation. By introducing a phase shift of $\pi/2$ to the two beams, the operating point is shifted to the region of maximum sensitivity as shown in part (b).

the photodetector. When the two counterrotating laser beams meet at the end of the pathway, the fringe pattern created due to interference is inspected. Rotation of the path compresses the fringes in one direction and expands the fringes in the other direction, resulting in a changed pattern in the fiber. The intensity pattern caused by constructive and destructive interference, shown in Fig. 16, is in the form of a cosine, which is symmetric and cannot distinguish between CW and CCW rotation. The peak intensity occurs at zero rotation rate, where the sensitivity of the intensity to small changes in rotational rate is minimum. To overcome these problems, the two beams are phase-modulated to introduce nonreciprocal phase shifts (2). If a phase shift of $\pi/2$ is introduced, the operating point is shifted to the region of maximum sensitivity and the direction of output can be determined from the sign of the output (34). The return signal from the interferometer traverses the laser and is recovered by a photodetector behind the rear laser facet. This signal is distinguished from the laser signal by the bias modulation. This minimal configuration eliminates at least one directional coupler, the separate photodetector, and at least two fiber splices.

The disadvantages of this open-loop configuration are the nonlinearity of the input–output relationship, bias instability, the long length of optical fiber required relative to other FOG designs, limited dynamic range in comparison with ARLGs, and the sensitivity of the scale factor to analog component drifts/tolerances and light source intensity (43). On the other hand, it offers reduced manufacturing costs, high tolerance to shock and vibration, insensitivity to gravitational effects, quick startup, and fairly good sensitivity in terms of bias drift and random walk coefficient. The coil geometry is not critical. Therefore open-loop FOGs are more suitable for low-cost systems for low- to medium-accuracy applications such as gyrocompassing in automobile navigation, pitch and roll indicators, and attitude stabilization (44). Hitachi Cable, Ltd., Tokyo, has developed several IFOGs for a number of industrial and commercial uses such as automotive applications, mobile robotic systems, and agricultural helicopters (45,46).

A popular example of an open-loop IFOG is the Andrew AUTOGYRO®, which is a single-axis all-fiber rate sensor that includes an interface to the vehicle odometer and backup lights for use in dead-reckoning navigation (47) (Fig. 17). The device integrates angular rate data and odometry information over an interval, and combines these into a serial digital data output. The sensing element is a coil fabricated from elliptical-core, polarization-maintaining optical fiber which does not depend

on stress-inducing members and operates from unconditioned vehicle power. The signal-processing electronics are stable with time and temperature, and the unit does not need to be recalibrated. An internal temperature sensor output enables further calibration in more accuracy-demanding applications. The packaging is rugged, consisting of an aluminum housing with weather-resistant gaskets.

Figure 18. Simplified block diagram of a closed-loop phase-nulling IFOG. The output of the demodulator is passed to a servo amplifier that drives a nonreciprocal phase transducer which introduces a frequency difference between the two beams.

Analog and digital output versions are available. The analog signal is the angular rate output, whereas the digital output is the result of integration of the rate output, which can be interpreted as either the incremental angle change during the measuring interval or the average rate. A wide analog bandwidth is maintained while reducing the output data rate. All required voltages are generated internally from a single, wide-range input voltage that can be directly connected to vehicle power.

The lack of moving parts implies longer life. Among other advantages of the device are stable operation, lack of sensitivity to rotation about or acceleration along other axes, good resolution, threshold and dynamic range, resistance to shock and vibration, high reliability, ease of interfacing, and freedom from preventive maintenance.

The device can detect input rotation rates between ± 100 deg/s with a minimum detectable rotation rate of ± 0.05 deg/s.

The AUTOGYRO® is used in a continuous positioning system (CPS) costing about 3000 US dollars, comprising the AUTOGYRO® and a GPS receiver. The CPS is used in automated bus stop announcement systems and emergency vehicles such as ambulances, police cars, and fire trucks. The price of the AUTOGYRO® is under a thousand US dollars. A more detailed discussion of the AUTOGYRO® is provided in Refs. 48 and 49.

Closed-Loop Interferometric Fiber-Optic Gyroscopes. For applications demanding higher accuracy, the closed-loop FOG is more suitable, with drifts in the average 0.001 to 0.01 deg/h and scale-factor stabilities greater than 100 ppm (43). In closed-loop systems, an active torquing feedback loop into a frequency or phase-shifting element is employed to cancel the rotationally induced phase shift (2). Since the system is always operated around a zero phase shift, the gyro accuracy and drift are improved, and intensity variations in the light source and analog component tolerances have an insignificant effect (34). Closed-loop systems, however, rely on costly high-speed optical and electronic components.

A simplified block diagram of a closed-loop IFOG is illustrated in Fig. 18. The output of the demodulator is passed

to a servo amplifier that drives a nonreciprocal phase transducer (NRPT), which is typically an electro-optic frequency shifter placed within the fiber interferometer (34). The NRPT introduces a frequency difference Δf between the two beams, resulting in a fringe shift Z_F given by (2)

$$Z_F = -\frac{\Delta f L n}{c} \quad (9)$$

where n is the index of refraction and c is the speed of light. The linearity and stability of the gyro depend only on the NRPT (34).

To null out the phase shift at the detector, the fringe shift Z_R due to gyro rotation must be precisely canceled out by the fringe shift Z_F due to the relative frequency difference of the two beams:

$$Z_R + Z_F = 0 \quad (10)$$

Substituting Eqs. (8) and (9) for Z_R and Z_F and solving for Δf yields (2,34,44)

$$\Delta f = \frac{4AN}{n\lambda L} w = \frac{4A}{n\lambda P} w = \frac{D}{n\lambda} w \quad (11)$$

where A is the area of the fiber loop, N the number of turns in the loop, and P and D the loop perimeter and diameter respectively.

The gyro output Δf is thus inherently digital, as opposed to an analog dc voltage level, and also linear. However, closed-loop digital signal processing is considerably more complex than the analog signal processing employed in open-loop IFOGs.

Resonant Fiber-Optic Gyroscopes. The resonant fiber-optic gyro (RFOG) has evolved as a solid-state derivative of the PRLG described above. A block diagram is provided in Fig. 19. A passive resonant cavity is formed from a multiturn closed-loop of optical fiber. Frequency-modulated (FM) light is coupled from a laser source into the resonant loop in both the CW and CCW directions. For the case of no motion, maximum coupling occurs when the frequency of the laser during the FM sweep is

Figure 19. Block diagram of a fiber-optic ring resonator. Frequency-modulated light is coupled from a laser source into the resonant loop in both directions. The output coupler samples and detects the intensity of the energy in the loop. (Courtesy of John Wiley & Sons, Inc., New York; adapted from Ref. 2.)

such that the perimeter of the loop is an integral multiple of the wavelength (38). If the loop is rotated, the path lengths for the two beams will no longer be equal and the resonant frequencies shift accordingly. The output coupler samples and detects the intensity of the energy in the loop. The demodulated output at the detectors will show resonance peaks separated by a frequency difference of Δf given by (38)

$$\Delta f = \frac{D}{\lambda n} w \quad (12)$$

In practice, the frequency of the laser is adjusted to maintain resonance in one direction, and an electro-optical frequency shifter is employed to drive the other direction into resonance (44). This results in a frequency shift twice that induced by the Sagnac effect.

Advantages of RFOG are high reliability, long life, quick startup, and light weight. It requires 10 to 100 times less fiber in the sensing coil than the IFOG configuration. Since the optical fiber can be as short as 50 to 100 m, the size of these gyros is comparable to that of a spool of thread. RFOGs are limited by the same shot-noise level as IFOGs (38). According to Sanders, this is due to the fact that light traverses the loop multiple times, as opposed to once in the IFOG. Two disadvantages are the need for a highly coherent source and the need for extremely low-loss fiber components (43).

Fiber-Optic Gyroscopes. Currently, RLGs are used for navigation applications requiring high accuracy, whereas FOGs are used for medium-accuracy applications such as in motion sensors. FOGs have certain advantages over RLGs. The latter rely on an active source of lasing for their operation and are very expensive to manufacture. FOGs do not require a coherent source, and their operation does not depend on a high-performance cav-

ity, significantly reducing manufacturing costs (50). The mass production price of FOGs is estimated to be one-third that of comparable RLGs. Utilization of optical fiber in FOGs provides considerably greater ruggedness. Among other advantages of FOGs are light weight, low power consumption, small size, potential for mass production, little or no lock-in, no plasma flow problems, no critical mirror fabrication or aging problems, smaller number of parts, absence of mechanical moving parts (which makes them durable), and high resistance to environmental influences. These gyros are immune to electromagnetic interference and can withstand large accelerations (42). An excellent treatment of the features, advantages, and disadvantages of RLGs versus FOGs is provided by Udd (2).

Typical drift rates are 0.01 deg/h (3). One similarity between RLGs and FOGs is that in both it has been relatively easy to achieve low performance, but much research has been needed to improve the performance to 0.01 deg/h levels. FOGs have been replacing RLGs in many civil and military applications, especially those with less demanding drift rates of approximately 1 deg/h. Accuracy has been the main disadvantage of FOGs when compared with mechanical gyroscopes and RLGs. Within a few years, however, FOGs are expected to achieve comparable drift rates to RLGs. Target values for precision FOGs are 0.001 deg/h drift rate, 0.0005 deg/h^{1/2} random walk, 5 ppm scale factor, and 500,000 h stability (51).

Miniaturized Gyroscopes on Chip. A number of products combining integrated optics and fiber optics have been developed recently. The cost of medium-performance FOGs of accuracy range 1 to 10 deg/h can be reduced by using an integrated optoelectronics module as the key component. The processes for fabricating the integrated optics components are similar to the batch processes used by the semiconductor industry to mass-produce integrated circuits. In addition, this technology allows

the use of inexpensive telecommunications optical fiber for the fiber coils. Such systems comprise a light source, its driver, a detector, a filter, an ADC, and an integrated optics coupler. Typically, all of the optical components are integrated optics, except for the fiber coil, light source, and optical detector–preamplifier and depolarizers.

The coils are mounted on a chassis along with the other components. The light source is typically a superluminescent diode or an edge-emitting LED, similar to those used in short-range telecommunications. These light sources have short coherence lengths and can be efficiently coupled into the core of a single-mode fiber. The low coherence is important for minimizing optical reflections and other disturbances that can affect performance and reliability. The fiber-optic couplers (normally 2.5 to 5 cm) and a phase modulator (normally 0.6 to 2.5 cm), when integrated, fit on a 2.5×2.5 cm integrated optics chip.

These optoelectronic chips are available in single-, dual-, and three-axis configurations for medium- and high-accuracy applications with bias performance in the 0.01 to 10 deg/h range. If the gyro is multiaxial, many of the optical and electrical components can be time-shared between the axes, resulting in significant reductions in cost, size, weight, volume, and number of parts. For example, a single chip is produced that allows all gyros to share a single laser diode, eliminating the need for three separate laser diodes. The reduction in the number of parts has the additional benefit of operation without mechanical gyro errors. An all-fiber gyro is less accurate than a fiber–integrated-optics gyro.

Many such devices incorporate intelligence on chip, and employ application-specific integrated circuits (ASIC) for operation, eliminating the need for a digital-to-analog converter (DAC). On-board processors take care of data handling, temperature compensation, scaling, and filtering. Such a chip can be designed with an operating wavelength between 630 and 3200 nm.

Optoelectronic gyroscopes can give rate outputs for angular accelerations up to 300,000 deg/s² and can withstand 30g shocks from six directions. Typical packaging volume is 100 cm³, and typical power consumption is 2 W.

In 1993, Hitachi Cable developed a business-card-size FOG, which integrates an optical coupler, polarizer, detector, and other components into an optical integrated circuit chip (52). The integrated circuit comprises a Y-branch glass optical waveguide and two phase-shift modulators. It connects a signal-processing circuit, sensing coils, and a fiber coupler to make up the phase-shift modulation gyro. The device is mainly used in car navigation systems and costs less than 10,000 Japanese yen.

Another device by Hitachi, named GyroAce V, which measures $80 \times 80 \times 35$ mm, is an analog-output gyro that uses a polarization surface protection optical fiber, which is not affected by temperature and vibration. The response speed of the device is 1 ms, the operating temperature ranges from -30 to 75 °C, and the price is about 200,000 Japanese yen.

The trend of the technology is towards greater integration, resulting in a gyro on chip in which the sensing element and the electronics to analyze it will be included in a single piece of silicon of size 1 cm², mass-produced with very low cost. One problem is the development of pigtail techniques (procedures to connect fiber to the integrated chip). This is challenging due to the alignment required. It is particularly important for higher-

accuracy (0.01 deg/h) FOGs. When polarization-maintaining fibers are employed, the major axes of these fibers need to be precision-aligned with the polarization axis of the waveguide and the light source.

Nuclear Magnetic Resonance Gyroscopes

Certain particles such as electrons, protons, neutrons, and nuclei intrinsically possess angular momentum. Employing this angular momentum as the basis for a gyroscope has long been considered, and such instruments have been suggested (53). All approaches suggested so far are based on nuclear magnetic resonance (NMR), where a net nuclear magnetization is established by some means (54).

The precession of the net nuclear angular momentum is observed in an applied magnetic field H_0 , from which rotation information is deduced. The frequency of precession about H_0 (the Larmor frequency) is proportional to the magnitude of H_0 : $w_0 = \gamma H_0$. The constant γ characterizes the particle used. If the frame is rotating at an angular rate w_r , then the observed frequency will be shifted: $w = \gamma H_0 - w_r$. For typical values of w_r for a practical navigational gyro, use of this equation would require very precise knowledge of H_0 .

Using two particles with different spins in the same magnetic field, two different Larmor frequencies w_1 and w_2 can be observed. The two unknowns, the magnetic field and the rate of rotation, can be found by solving the following pair of equations:

$$w_1 = \gamma_1 H_0 - w_r \quad (13)$$

$$w_2 = \gamma_2 H_0 - w_r \quad (14)$$

Any method based on these equations relies upon the constancy and knowledge of the gyromagnetic ratios γ_1/γ_2 . This dependence can be eliminated by the use of two magnetic fields in opposite directions and a resonance cell containing both kinds of nuclei in each magnetic field (5).

Factors characterizing the performance of an MRG are noise on the angle output, angle random walk, and bias effects. The drift rate is approximately a few hundredths of a degree per hour. Research on the development of this type of gyro is ongoing (55,56).

APPLICATIONS

Ships and Aircraft

Gyrocompass. A gyrocompass is an instrument that is used in ship or aircraft navigation to provide a fixed reference direction by pointing toward true or geographic north. The device is basically a special configuration of the rate-integrating fly-wheel gyroscope, employing a gravity reference for the north-seeking function. A compensated magnetic compass indicates magnetic north, which is different than true north. A gyrocompass, however, when properly adjusted, can be made to indicate true north. A gyrocompass is more reliable than a magnetic compass because it is not affected by magnetic disturbances such as those due to the steel hull of a ship. The gyrocompass is not dependent on the magnetic field of the earth and should not be confused with gyromagnetic compasses such as the Gyrosyn Compass described later.

Figure 20. MK 37 VT Digital Marine Gyrocompass by Sperry Marine Inc. (Photo courtesy of Sperry Marine Inc., Charlottesville, VA.)

Marine Gyrocompass. Almost every large ship carries at least one master gyrocompass installed in its own gyro room. An example is shown in Fig. 20. A transmission system links the master compass to *repeaters*, which are used on the ship for steering, positioning, and course recording. A marine gyroscope can take a number of different forms, all of which make use of the principle of the gyroscope and the pendulum. In its simplest form, the instrument consists of a rapidly spinning wheel, driven by a motor, and suspended so as to function as a pendulum and to respond to the earth's gravity. It is a three-frame gyroscope with its spin axis horizontal. As the earth rotates, the gyroscope finds an equilibrium position with its axis of spin parallel to the local meridian—that is, the axis assumes a north–south orientation. The gyrocompass incorporates damping features to control its motion as it aligns itself with the local meridian. It also needs to be compensated for the rolling, pitching and other motions of the ship on which it is placed.

In another form of a gyrocompass, a gimbal ring is attached to a support rod extending from the diameter of the ring. The axis of the spinning wheel and the support rod are perpendicular to each other. In most pendulum suspensions, a knife-edge is used as the top support point, restricting the motion of the pendulum and placing unwanted torques when a twist occurs. In this case, a ball floating in mercury is employed so that pendulum motion can take place freely in any vertical plane. This way, the support point can twist freely about a vertical line without placing an unwanted torque on the gyroscope pendulum.

In order to understand the north-seeking (or meridian-settling) property of the gyrocompass, consider a gyroscope at the equator whose axis is lying along the east–west direction. Since the gyroscope is supported as a pendulum, the support point, the center of mass of the gyroscope, and the center of the earth tend to lie along the same vertical line. However, as the earth rotates, the vertical line sweeps through space along the

equator. The gyroscope cannot maintain its initial orientation due to gravitational forces. A torque, or twist, is impressed on the gyro, with the torque vector lying along the north–south direction. As soon as a tilt develops, the pendulum introduces torques that precess the spin axis towards the meridian and tries to align the gyroscope axis in the same direction as the torque. The gyroscope precesses from its original westward direction until its axis also points along a north–south direction. Depending on the amount of damping, it follows a spiral with an ever-decreasing radius. When stabilized, the spin axis is maintained in the meridian plane by a precession equal but opposite to the drift at the particular latitude. Once the alignment with the north–south direction is complete, the earth's rotation cannot impress any further torque on the gyro, because the torque cannot be transmitted through the bearings of the spinning wheel when in that direction. As the ship that carries the gyrocompass continues its motion, the torque redevelops and the gyroscope realigns itself with the local meridian. A gyrocompass functions at other latitudes besides the equator also, but only the motion of the component of the vertical line that is perpendicular to the earth's axis can impress a torque on the gyrocompass. When there is no tilting effect, the marine gyrocompass will lose its directional properties and become useless. This is the case at the poles of the earth, where the vertical line is parallel to the earth's axis and no torque can be transmitted to the instrument. Thus, the sensitivity of the gyrocompass is maximum at the equator and decreases to zero as the north or the south pole is approached. Also, when a vehicle moves to the west with a speed equal to the surface speed of the earth, the gyrocompass loses its sensitivity. This device cannot be used for air navigation because this condition can easily occur in the middle and upper latitudes.

Aircraft Gyrocompass. Aircraft gyrocompasses are almost always of the magnetic type, stabilized by a gyroscope. These are based on automatically monitored directional gyroscopes spinning on a horizontal axis, in which the monitoring device senses the direction of the meridian and ensures that the gyroscope axis is maintained in this direction, pointing towards the magnetic north pole.

Gyrosyn Compass is the tradename for a magnetic compass developed by Sperry Gyroscope Company and that came into use following World War II. Unlike an ordinary magnetic compass, it is driven electrically, and it adjusts more quickly to course changes of the aircraft. The monitoring device consists of a magnetic sensing unit, called the *flux valve*, which is mounted in the wing tip or some other remote location on the plane. Any relative change between the aircraft and the earth's magnetic field results in a voltage signal in the flux valve, making allowance for variation in the direction of the earth's magnetic field. This voltage signal is amplified electronically and applied to the gyroscope to keep it pointing towards magnetic north. The device can operate repeater compasses wherever they are needed in the aircraft.

Gyrostabilizer. When its rotor is very heavy, a gyroscope can function as an actuator: a device that directly controls a vehicle. The stiffness of the rotor is used to maintain the orientation of vehicles such as spacecraft, ocean ships, and automobiles. A gyrostabilizer is a large gyroscope that counteracts the rolling motion of a ship at sea and makes travel more comfortable. The device is mounted on pedestals bolted to the ship's framework. A self-contained electric motor drives the rotor. A number of

Figure 21. A ship stabilizer with fins controlled by a gyroscope. The gyroscope is unaffected by the rolling motion of the ship. It controls the pitch of the stabilizing vanes that counteract the rolling.

ships and yachts built between World War I and World War II used gyrostabilizers, which accounted for about $1\frac{1}{2}\%$ of the entire weight of a ship. Such large gyroscopes, by themselves, are no longer used to stabilize ships, because they would have to be very large and heavy in order to control the large ships of today. The US Navy uses them only aboard Polaris missile-firing submarines.

Modern stabilizers make use of a set of fins controlled by gyroscopes as illustrated in Fig. 21. The fins extend out from the ship's hull and are operated so that the forward motion of the ship produces a tilt in one direction on one fin, and in the opposite direction on the other fin. The gyroscopes sense the vertical angular displacement and the roll velocity and provide the proper control for the fins to oppose the rolling motion caused by waves beating against the ship.

Gyropilot. The gyropilot, also called an automatic pilot or autopilot, is a device which automatically steers ships or aircraft closer to a course than a human helmsman or pilot can. The gyropilot allows more accurate navigation and economical operation. If autopiloting can be done very accurately and reliably, unmanned aerial vehicles or ships can be realized. An autopilot uses the artificial horizon and the gyrocompass to operate the mechanisms controlling the rudder, elevators, and ailerons, thus allowing the craft to fly long distances without a human pilot.

In modern gyropilots, rate detection is the principal reference, and displacement detection plays a secondary role. Basically, the gyropilot consists of three devices. Each device detects deviations of the aircraft from its proper course and attitude in one plane and generates a corrective signal to correct for the disturbances. The corrective signals are voltage displacements, which are amplified and sent to servo units, which have small electric motors that move the aircraft's controls. The controls are: rudder control for azimuth and sudden change in heading disturbances (yaw), aileron control for roll disturbance, and elevator control for pitch disturbance. First, corrective rudder control is applied to the rudder servomotor. The roll disturbance is detected by a roll rate gyroscope and a roll angle pendulum, which senses displacement. The aileron servo applies corrective action. Pitch disturbance is detected by a pitch rate gyroscope

and a pitch pendulum. The elevator servo also applies corrective action.

The gyropilot for ships controls the rudder according to corrective signals from a gyrocompass. The first automatic pilot for ships was used in the early 1920s. The automatic pilot aboard ships is often called "iron mike" or the "iron quartermaster."

Other Aircraft Instruments. In aircraft, gyroscopes are used in several other instruments which are either part of the autopilot or are used for visual reference. The three primary gyroscopic instruments fitted to the flight panel are a rate-of-turn indicator (or turn-and-bank indicator), which is simply a rate gyro; a directional gyroscope; and an artificial horizon. These gyros may be driven either by electric motors or by air jets.

The directional gyroscope forms a standard reference for the pilot and navigator, indicating in what direction the aircraft is heading. It is a three-frame gyroscope with its spin axis on the horizontal plane. As soon as tilt develops, a switch is closed between the gyroscope housing and the vertical gimbal ring, and a motor introduces a torque in the horizontal plane that causes the gyroscope to precess back toward the horizontal.

The artificial horizon, or horizon indicator, indicates the orientation of the aircraft relative to the horizon and displays the rolling and pitching motion of the aircraft, without the pilot's having to look at the ground or horizon. It consists of a three-frame gyroscope with its spin axis vertical, and automatic correcting devices to counteract the apparent motion of the spin axis around the celestial pole and any other random precessions.

Inertial Navigation (Guidance) Systems. One of the most important uses of the gyroscope is in INSs for aircraft, spacecraft, or military equipment. These depend on the inertia of an extremely precise gyroscope to keep the craft traveling in exactly the right direction. Gyroscopes are the primary source of navigation and guidance information on spacecraft, since magnetic compasses are useless in outer space and there is no local horizon to sight on. Gyros are also used to accomplish the orientation control of the accelerometers, which are key components of INSs. INSs are nonradiating, nonjammable, dead-reckoning systems.

When INSs emerged for civil aviation in the 1970s, they were so large, heavy, expensive, and costly to maintain that they were used only on very large transoceanic transports. In the early 1980s, smaller, lighter, more reliable RLG-type gyroscopes were developed, and the civil market was expanded to a greater number of potential applications such as inertial navigation of larger business aircraft.

Modern INSs require a small platform very accurately stabilized by gyroscopes. This type of platform was perfected only in the 1950s after advances in the design of air-supported bearings and flotation gyroscopes. The inertial platform is extremely small and must be stabilized to an extraordinary degree of precision. The two types of self-contained INSs are the *gimbaled* INS and the *strapdown* INS. In a gimbaled system, the gyros and accelerometers are isolated from the rotations of the vehicle so that they can be maintained in a specific orientation with respect to the earth or inertial space. The stabilized INS physically represents the inertial reference frame. This greatly simplifies the position and velocity computations and reduces the dynamic-range requirements on the gyros. In a strapdown INS, the gyros measure the full rotation rates of the aircraft and

keep track of the instantaneous orientation of the accelerometers in order to properly integrate the accelerations into velocity and position. This is done by applying control torques to the gyros, causing them to precess at precisely the same rate as the combination of the earth's rate of rotation plus the angular rate of the vehicle's position with respect to the earth. This way, two of the accelerometers are locally leveled, and the third one is kept vertical at all times. Since computation of a reference attitude matrix is required, strapdown INSs were made possible only by the advent of small and speedy digital computers (3). Most of the modern aircraft and marine INSs today are of the strapdown type. The errors caused by vehicle maneuvers and accelerations can be larger in strapdown systems. For gimbal systems, the typical gyro drift rate is 0.01 deg/h; for strapdown systems, the error is 20 to 50% worse.

If single-degree-of-freedom gyros are to be used, three mutually orthogonal gyros are required for the north, east, and vertical coordinates. If two-degree-of-freedom gyros are to be used, only two gyros need be installed. The types of gyros currently found in INSs include floated rate-integrating gyros, electrostatically supported gyros, dynamically tuned rotor gyros, and RLGs (57).

Military

Gyroscopes have also been exploited for military applications such as guiding and controlling the automatic steering mechanisms of torpedoes, missiles, and projectiles, and smart and terminally guided or precision-guided munitions for large-caliber guns (or field artillery) on tanks and howitzers. Gyroscopes are also employed underwater to steer torpedoes toward the target regardless of underwater conditions.

Many of the most accurate long-range missiles are steered by INSs using gyroscopes. Conventional three-frame gyroscopes are used in ballistic missiles for automatic steering together with two-frame gyroscopes to correct turn and pitch motion. German engineers made significant advances in this field during the 1930s, and their knowledge was later used in the design of guidance systems for the V-1 flying bomb, a pilotless aircraft, and the V-2 rocket, an early ballistic missile. Most tactical-grade missile systems require an accuracy of 1 deg/h.

The ability of gyroscopes to define direction very accurately, when used in conjunction with sophisticated control mechanisms, led to the development of stabilized gunsights (or predictor sights), bombsights, antiaircraft systems, and platforms to carry guns and radar antennas on ships during World War II. The gyroscopic gunsight revolutionized aerial gunnery for jet fighter planes that automatically aim guns, rockets, and bombs. The method of stabilization used for gun platforms is essentially the same as the principle of stabilizing an inertial platform. The gyroscopes that detect platform displacement are not as accurate as the flotation type. The sight fitted on the gun contains a rate gyroscope capable of measuring angular velocities in two planes at right angles to each other. The gyroscope is a three-frame one constrained by horizontal and vertical springs to the inner and the outer gimbal, respectively. Sometimes, variable-strength magnetic fields are employed to constrain the rotor axle in azimuth and elevation instead of a mechanical spring arrangement. The field coils for producing the horizontal component of this magnetic field are coupled to the rangefinder. The current through the vertical coils is adjusted so that the field depends on the drop of the projectiles

due to gravity. The sensitivity of the gyroscope in the horizontal plane is a function of the sighting range; in the vertical, it is a function of the gravity drop. In operating the gunsight, the gunner holds the image of a central dot over the target while the gun is automatically aimed by the gyroscope at the predicted target position when the projectile motion is completed. This way, correct aiming to direct antiaircraft guns, guns of warships, and bombs to moving targets is provided.

Automotive

Among the automotive applications of gyroscopes are antiskid braking systems for vehicles and active suspension systems. In antiskid braking systems, a single-axis yaw-rate gyroscope senses any tendency of the vehicle to spin and sends signals to the braking and steering systems to prevent skidding (20). In active suspension systems, the springs and shock absorbers of conventional suspensions are replaced with computer-controlled hydraulic units for dynamic ride control. Gyroscopes find use in such systems as yaw-rate units to provide rate data, as well as instrumenting the vehicles for crash studies.

Robotics

Control of robotic tools in space by robot arms, machine control, development of autonomous warehouse and factory robotic systems and mobile platforms, as well as rough-terrain navigation, are some of the applications that immediately come to mind.

A number of robotic systems have been described which use some form of absolute sensing mechanisms for guidance (see Ref. 5 or 58 for surveys). Such systems typically rely on the availability of easy-to-see beacons or landmarks, using simple encoder information to predict vehicle location between sensing locations. This works well when the density of beacons or landmarks is high and the ground over which the vehicle travels is smooth. In cases where the beacon density is sparse or the ground is uneven, such systems can easily lose track of their position. This is particularly a problem for vehicles operating in outdoor environments. INSs can potentially overcome this problem. Inertial information can be used to generate estimates of position over significant periods of time independent of landmark visibility and the validity of encoder information. Clearly, positions derived from INS must occasionally be realigned using landmark information, but a system that combines both inertial and landmark sensing can cope with substantially lower landmark density and can also deal with terrain where encoder information has limited value.

INSs have been widely used in aerospace applications (5,59,60) and have been only recently exploited in robotics applications, where they have considerable potential. In work reported in Ref. 61, inertial sensors were used to estimate the attitude of a mobile robot. With a three-gyro, two-accelerometer configuration, experiments were performed to estimate the roll and pitch of the robot when one wheel climbs onto a plank using a small inclined plane.

One reason that INSs are widely used in aerospace applications but not as much in robotics is simply that high-quality aerospace inertial systems are too expensive for most robotics systems. However, low-cost solid-state INSs, motivated by the needs of the automotive industry, are increasingly being made available commercially. Although a considerable improvement on past systems, they clearly provide substantially less accu-

Figure 22. A low-cost INS comprising three gyroscopes, a triaxial accelerometer and two tilt sensors, developed for a mobile robot platform. (See B. Barshan and H. F. Durrant-Whyte, *IEEE Trans. Robot. Automa.* 11 (3), 328–342, June 1995. Copyright IEEE, 1995.)

rate position information than equivalent aerospace systems. However, such systems are at a point where, by developing reasonably detailed models of the inertial platform, they can provide valuable information in many robot positioning tasks (25,62). An inexpensive INS developed for a mobile robot platform is illustrated in Fig. 22.

In a robotics context, the primary motivation has been the need to develop a system capable of providing low-cost, high-precision, short-time-duration position information for large outdoor automated vehicles and mobile platforms. In particular, the interest has been in obtaining location information for short periods when the vehicle is not in contact with any beacon or landmark information. Rough terrain, variations in wheel radius, tire slip, and body deflection cause the encoder information to be unreliable for location estimation except over very short sample intervals. Inertial sensing offers a potential solution to this type of problem.

Positioning Systems

Another system that is potentially of great value for vehicle localization is the global positioning system (GPS) (63). It is a satellite-based radio navigation system that allows a properly equipped user access to useful and accurate positioning information anywhere on the globe. The fact that an absolute identification signal, rather than a direct measurement of range or bearing, is used to compute location means that measurements are largely independent of local distortion effects. The position accuracy that can be achieved with GPS is 5 m in the military band, and 50 m in the civilian band. However, using a technique known as differential GPS, in which a separate base receiver is employed, civilian accuracy may be improved to 5 m. Although this is not as good as can be achieved using high-frequency radar, it may still be adequate for some applications. It is also worth noting that the cost of GPS receivers is remarkably low (about \$1000). In Ref. 64, integration of GPS with INS is described for precision navigation in aerospace applications. The cost of these hybrid systems has been considerably reduced due to the dramatic drop in the cost of GPSs, the expected mass-

production cost being \$15,000, about one-third the price of a comparable system using RLGs.

A hybrid INS–GPS offers important benefits, especially for military applications. The accuracy required of an INS can be relaxed significantly when used in combination with a GPS receiver. Overall system performance can be improved by fusing INS data with GPS signals to correct for inertial drift errors. Although GPS offers higher accuracy, most military planners would not want to rely solely on GPS, since the GPS satellites can be attacked by the enemy and the received signals are vulnerable to short-term interference and jamming, unlike INS. The possibility of jamming increases the requirement for inertial accuracy. For weapons, in the event that the GPS were jammed after launch, the INS must be sufficiently accurate to complete the task by itself. Many hybrid INS–GPS systems need the INS for short signal blockages that occur during aircraft maneuvering, and for navigation through clutter or adverse weather conditions. As an example, an augmented GPS-based system outfitted with 0.1 deg/h FOGs can tolerate a loss of GPS signals for 10 min and still arrive within 30 m of its intended target (12).

Although GPS is excellent for navigation, it does not sense dynamic changes rapidly enough for air vehicle flight control systems. GPS provides location data but not in real time, since it relies on satellite transmission received at certain intervals. During the gaps between satellite updates, localization by GPS is impossible.

Development of such accurate positioning systems would allow unmanned autonomous transport vehicles, seekers, and intelligent-vehicle highway systems for land navigation (65). More widespread installation of hybrid INS–GPS systems on emergency vehicles such as police cars, ambulances, and fire engines is expected in the near future.

Industry and Mining

Gyros suitable for surveying tasks were developed in Germany between 1947 and 1949. Later, the instruments were improved for practical applications. Road mappers and surveyors find gyroscopes useful in recording curves and grades. Wellbore-logging systems in oil and gas exploration have used gyroscopic devices to control the orientation of the shaft to ensure that the drilling is performed in the correct direction (66). Survey gyros are mainly employed for geodesy, subterranean geometry, surveying tunnels and boreholes in underground mine exploration, and shield excavators used in tunnel construction. Frequently, the rate gyros or gyrocompasses are designed to allow the fitting of optical measuring instruments or to allow combination with a theodolite (gyro theodolite). In these applications, gyrocompasses are preferred, since magnetic compasses would be disturbed by metal deposits. Ligament-suspended surveying gyros attain accuracies of one minute of arc within about 2 to 5 min in the absence of disturbances (57).

Other Applications

Vertical three-frame gyros with pen recorder attachments are often used to analyze rolling and pitching movements of ships and rocking motions of trains and to record the conditions of railroad tracks. With a very accurate gyro, almost every fault in the level of tracks can be detected. Other motion measurement systems that employ gyroscopes are those used in sports

training or at remote buoys for long-term recording of wave motion.

Gyroscopes are utilized as steadiers, stabilizers, and jitter/motion compensators for equipment such as hand-held video camcorders, ground cameras, lenses in satellites, binoculars, and other optical instruments. On the larger scale, gyroscopes are used to stabilize and compensate for the random motion of millimeter-wave seekers in long-range rocket systems, communication or shipboard satellites, radar-tracking antennas, antennas on remotely piloted vehicles, and weapon platforms. They are also used for the stabilization of the line of sight in various instruments.

Geophysical applications include measurement of the earth's rotation, continental drift, and earthquakes. A recent example is a Zerodur glass RLG manufactured by Carl Zeiss (67). This gyro is capable of achieving a relative resolution of 0.1 ppm over long periods of time. This allows high accuracy in determining the fluctuations in the earth's rotation, which is of importance to geophysicists who use such fluctuations to study the earth's interior structure, continental drift, and the occurrence of earthquakes. A 1.2×1.2 m block of Zerodur glass with a thickness of 180 mm and a weight of approximately 600 kg comprises the body of the RLG. The use of Zerodur stabilizes the length of the laser beam path and guarantees the required measuring accuracy by virtue of the nearly zero thermal expansion coefficient of the material. Inside the Zerodur block, there are four 1 m long longitudinal bores for the laser beam. A closed square resonator is produced by four deflecting mirrors fitted at each of the corners of the block. The principle of operation is otherwise the same as other RLGs. The gyro is installed in a subterranean cave on the Banks Peninsula in New Zealand.

Another device for measuring the rotation of the earth, a superfluid gyroscope designed like an ac superconducting quantum interference device (SQUID), has been demonstrated by R. Packard and his colleagues at the University of California, Berkeley. In their demonstration, the metrologists measured earth's rotation with a precision of 0.5% (68). In a superfluid, fluid circulation is quantized, which can be exploited to measure tiny rotations. In the Berkeley experiment, the flow of superfluid helium through a ring-shaped vessel is interrupted by a very thin barrier containing a sub- μ m-sized pinhole. When the vessel is rotated, the helium must squirt back through the hole to maintain constant circulation in space. By monitoring the squirting, it is possible to measure the rotation of the earth.

Researchers at Stanford University and NASA have developed an experiment, known as Gravity Probe B, involving very precise gyroscopes for testing two unverified predictions of Albert Einstein's general theory of relativity (69–71). The experiment is based on measuring how space and time are affected by the presence of the earth ("the geodetic effect"), and how the earth's rotation drags space-time around with it ("frame dragging"). These effects are detected by precisely measuring tiny changes in the direction of spin of four gyroscopes. The gyroscopes will be contained in an earth satellite orbiting at an altitude of 400 miles directly over the poles. Since the gyroscopes are free from any disturbance, they provide an almost perfect space-time reference system.

Gyroscopes have also found some applications in medicine. The alignment and rotational motion-sensing properties of gyros can be used for diverse medical applications such as precise positioning of surgical instruments, analyzing back motions for

orthopedic diagnosis, orthotics, and prosthetics, and measurement of human movement and diagnosis of motion disorders. For example, measuring the tremors associated with Parkinson's disease aids in diagnosis and treatment of the disease.

Enhanced pointing technology for computers has been developed in the form of a three-dimensional mouse equipped with a very small gyroscope (the GyroEngine), which is no longer restricted to the desktop and can be operated in free space (72,73). This is useful for three-dimensional applications such as airplane design.

Other miscellaneous applications include flight simulators, flight training systems, measurement of wave motion, and development of smart tools such as carpenter's levels for instrumentation.

Ref. 74 provides a detailed literature and patent survey on gyroscopes and their applications.

FUTURE TRENDS

Current gyro technology is progressing along several fronts. On one front, traditional spinning gyros are made smaller, lighter, and more reliable. In some cases, optics is integrated with mechanics, resulting in optomechanical gyroscopes. However, new types of gyroscopes with no moving parts have greater potential importance. Conventional flywheel gyroscopes are being replaced by solid-state gyroscopes with no moving parts that are smaller, less expensive, more versatile, rugged, accurate, and reliable. Computer chips are replacing mechanical components, which wear out and are expensive to fabricate. Advances in optical fiber research and solid-state technology have a direct impact on the development of modern gyroscopes. It is expected that by the turn of the century, gyroscopes will be more widely used in the control systems of automobiles, trucks, and emergency vehicles, among many other applications.

HYGROMETERS

INTRODUCTION

The presence or absence of water vapor in air or other gas influences a vast range of physical, chemical, and biological processes. Humidity measurements are important for a wide range of industries and to some they are a critical aspect of business costs, product quality, and health and safety.

There are many different techniques for measuring humidity. The subject is also complicated by the confusing variety of ways of expressing humidity. As for other fields of measurement, a consistent and harmonized approach to humidity measurement is increasingly important, as is a common understanding of humidity terms and definitions.

Humidity is a relatively difficult quantity to measure in practice, and the accuracy achievable is not as good as for many other areas of measurement. For example, the mass of objects can be found by weighing in a typical laboratory to within 1 part in 100,000. Similarly, atmospheric pressures can often be measured to within 5 parts in 10,000. Humidity, however, can commonly be measured to only about 3 parts in 100, that is, with an uncertainty in the result of $\pm 3\%$.

To make a reliable humidity measurement at any given level of accuracy, it is necessary to use an appropriate measuring technique in a sound way. To do so, one must be able to define the measurement task, select a suitable method of measurement underpinned by reliable calibration, carry out the

measurement correctly without introducing errors, and interpret the result of the measurement.

Water in Air or Gases

The word “humidity” denotes the presence of water vapor in air or other gas. Water vapor is the gaseous form of water and can be thought of much like any other kind of gas. It is normally transparent, and makes up about one hundredth (or 1%) of the air around us.

Humidity arises in practice because, in the same way that hot water gives off steam, so water at lower temperatures—including ice—also gives off water vapor. Wherever there is water or ice, there is evaporation (or its opposite, condensation). The extent to which this happens depends on a number of factors, the most important of which is temperature. Similarly, other liquid or solid materials—most of which have some water content—will give off (or sometimes soak up) water vapor. Of course, water vapor can also be found in places where there is no liquid or solid nearby, for example, in remote parts of the Earth's atmosphere.

Air (or empty space, or any other gas) has a given capacity to absorb water vapor. This capacity depends mainly on temperature. Generally speaking, the hotter the air, the more water vapor it can hold. At any particular temperature, air that contains its full capacity of water vapor, is said to be “saturated.” The “relative humidity” of the air expresses how fully saturated it is with water vapor. A variety of other (“absolute”) measures are used to express how much water vapor is actually present (regardless of temperature or level of saturation). Definitions and explanations of the most important of these terms are given in the next Section.

Humidity Terms and Definitions. Some vocabulary specific to humidity (and other common words with specialized meanings in this context) are as follows:

Absorption (of water vapor)—retention (of water vapor) by penetration into bulk of a material

Adsorption (of water vapor)—retention (of water vapor) as a surface layer on a material

Condensate—condensed material, such as liquid water or ice

Desorption—release of adsorbed or absorbed substance

Humidity—the presence of water vapor in air or other gas. Some people use the word *humidity* to mean relative humidity only. Strictly speaking, “humidity” also refers to all kind of absolute indications of humidity. For very low humidities, other more specific terms tend to be used.

Hygrometer—any instrument for measuring humidity

Hygroscopic—tending to absorb water vapor

Absolute humidity—The mass of water vapor present in unit volume of moist air of a given temperature and pressure. SI (metric) units are grams of water per cubic meter of air (g m^{-3}). Older references may be in terms of pounds per million cubic feet (lb ft^{-6}) or in grains per cubic foot (gr ft^{-6}) or in grains per cubic foot (gr ft^{-1}). (One grain ≈ 0.0648 gram.)

Dew point (or dew-point temperature)—The temperature at which dew, or condensation, forms on cooling a gas. This is, in effect, the temperature at which air becomes

saturated in equilibrium with water. Expressed in degrees Celsius ($^{\circ}\text{C}$) or occasionally in other units of temperature (e.g., in degrees Fahrenheit ($^{\circ}\text{F}$) in the United States).

Relative humidity—The ratio of the actual vapor pressure to the saturation vapor pressure over a plane liquid water surface at the same temperature, expressed as a percentage. This is commonly understood when the term “X percent relative humidity” is used.

Saturation vapor pressure (of water)—maximum pressure of water vapor that can exist at a given temperature. Expressed in units of pressure, such as in pascals (Pa), or in non-SI units such as millibars (mbar) or millimeters of mercury (mm Hg).

Vapor pressure—that part of the total pressure contributed by the water vapor. Expressed in units of pressure, such as in pascals (Pa), or in nonmetric units such as millibars (mbar) or millimeters of mercury (mm Hg).

TYPES

In the past moisture in the air or other gas was measured by mechanical hygrometers. Today there are a number of hygrometer types available, the following being the mostly frequently used: mechanical, wet- and dry-bulb, adsorption, dew-point, impedance, piezo electric, electrolytic and optical fiber hygrometers.

MECHANICAL HYGROMETERS

In a simple mechanical type of hygrometer the sensing element is usually an organic material that expands and contracts with changes in the moisture in the surrounding air or gas. The material used most often is human hair. Other materials may be paper, animal tissues, and wood. As illustrated in Fig. 1, a bundle of hair is held under slight tension by a spring, and a magnifying linkage actuates a pointer. The usually designed operating range of this type of hygrometer is from about 4°C to 38°C . For very short periods these hygrometers may be used down to 0°C and up to 60°C . When used within the range of usual room conditions, these instruments show very little drift in their measurement over periods of a year or more, but if exposed for any length of time to extremes of humidity or temperature, a permanent change in the

Figure 1. Hygrometer that uses hair as the sensing element.

sensitive material may result. The time required to respond fully to a sudden wide change of humidity may be as much as 5 min (1).

WET- AND DRY-BULB HYGROMETERS

A wet- and dry-bulb hygrometer consists of two matched temperature sensors over which humid air is drawn. One sensor is enclosed in a porous medium (wick or “wet sock”) which is maintained wet by capillary action from a reservoir of water. Water evaporates from the wick at a rate related to the humidity of the air. The evaporation causes the wet sensor to be chilled. The temperatures of the wet and dry sensors are used to calculate the humidity of the air. Relative humidity from vapor pressure is determined by Eq. (1):

$$\text{Relative humidity (in\%)} = \frac{p_d}{p_s} \times 100 \quad (1)$$

where p_d is the actual vapor pressure of water and p_s is the saturation vapor pressure of water at the prevailing temperature and barometric pressure (2). Water vapor pressure, p_d , in air is found from the actual or dry-bulb temperature t and the wet-bulb temperature t_w using the equation

$$p_d = p' - A \cdot P \cdot (t - t_w) \quad (2)$$

where p' is the saturation vapor pressure of water at temperature t_w , P is the total barometric pressure (in the same units), and A is a coefficient established for the psychrometer. Widely recognized values of A for t_w above 0°C are:

$A = 6.66 \times 10^{-4} \text{ }^{\circ}\text{C}$ for moving air as in the Assmann ventilated psychrometer

$A = 8.0 \times 10^{-4} \text{ }^{\circ}\text{C}$ in a Stevenson screen as used by the Meteorological Office

The values of A given above yield approximate values of humidity, to which corrections can be added or subtracted, on the basis of a traceable humidity calibration. Alternatively, on the basis of a calibration of a given psychrometer, an individual value or formula for A may be assigned for that particular instrument. The use of a particular value of A is only valid if the correct conditions of air flow are provided for the instrument in question. An aspirated psychrometer with a fan for adequate air flow over the thermometers is the recommended basis for this measurement. Other approaches, such as Mason’s (nonaspirated) psychrometers and whirling (hand aspirated) psychrometer, are less successful realizations of this principle and are prone to errors, as are “home-made” psychrometers (2).

Psychrometer

The psychrometer consists of the wet- and dry-bulb thermometers. Their temperature difference (psychrometric difference) enables the relative humidity to be calculated. The basis for

Figure 2. Assmann's aspirated psychrometer (4).

calculation is Sprung's psychrometric approximate formula (3).

$$p_d = p_f - k \cdot (t_d - t_f) \cdot p \text{ in mbar}$$

t_d = the temperature of the dry-bulb thermometer in °C

t_f = the temperature of the wet-bulb thermometer in °C

p_d = the partial vapor pressure of water in mbar

p_f = the vapor pressure at the temperature of the wet-bulb thermometer in mbar

$$k = \text{constant} = 0.61 \times 10^{-3} \text{ deg C}^{-1} \text{ for water/air} \\ = 0.57 \times 10^{-3} \text{ deg C}^{-1} \text{ for ice/air}$$

We can obtain a much better result if the measured air passes by the wet-bulb thermometer with a velocity of approximately 2 m/s. In case of nonventilated air the measurement is very inaccurate. For practical measurement the Assmann's aspirated psychrometer is the most widely used. Figure 2 shows its construction which uses a small clock mechanism with ventilator (nowadays the electric ventilator) to artificially create the air flow.

Relative humidity may be determined by comparing temperature readings of wet- and dry-bulb thermometers as in Fig. 3 (4). Table 1, extracted from more extensive US National Weather Service tables, gives the relative humidity as a function of air temperature t_d (dry bulb) and the difference $t_d - t_w$ between dry- and wet-bulb temperatures (t_w = wet-bulb temperature) (5). The data assume a pressure near normal atmospheric pressure and an instrumental configuration with forced ventilation.

The psychrometer is principally suited to large spaces and medium or high humidities. The uncertainty of measurement is around $\pm 2\%$ rh to $\pm 5\%$ rh, at best.

Following are advantages (+) and disadvantages(–) of wet- and dry-bulb hygrometers:

- + Psychrometers are relatively simple, cheap, reliable, and robust instruments.

Figure 3. Psychrometric diagram for determining the relative humidity of the air from the reading of the temperature of wet- and dry-bulb thermometers.

- + They can have good stability.
- + They tolerate high temperatures and condensation.
- Some skill is usually required to use and to maintain the instrument.
- Results may have to be calculated from temperature readings (although some are automatic).
- A large air sample is required for the measurement.
- The sample will be humidified by wet-sock evaporation.
- Airborne particles or water impurity may contaminate the wick; this can and should be remedied by regular cleaning or replacement.
- Measurement can be complicated below about 10°C because of the uncertainty regarding the presence of water or ice on the wick when the temperature falls below 0°C.

ADSORPTION-TYPE HYGROMETERS

Adsorption-type humidity measurement is based on the phenomenon that a hygroscopic material gives off water according to absorption–desorption hysteresis as shown in Fig. 4 (6).

Centrifugal Method

This method is based on a well-known desorption method of relative humidity determination in alkaline solutions. In the case of cellulose, for instance, the cellulose fiber is first plunged into hydrochloric acid. With the help of centrifugation

Figure 4. Absorption-desorption characteristics. The humidity of material exposed to increasing air humidity rises according to absorption curve. The humidity of material exposed to decreasing air humidity drops according to desorption curve.

(desorption method), humidity is adsorbed from fiber, as can be seen in Fig. 4. Thus the degree of humidity in cellulose fiber can be controlled with the rate of centrifugation (7,8).

Hygrometers Based on Adsorption of Ceramic

Adsorption of gases is an important property of solid surfaces. There are probably at least two different types of adsorption, namely, physisorption and chemisorption. Adsorption isobars often appear like those shown in Fig. 5 (9). Three or more regions are found for the adsorption of a particular gas on a particular solid.

At low temperatures of region a-b, physisorption occurs, where the surface coverage is at equilibrium and decreases with increasing temperature (Fig. 5).

At some temperatures in region b-c, irreversible chemisorption occurs. The activation energy increases with coverage, and the rate of adsorption decreases with coverage. If at each temperature the outgassed sample is permitted to adsorb gas for a given time, a curve shaped as indicated by the dashed line may be obtained. At this temperature, desorption will not occur by simply lowering the pressure. High-temperature outgassing is required (Fig. 5).

At temperatures high enough to overcome the activation energy (region c-d), reversible chemisorption is in principle reached, and the volume chemisorbed decreases with increasing temperature. However, behavior in this high-temperature region is often masked by chemical reactions (Fig. 5).

Figure 5. Adsorption isobar. The three adsorption regions of a particular gas on a particular solid (a-b physisorption, b-c irreversible chemisorption, c-d reversible chemisorption).

The surfaces of most metal oxides usually exhibit a complex structure comprising metal ions, oxygen ions, impurities, and imperfection. Thus there are many interactions between adsorbates and surface state. In atmospheres containing water vapor, for example, the surfaces of metal oxides are covered by hydroxyl groups on which water molecules adsorb through formation of hydrogen bonds. The surface hydroxyl groups can generally be removed by dehydration at higher temperatures. However, the surface structure of metal oxides in powder form is easily subject to permanent change by repeated heat-cleaning cycles at high temperatures. On the other hand, a ceramic body sintered at high temperature is essentially more stable physically, chemically, and thermally than the powder form. As with many porous systems, controlled-pore ceramics adsorb gases throughout the pore structure. The adsorption of gases generally tends to occur preferentially on the necks of the grain surfaces. The neck usually exhibits properties closely related to the crystal grain itself. In particular, a metal oxide ceramic semiconductor tends to exhibit changes in electrical conductivity due to the adsorption of gases on the necks.

DEW-POINT HYGROMETER

The relative humidity may be determined from the dew point at the temperature, t_d , at which the humidity in the air condenses when the mixture is cooled from an initial temperature t . A simple equation relating saturation vapor pressure and dew point is the Magnus formula (3). At a temperature t (°C), the saturation vapor pressure $e_w(t)$, in pascal, over liquid water, is

$$\ln e_w(t) = \ln 611.2 + \frac{17.62t}{243.12 + t} \quad (3)$$

The Magnus formula given above can be restated in alternative form, to derive dew point values from vapor pressure.

Figure 6. Dew-point hygrometer by a Peltier element. The appearance of dew on the metal mirror changes the reflected light flow.

For vapor pressure e_w (Pa) over water, the dew point t_d ($^{\circ}\text{C}$) is given by

$$t_d = \frac{243.12 \cdot \ln(e_w/611.2)}{17.62 - \ln(e_w/611.2)} \quad (4)$$

(100 Pa = 1 mbar). The uncertainty in values of t_d given by this equation is less than $\pm 0.04^{\circ}\text{C}$ in the range -45°C to $+60^{\circ}\text{C}$. For vapor pressure e_i over ice, the frost point t_i (in $^{\circ}\text{C}$) is given by

$$t_i = \frac{272.62 \cdot \ln(e_i/611.2)}{22.46 - \ln(e_i/611.2)} \quad (5)$$

The uncertainty in values of t_i given by this equation is less than $\pm 0.08^{\circ}\text{C}$, in the range -65°C to $+0.01^{\circ}\text{C}$ (10).

Dew-Point Hygrometer Using a Peltier Element

In modern dew-point hygrometers a small silver-plated mirror is placed in the measured air flow and cooled with the help of a Peltier element (Fig. 6). The latter, together with the amplifier and the thermoelement, enables the dew-point temperature to be measured. The appearance of dew on the metal mirror changes the reflected light flow. This change has influence on the amplifier and consequently on the dc current of the Peltier element. As soon as the dew point is formed, we can measure the dew-point temperature. The setting time of the measuring device is only a few seconds. A dew-point hygrometer using a Peltier element can also be used for aggressive and other condensing gases (11).

LiCl Hygrometer

The sensing medium, which is a hygroscopic salt (LiCl), absorbs water from the air. An electrical voltage is applied across the salt, and a current passes according to the amount of water vapor that has been absorbed. The insulating tube is covered with a glass wool and then coiled up with a wire in the shape of a double screw (see Fig. 7). The wire warms the thermometer placed inside the tube. The glass wool is moistened with LiCl, which also contains water molecules. The current running through the conducting moistened glass wool warms the coil. This causes the lowering of the glass wool conductivity (due to water evaporation), until the partial pressure of water vapor does not exceed the equilibrium point. The temperature of the thermometer, too, exceeds the equilibrium temperature. The reduction of water in LiCl salt reduces the glass wool conductivity and the thermometer warming. Consequently, the temperature of the thermometer falls, LiCl absorbs the humidity again, the

Figure 7. LiCl dew-point hygrometer.

conductivity increases, and as a result a higher current is once more obtained. This current again warms the coil and thus reduces the humidity in the LiCl salt. This process repeats until the equilibrium dew point is achieved. The temperature at which this occurs is related to the water vapor pressure. The measuring range is -20°C to $+60^{\circ}\text{C}$ (dew-point temperature). Long-term stability is within $\pm 0.5^{\circ}\text{C}$ to 1°C of the dew-point temperature. The electrical power used for this process is 1 W. The setting time is approximately 1 minute (1–3). The instrument is usually in probe form, with reading displayed in terms of dew point.

Conversion Between Dew Point and Relative Humidity

There is no simple direct formula for converting in either direction between dew point and relative humidity. Conversion between these two parameters must be carried out via the intermediate step of evaluating both the actual vapor pressure of water and the saturation vapor pressure at the prevailing temperature. Values of relative humidity or dew point can then be calculated using the appropriate formula above. Table 2 shows values of relative humidity at selected temperatures and dew points.

Table 2 gives relative humidity as a function of the dew-point depression t_d for several values of the dew point. This table is used to estimate relative humidities between the values listed; the uncertainty may be up to $\pm 1\%$ or $\pm 2\%$. Small differences in air pressure within the normal atmospheric range will affect these figures by less than 0.1% relative humidity (rh) (10,14).

IMPEDANCE-TYPE HYGROMETERS

This general type of sensor is fabricated from a hygroscopic material, and the electrical properties are altered as it absorbs

water molecules. Changes in humidity are measured as changes in the sensor's electrical capacitance or resistance or some combination of the two. The majority of modern impedance sensors use thin-film technology. Impedance hygrometers are usually also fitted with temperature sensors. Readings are displayed directly, sometimes with a choice of units (e.g., relative humidity or dew point), and output of an electrical signal may also be available (15). There are several distinct types of electrical sensors.

Capacitive Sensors

Capacitive sensors respond most closely to relative humidity, rather than dew point, with best linearity at low relative humidities. Figure 8 shows the capacitive sensor for measuring humidity. It consists of a perforated housing inside of which

**Figure 8.** Capacitive sensor for humidity measurement.

there is a thin hygroscopic film layer coated with gold. This thin film layer represents acts as a dielectric for the capacitor. Under the influence of humid air, the dielectric constant of the thin film layer and consequently the capacitance of the capacitor change, as can be seen in Fig. 9. With the help of a simple measuring circuit we obtain the change of the voltage, which depends on the relative humidity (16).

Resistive Sensors

Resistive sensors correspond most closely to relative humidity hygrometers, rather than to dew point hygrometers. The

**Figure 9.** The dependence of sensor capacitance on the relative humidity.

Figure 10. Humidity characteristics of the thick film resistive sensor for various molar ratios of $\text{TiO}_2/\text{SnO}_2$ (curves A, B, C, and D correspond to 2.9:1, 1.9:1, 1:1, and 0.5:1, respectively).

linearity of resistive sensors is best at high humidities. Most resistive sensors cannot tolerate condensation. However, some are “saturation guarded,” with automatic heating to prevent condensation. Figure 10 shows the humidity characteristic of devices at 40°C for various mole ratios of $\text{TiO}_2/\text{SnO}_2$. The mixture in mole ratio of $\text{TiO}_2:\text{SnO}_2 = 2.9:1$, $1.9:1$, $1:1$, or $0.5:1$ was sintered at 1200°C for 2 h with Ta_2O_5 (several mole %). The results indicate that the electrical resistance of the device in any mole ratio decreases exponentially with an increase in rh, and the increase in mole ratio of $\text{TiO}_2/\text{SnO}_2$ causes an increase in the whole device resistance and moisture-sensitivity (17).

Dew-Point Type Impedance Sensors

Dew-point type impedance sensors are a special case of impedance hygrometer, used to measure in absolute units rather than relative humidity. Following a similar general principle, the sensor may feature aluminum oxide or other metal oxides, or a silicon base for the active element. This type of sensor responds to the partial pressure of water vapor. Commonly the signal is converted into other absolute units, resulting in values displayed by the instrument in dew point or parts per million by volume. These sensors can have a wide range of measurement, including very dry gases. They are often used at high pressure, or to sample gas originating from the system at high pressure (15). Figure 11 shows the change of impedance in an Al_2O_3 sensor. The latter consists of an aluminum plate having a surface of 4 mm^2 onto which first a thin layer of aluminum

Figure 11. Cross section of an Al_2O_3 sensor.

Figure 12. Schematic view of the electrical circuit equivalent to the Al_2O_3 sensor.

oxide and then a gold film are deposited. The absorption of water molecules which pass through the $0.3\text{ }\mu\text{m}$ thick gold layer to the pores of aluminum oxide depends on the partial pressure of water vapor. Consequently the resistance and the capacitance of the aluminum oxide change. Figure 12 shows the equivalent electrical circuit of an Al_2O_3 sensor shown in Fig. 11 (18).

Resistive and capacitive sensors are used for a variety of applications in ambient conditions, including control of air conditioning and other processes. Some are used in more extreme environments. “Dew-point” types are distinct from others in this group in that they cover much lower levels of humidity, in absolute units, and are used in the control and monitoring of relatively dry gases. They include aluminum oxides and other metal oxides, and silicon-based sensors. Relative humidity types can achieve uncertainties of 2% to 3% of value, at best, while dew-point types have uncertainties of around 2°C in dew point, at best, to 5°C at low dew points (15).

Advantages(+) and disadvantages(–) of these sensors include the following:

Capacitive sensors in particular

- + Usually tolerate condensation (though calibration may shift)

Resistive sensors in particular

- May be damaged if condensation occurs (though some sensors are protected)

Dew-point impedance sensors in particular

- + Usually tolerate condensation (though calibration may shift)
- + Can have wide measuring range
- May be slow to settle at very low (absolute) humidity
- Have some tendency to drift

PIEZOELECTRIC HYGROMETERS

Humidity-gas sensors have been developed using AT-cut quartz-crystal resonators vibrating in the thickness-shear mode. The sensing element is a radio-frequency quartz crystal coated with a hygroscopic polymer material. In a simple circuit using such a crystal, the frequency of oscillation decreases when the crystal gains weight due to water absorption by the

Figure 13. Three-layer model.

coating. Since frequency changes can be measured accurately and rapidly, this results in an accurate and simple moisture analyzer. In a SAW device a surface acoustic wave is electrically excited in a piezoelectric single-crystal plate substrate (e.g., quartz, lithium niobate, lithium tantalate) by use of a metallic (e.g., aluminum) interdigital transducer (IDT) structure. It is also possible to use the quartz crystal as a stable oscillation element whose substitutional electrical structure only is being changed through the variation of the serial capacitance. The sensor probe C_x is an open capacitor (having the form of a comb).

Coated Quartz-Crystal Humidity Sensor

While a coated quartz-crystal resonator is vibrating in ambient air (assuming only one surface is in contact with the ambient air), it can be simplified as a three-layer model. Figure 13 shows such a model, where layer I consists of the quartz crystal (including the lower electrode), layer II consist of the upper electrode and absorbent/absorbate materials that can be regarded as solid phase, and layer III is a pure fluid layer where shear vibration will be damped rapidly (19).

The principle is mainly based upon Sauerbrey's formula (20,21):

$$\Delta f = \frac{-2\Delta m n f_0^2}{A(gm_q \phi_q)^{1/2}} \quad (6)$$

where Δm = mass of substances absorbed on the surface, Δf = shift of frequency, ϕ_q = density, μ_q = shear modulus, A = surface, $m = 1$ (when the effect of generalized viscosity of layer III can be neglected).

When the resonant frequency f_0 is 3.5 MHz, the frequency change between 20% and 95% humidity is approximately 1000 Hz. Typical data obtained by an instrument using this principle of measurement are as follows: range: 0.1 to 33,000 ppm; speed: 99% dry-down in one minute; minimum detectable: ± 0.1 ppm; selectivity: hydrogen, hydrocarbons, olefins, alcohols, acid gases, and chlorinated solvent vapors cause only negligible interference.

SAW Resonator for Absolute Humidity Measurement

The frequency range covered starts at about 50 MHz and ends up at a few gigahertz, corresponding to a state-of-the-art interdigital finger linewidth below $0.5 \mu\text{m}$ (22). Because many parameters may contribute to a frequency change of the SAW device, the reverse determination of a parameter change from a measured frequency change is ambiguous. The most common solution of the problem is the use of two equal devices, where only one of the devices is coated with a layer that produces a known unique sensitivity to the measured gas (e.g., analytic concentration), while the other device is used as a reference element as in Fig. 14. The difference of the frequency changes of both devices is only sensitive to the measured gas, with the frequency changes caused by all other influences being compensated by this difference principle.

The SAW sensor is a 200 MHz two-port resonator fabricated on ST-cut quartz with aluminum metallization. The interdigital transducers were designed with split fingers apodized for narrow bandwidth. They are coated with a radio-frequency 20 nm thick sputtered with silicon dioxide layer as the sensing film. The coated SAW resonator and the reference resonator are fabricated on separate substrates. Responses of the coated SAW sensor to water vapor provide shifts in SAW resonator frequencies using modulation circuits. The frequency shift which is caused by the change of humidity from 1 to 6 g/m³ is approximately 500 Hz (23).

Figure 14. SAW sensor using the difference principle.

Figure 15. Hygrometer using the sensitive capacitive dependent crystals.

The absolute humidity of water-vapor density ρ_w in saturated moist air is given by the following equation (24):

$$\rho_w = \frac{18.0152 f(P, T) e_w(T)}{V_m P} \times 10^6 \text{ gm}^{-3} \quad (7)$$

where V_m is the molar volume of the moist air, P is the total pressure, $e_w(T)$ is the saturation water-vapor pressure at the absolute temperature T , and $f(P, T)$ is the enhancement factor. The molar volume, V_m , is obtained by solving the equation of state for moist air as described in Ref. 23. In the range of water-vapor density from 1 to 30 g m^{-3} , the estimated maximum relative uncertainty is 0.1%.

The Piezoelectric Hygrometer Using Sensitive Capacitive-Dependent Crystals

The frequencies of oscillator 1 and oscillator 2 of the sensor depicted in Fig. 15 are 18 MHz. The output of the pulse-width modulator (PWM) is a pulse-width signal which is compensated for temperature and voltage drift (Fig. 15) (24).

The sensor probe C_x is an open capacitor (having the form of a comb) (Fig. 16). The distance between the open capacitor plates (C_x) is 0.3 mm. The sensor probe is formed on an Al_2O_3 basis together with electronics and a temperature-sensing element. The crystal is used as a stable oscillation element whose electrical structure only is being changed through the variation of the serial capacitance C_x .

The humidity measurement is determined by Eq. (8). (K = constant depending on mechanical realization).

$$\Delta f = K^{\text{humidity}} \quad (8)$$

The sensor probe [open capacitor in the form of a comb which does not charge itself statically (Fig. 16)] has the surface $A1(C_{x1} = 9 \text{ pF})$, $A2(C_{x2} = 6 \text{ pF})$, $A3(C_{x3} = 3 \text{ pF})$ (Fig. 17).

The frequency measurement uncertainty is $\pm 0.1 \text{ Hz}$. The fact that the capacitor does not charge itself statically gives this

Figure 16. Sensor probe C_x .

Figure 17. Air-humidity measurement.

method the advantage over the others. The typical uncertainty of high-air-humidity measurements is about $\pm 2.5\%$ ($T = 15$ to 25°C and humidity = 50 to 98%); however, this sensor presented has an improved uncertainty of $\pm 0.1\%$. The fact that the sensor is not made of absorption materials that can be affected by dust ensures long-term repeatability even after calibration. (Sensor probe is the only open capacitor.)

ELECTROLYTIC HYGROMETERS

There are two basic methods of electrolytic hygrometer: The first method is based on the measurement of conductivity and the second uses phosphorous pentoxide. The basis of the conductivity method represents the measurement of conductivity of electrolytic hygroscopic material (Fig. 18). The electric current flowing through the hygroscopic material causes the ionization of water molecules in the electrolyte which results in ionic conductivity. The second method uses phosphorous pentoxide, which absorbs humidity from the air.

Figure 18. Temperature and resistance characteristics of an electrolytic hygrometer. The temperature rises from the lowest curve to the highest ones.

Figure 19. Electrolytic probe. Gold plated electrodes covered with either porous textile or cotton wool or glass wool or porous ceramic.

Method Based on the Measurement of Conductivity

The rate of humidity absorbed from the air affects the electric conductivity of hygroscopic material. The voltage applied is alternating due to polarization.

Figure 19 shows gold-plated electrodes covered with either porous textile or cotton wool or glass wool or porous ceramics. The uncertainty of the humidity measurement is $\pm 3\%$ (25,26) (Fig. 20).

Electrolytic Hygrometer Using Phosphorus Pentoxide

The sensor consists of a film of powerful desiccant, phosphorus pentoxide (P_2O_5), which strongly absorbs water vapor from the surrounding gas. A voltage is applied across the P_2O_5 and electrolysis takes place, dissociating the water into its constituents, namely, hydrogen and oxygen. The current that flows in this process is related (by Faraday's Law) (27) to the amount of water electrolyzed. Thus the magnitude of the current indicates the humidity of the gas being measured. These sensors are suitable for measuring very low humidities, though they require a steady (known) flow rate of gas. They are normally used in flow sampling configurations, rather than in probe form (27). In the electrolytic hygrometer the gaseous sample flows at a steady rate (conveniently 100 mL/min) through a polytetrafluorethylene (PTFE) tube about 76 cm long and with a 0.7 mm bore. Inside the tube are two interlaced but separate helical electrodes of fine platinum wire. The electrodes are covered with a thin film of partially hydrated phosphorus pentoxide, and a voltage of about 70 V dc is maintained between them. The sensitive element (which is flexible) is coiled and

Figure 20. Humidity measurement based on conductivity method.

Figure 21. Cross section of detector. 1, Inlet end of sensitive element; 2, Fluo bush; 3, 6.35 mm male flare union brazed to part No. 4; 4 and 4a, brass end pieces; 5, brass tube filled with Seekay wax R93C; 6, boss brazed to brass tube; 7, Tufnol bush secured with Araldite; 8, metal cap secured with Araldite; 9, electrode soldered to metal cap.

potted in Seekay wax (chloronaphthalene wax) in a 1.905 cm bore brass tube 10.16 cm long (Fig. 21) and provided with connections for the gas supply with the terminals of the electrical circuits (28).

The principle of this method is that an equilibrium is set up (often within a few minutes) between the rate of absorption of water and the rate of electrolysis of the absorbed water. For a gas flowing at 100 mL/min at 20°C and 100 kPa (760 mm Hg), the equilibrium current is 13.4 μ A per part per million by volume of water vapor (28). Since the equilibrium current I is proportional to both the water content W and the sample flow rate R , the water content in ppm v/v at 20°C and 100 kPa is given by

$$W = \frac{100 I}{13.4 R} \quad (9)$$

where I is in microamperes and R is in milliliters per minute.

In some cases (e.g., Arcton 6) the film does not absorb all the water from the sample; the water content can then be obtained by the absorption efficiency of the detector for the particular gas being used. A method of determining the efficiency is described later. Equation (9), which is applicable to any gas, is used throughout this article. In the refrigeration industry, however, water contents are usually specified as a proportion by weight; the conversion factor for Arcton 6 is 1 ppm w/w = 6.7 ppm v/v .

This is a long established method for use in dry environments. The uncertainty is ± 3 to $\pm 10\%$ of reading at best (29). (+ advantages, – disadvantages)

- + Compatible with some corrosive gases
- + Can have good sensitivity
- Measuring cells have a limited life, after which they must be recoated (and recalibrated)
- Flow rate of gas is critical
- Damaged by exposure to normal ambient humidities and by periods of extremes of dryness (below 1 ppm)
- Slow response at lowest humidities
- Hydrocarbons, butadiene, ammonia, and some other contaminants prevent proper operation
- Adds traces of hydrogen and oxygen to the gas sample, which can recombine, leading to errors

Figure 22. Optical fiber hygrometer.

OPTICAL FIBER HYGROMETERS

The optical fiber hygrometer is a sensor consisting of two optical fibers. One end of these two fibers is attached to the humid reflexive optical system as shown in Fig. 22. The other two ends are connected to the light source and attached to the optospectral measuring device and polychromator. Fibers are used only for the transmission of light (30).

The humidity sensing element is a multilayer system with good measuring reflective spectrum (Fig. 23). This is a Dünuschicht-Fabry-Perot interference filter, which consists of several consecutive high and low refractive dielectric $\lambda/4$ layers. The optical efficiency of the thickness of a single layer as a product of the geometric thickness and optical refraction of light (n_L for low and n_H for high refractive layers) needs to be set to the medium working light source wavelength λ . The polychromator has to be adjusted to that wavelength as well. The multilayer system consists of 8 dielectric $\lambda/4$ layers with low and 10 layers with high refractive index. The reflexive minimum is situated near 800 nm working wave range. All layers together are approximately $2 \mu\text{m}$ thick. SiO_2 with low refractive index and TiO_2 , ZrO_2 or HfO_2 with high refractive index are used as dielectric material. They are temperature stable and their chemical resistance is known. A more or less large structure of pores depends on the degree of evaporation in vacuum (30).

In humid environments water molecules can be reversibly sorbed. The optical refractive index of layers is changed and the reflexive spectrum is shifted towards longer wavelengths. The shift reversibly depends on the partial pressure of water vapor. The volume of different size pores and their probable distribution determine the functional course of the spectrum shift. To achieve the wanted porous structure, technological parameters of certain layers need to be preset. The final sensitivity depends on the optical resolution of the polychromator.

The Sensor's Measuring Range

The sensor's porous structure is designed to measure the dew-point temperature in the range from $+10$ up to -100°C . It is interesting to note that the temperature above 300°C does not destroy the sensor. In such case the sensor only needs a regeneration time and a new calibration. The dew also does not damage the sensor. Once the latter is dry again, it is like newly calibrated.

Figure 23. Multilayer structure.

The optical fiber sensor has the following advantages:

- it is very small ($\phi < 1 \text{ mm}$)
- it can be more than 100 m away from the measuring electronics
- the measuring results are not influenced by electromagnetic disturbances, capacitance and inductance between the conductors, parallel resistance
- it can work in an explosive environment
- it is temperature and corrosive stable
- it works up to 100°C
- it has a short reaction time (5 s)

CALIBRATION

Calibration is the process of comparing a measuring instrument with a fixed reference for the same type of measurement, to identify any bias or systematic error in the readings. The outcome of a calibration is normally a certificate listing any corrections that need to be applied to the values indicated by the instrument, together with an estimate of the uncertainty in the calibration, and other relevant information. For example, a calibration of a given instrument at, say, 50% rh, might show it to read too high by 1% rh. If so, a required correction of -1% rh would be shown on the certificate.

Humidity Generation

The main methods of humidity generation are as follows (12):

Dew-Point Generator. Gas is humidified by bubbling it through (or flowing it over) water or ice at a given temperature. Depending on the efficiency of the design, this will produce gas with a dew point more or less close to the temperature of the saturator.

Two-Temperature Generator. Gas is humidified at a given temperature, defining its dew point, or vapor pressure. The gas is then fed to a chamber at another (higher) temperature. By varying one or both temperatures, it is possible to obtain any chosen value of relative humidity or dew point.

Two-Pressure Generator. Gas is humidified at elevated pressure and then expanded to a lower pressure (at the same temperature). As the total pressure of the gas falls, so does the partial pressure of water vapor. Knowing the initial humidity allows the humidity after expansion to be found. By varying the initial pressure or temperature or both, it is possible to obtain any chosen value of relative humidity or flow dew point.

Mixed Generator. Gas is humidified by any convenient method and is then mixed with drier gas. The value of humidity achieved depends on the mixing proportions and on the water content of the two gas streams.

Salts. Saturated (or unsaturated) salt solutions, and certain other chemicals, can be used to generate an environment of a particular relative humidity in an enclosed space. The value of relative humidity obtained depends on the particular chemical salt, the concentration of the solution, and the temperature of use, among other things.

Table 3. Standard Salt Solution for Humidity Calibration

Temperature (°C)	LiCl	MgCl ₂	Mg(NO ₃) ₂	NaCl	KCl
0		33.66 ± 0.33	60.35 ± 0.55	75.51 ± 0.34	88.61 ± 0.53

65	10.86 ± 0.29	28.54 ± 0.21			79.85 ± 0.48
70	10.75 ± 0.33	27.77 ± 0.25			79.49 ± 0.57
75	10.64 ± 0.38	26.94 ± 0.29			79.17 ± 0.66
80	10.51 ± 0.44	26.05 ± 0.34			78.90 ± 0.77

Humidity Chambers. Test chambers are available with both temperature and humidity control based on steam or spray injection, or on one of the principles outlined above.

Bottled Gases. Cylinders of compressed gas are available which supply gas of fixed humidity, at a selection of values of a few hundred ppm or below. The method relies on a special coating of the cylinder interior.

Used appropriately, any of the above methods can provide a stable humidity for use in comparing one hygrometer with another, already calibrated, one. This may mean supplying a flow of gas to pass through both instruments to be compared, or placing both instruments in a chamber where they are exposed to the same humidity. Humidity generators can be calibrated, but only at national standard level are they accurate and authoritative enough to act as absolute references.

Calibration Using Salt Solutions

Salt solutions generate characteristic values of relative humidity which depend on the particular chemical salt, the concentration of the solution, and the temperature of use. Saturated salt solutions, with solid salt present, have the special property that a stable concentration—and hence a constant relative humidity—is maintained even if water migrates to or from the solution. Ready-made capsules are commercially available for a variety of relative humidity “fixed points.” Such capsules are designed to seal over the end of relative humidity probes, providing a small enclosed atmosphere of defined relative humidity. Certain of these, if in the form of a solution with a solid salt present, are reusable and can be calibrated to assign a traceable value to the reference humidity they provide.

Table 3 shows values of humidity generated over saturated solutions of various salts (13,31). Just as it is for relative humidity in general, temperature stability is critical for calibration with salt solutions, particularly since the properties of the salt solutions change with temperature (Table 3, Fig. 24). Stabilization after a change in temperature may take an hour, or many hours, depending on the size of the change. For freshly mixed

solutions, full stabilization may take a long time, sometimes weeks (31,32).

Some Practical Recommendations for Calibration of Hygrometers

Hygrometers should be calibrated in terms of the quantity to be measured. For example, the performance of a wet- and dry-bulb hygrometer cannot be characterized by calibrating the thermometers alone; a humidity calibration of the hygrometer as a whole is needed. Where a hygrometer consists of separate parts (e.g., probe and electronics) the pair should be calibrated together as one item and used together. Wherever possible, calibrations should be performed under the

**Figure 24.** Temperature stability of salt solutions.

intended conditions of use—that is, at similar values of humidity and temperature, and preferably under similar conditions of pressure, air flow, and so on. Hygrometer readings in some units of measurement (such as grams per cubic meter) are specific to gas type. Therefore a calibration in these units is valid only for a selected gas. This is so because the ratio of molecular masses of water and air, for instance, is about 0.62, whereas the ratio for methane is about 1.1. However, calibrations in terms of (say) parts per million by volume are not necessarily gas-specific, or only very slightly so (provided the instrument genuinely senses this quantity and does not simply give a numerically converted result from some other parameter) (33).

A general guideline for calibrating the various types of hygrometers might be as follows:

- Hygrometer types with relatively good stability (e.g., condensation dew-point hygrometers, wet- and dry-bulb hygrometers): 6 to 12 months after first calibration; thereafter every 1 to 12 years, depending on requirements.
- Moderately stable hygrometer types (e.g., electrical relative humidity instruments): perhaps 6 months after first calibration; thereafter every 6 to 12 months, depending on requirements.
- Less stable hygrometer types (e.g., aluminum oxide hygrometer) every 6 months, or sooner if desired.

Where a choice of intervals is suggested above, the longer intervals are for hygrometers confined to use in ordinary room or laboratory conditions, whereas the shorter intervals are for those used in more varied conditions. If used in extreme conditions or if accuracy is critical, then measurement checks of some kind at much shorter intervals are recommended. Where hygrometers are strongly prone to drift, this will remain a significant source of uncertainty almost irrespective of the frequency of calibrations.

LONG-TERM STABILITY

The measurement characteristics of an instrument will change with respect to time, due to gradual changes in its electrical or material components. Estimates of long-term stability, or drift, refer to the likely change in the instrument's measurement performance with respect to time. Regular checks of calibration should be made to quantify this problem. Although sometimes adjustments can be made to the hygrometer reading in the light of drift, performance could be compromised by the adjustment process, and the overall drift characteristics could be masked by frequent adjustments (34,35).

Speaking about the measurement characteristics of hygrometers, we also have to take into consideration the following terms:

Uncertainty. The uncertainty of a measurement is defined as the parameter characterizing the range in which the “true value” can be expected to lie. It defines a “margin of doubt” about a reading or estimated value, together with a level of confidence (normally 95%) that the “true value” will lie within this range. Often, the uncertainty for an instrument is specified for ideal operating conditions at a temperature of 20°C or 23°C.

Table 4. Effect of a Temperature Change of 1 °C at Various Levels of Temperature and Relative Humidity

Relative Humidity	Temperature				
	10 °C	20 °C	30 °C	50 °C	70 °C
10% rh	±0.7% rh	±0.6% rh	±0.6% rh	±0.5% rh	±0.5% rh
50% rh	±3.5% rh	±3.2% rh	±3.0% rh	±2.6% rh	±2.3% rh
90% rh	±6.3% rh	±5.7% rh	±5.4% rh	±4.6% rh	±4.1% rh

The method of use may make an important contribution to the overall uncertainty achieved.

Accuracy. Strictly speaking “accuracy” is a qualitative term only. For example, an instrument or measurement might be described generally as “accurate” or “not accurate.” However, the word “accuracy” continues to be used loosely in specifications to refer to the maximum difference that can be expected between the reading given by an instrument and the “true value” being measured.

Repeatability. In general terms, the repeatability of an instrument is the closeness of agreement of multiple readings repeated under the same conditions of measurement. To quantify repeatability, the spread or dispersion of results may be quoted, for example, in terms of a standard deviation of a number of readings.

Reproducibility. In general terms, reproducibility is an instrument's capacity to reproduce a previous measurement. This may be at a later date or after undergoing significant changes in conditions, for example, after a change of operator or location. To quantify reproducibility, the spread or dispersion of results may be quoted, for example, in terms of a standard deviation of a number of readings.

Temperature Influence on the Stability of Relative Humidity Measurement

Relative humidity is highly dependent on temperature. Roughly speaking, at room temperature, a change in dew point of 1°C corresponds to a change in relative humidity of 6% of the relative humidity value. At 50% rh, for example, an uncertainty in dew point of ±1°C corresponds to an uncertainty of ±3% rh. A change of 1°C in the measurement of the ambient temperature has almost exactly the same significance. The size of the effect under different conditions is illustrated in Table 4.

Overall, a useful rule of thumb is that ±1°C uncertainty in either dew point or temperature leads to an uncertainty of ±6% of the relative humidity value. The change in the relative humidity levels is not symmetric (36–38).

PYROMETERS

Infrared (IR) temperature measurement has been in use for a century. It has gained wide acceptance in industry and science wherever the target of interest cannot be contacted because it is too hot, moving or, for other reasons, not accessible to a contact probe such a resistance or thermocouple element. The worldwide annual market for IR pyrometers is now around 1/4 billion US dollars. There are about two dozen firms offering pyrometers, the most important of which are listed in Table 1.

The following sections deal with concepts and implementation of all practical pyrometers that are in use today or are about to enter the market.

FUNDAMENTALS OF PYROMETRY

At temperatures above absolute zero all bodies emit electromagnetic radiation. Planck's radiation law (1) describes the relationship between a body's surface temperature and the associated spectral radiance

$$L(w, T) = E(w, T)c_1w^{-5}[\exp(c_2/wT) - 1]^{-1} \quad (1)$$

where $L(w, T)$ is the spectral radiance as a function of wavelength w and absolute temperature T . $C_1 = 3.7413 \times 10^{-12} \text{ W} \cdot \text{cm}^2$, $C_2 = 1.4388 \text{ cm} \cdot \text{degree}$ are the first and second radiance constants, and $E(w, T)$ is the spectral emissivity of the surface, which also is a function of temperature. For a black body $E(w, T) = 1$. Figure 1 shows graphs of spectral radiance vs. wavelengths for different temperatures T , the so-called Planck curves. For all other bodies $E(w, T) < 1$. From Eq. (1) then

follows that $E(w, T)$ is the ratio of the radiance of a surface at a certain temperature T to the black body radiance at the same temperature T . A special case occurs when $E(w, T) = \text{constant} < 1$. Such objects are called gray bodies. The Planck curves exhibit several important features (see Fig. 1):

1. They do not intersect each other, which means that the radiance at any wavelength increases monotonically with temperature.
2. For each temperature there is a wavelength of peak emission that shifts to longer wavelengths with decreasing temperature. This shift is expressed by Wien's displacement law (2)

$$w_{\max} \cdot T = 2897.6 \mu\text{m} \cdot \text{degree}$$

3. If one sets $E(w, T) = 1$ and integrates Eq. (1) over all wavelength, one gets the Stefan-Boltzmann law for the total radiance of a black body:

$$L_{\text{tot}} = s \cdot T^4$$

where $s = 5.669 \times 10^{-12} \text{ W} \cdot \text{cm}^2 \cdot \text{degree}^{-4}$ is the Stefan-Boltzmann constant. If the object is *not* a black body, the

total radiance is given by

$$L_{\text{tot}} = E_{\text{eff}}^* s \cdot T^4$$

where E_{eff} is an effective emissivity.

Total Radiance Systems

The emissivity functions $E(w, T)$ depend on the chemical composition of the surface and its texture. Emissivity values have been measured and tabulated for many different materials, but even a thin coating by a different material can change the emissivity drastically. One important industrial example is hot steel being sheared in a processing plant, exposing a pure iron surface. The emissivity of pure steel is about 0.40 in the near infrared spectrum. Hot steel oxidizes rapidly, thereby increasing the emissivity, which can double the emissivity in minutes. Another example is from the semiconductor industry, namely that of a silicon wafer during thermal processing. Such a wafer would typically have on its surface films of materials with different optical refraction indices than that of the silicon substrate. The emissivity of such a wafer is substantially changed from that of the uncoated wafer due to optical interference effects, which occur on such coated surfaces, and which depend strongly on the wavelength of observation. Great temperature errors can result in both above cases if the change in emissivity is not taken into account.

The oldest automatic instruments measured the radiance over the whole infrared spectrum. This yields the most radiative power at the detector, which in early days was a thermocouple element of very low responsivity requiring a maximum of radiant power.

Narrow-Band Systems

With the development of more sensitive detection methods, particularly quantum detectors coupled to transistor amplifiers, it became feasible to measure small spectral portions of the radiant spectrum. There are several reasons why one wants to use small portions of the radiant spectrum:

1. The shorter the wavelength, the steeper the local exponential slope of radiance versus temperature. Operating at the shortest possible narrow-wavelength band minimizes temperature error due to emissivity uncertainty and calibration drift.
2. Some materials are opaque at certain wavelength bands. Spectral absorption curves for several materials are shown in Fig. 2.
3. Multiwavelength pyrometry.

Wavelength Choices

As illustrated by the Planck curves, the radiance peaks shift to longer wavelengths as the target temperature decreases. It is therefore necessary to match the operating wavelength band of the pyrometer to the temperature range of interest. Here one must consider the available radiation detectors (3). The major detectors and their associated temperature ranges are listed in Table 2. For free radiating targets, one should work at the shortest wavelength at which one still obtains reasonable signals. At this point the local exponential slope and the suppression of temperature errors are largest.

Figure 1. Planck curves (curves are for constant blackbody temperature, in K).

Disappearing-Filament System

Prior to the widespread use of infrared detectors, optical pyrometers were the instruments of choice. The operating principle is a visual comparison of the brightness of an electrically heated wire to that of the target seen through a red filter within the pyrometer’s viewing optics. By varying the electrical current in the wire, one can adjust its brightness until it blends into the target surface. The wire current is then a measure of the target’s radiance temperature. The drawback with these instruments is that they require operator judgment, which may differ from person to person. Also there is usually no provision for emissivity correction.

A newer version of this instrument projects a bright line of variable intensity into the field of view. The line illumination is provided by a small commercial lamp. Its intensity is monitored by a silicon photodetector. Another method is to hold the filament at a constant temperature, and use a narrow filter coupled with a neutral density filter to match the brightness of the filament with the target.

Dual-Wavelength Method

Dual-wavelength pyrometers exploit the nonlinearity of the Plank equation by determining the temperature from the radiance ratio at two different wavelengths (4). Here, uncertain emissivity ratio leads to error. The real advantage of dual-wavelength pyrometers over single-wavelength systems is the insensitivity of the dual-wavelength measurement to partial obstructions in the line of sight such as dust, steam, and vignetting, since both radiance values attenuate by the same factor. For the same reason there is no lower limit to the

Figure 2. Spectral emissivity of materials: silicon at 270, 470, and 600°C; lime glass at 500°C; polyethylene at 50°C.

Table 2. Lower Temperature Limits

Lower Limit of Temperature	Infrared Detector ^a	Wavelength (μm)
600°C	Si	0.4–1.0
200°C	Ge and InGaAs	0.8–1.8
100°C	PbS	1.0–3.6
50°C	PbSe	1.5–5.8
–50°C	Pyroelectric detector	No wavelength dependency

^a Operating at room temperature.

target size, as long as the signals at the two wavelengths are measurable.

Active Method

In the following we distinguish between passive and active pyrometry. The former are the traditional instruments which only *receive* radiation, hence the term “passive.” New types of pyrometer have been introduced in the last decade, which augment the traditional optical receiver with a reflectometer, sending radiation to the target as well receiving radiation from it; thus the term “active.” The fundamental shortcoming of passive pyrometry, namely, its dependence on an estimate of emissivity, was recognized from its inception. For pure materials, such as most metals, the emissivity is known from special sample measurements. But even a thin oxide surface layer can change the emissivity drastically, leading to large temperature errors. In 1905, Rubin (5) proposed a method of measuring the target emissivity E by recognizing that for opaque bodies their hemispheric reflectivity R_{hemisph} is always the unity complement to its emissivity, $E = 1 - R_{\text{hemisph}}$. When a distant target reflects diffusely, R_{hemisph} (and therefore E) can be determined from a measurement of the reflected energy into a relatively small solid angle (6). In practice, one calibrates the reflectance measurement against a diffuse surface of known reflectivity, such as CaCO_3 at a known distance d_c and then scales all reflectance values of proper targets at distance d by the factor $(d/d_c)^2$. This is so, since for a particular receiver system the solid angle over which reflected radiation is collected scales with the square of the target distance. The reflectance measurement must, of course, be made at the same wavelength as the radiance measurement. This method is also referred to as “reflection-supported pyrometry.”

Furnace Applications

Objects are placed into furnaces to heat them up. By the nature of this process, such objects (targets) are surrounded by heat sources of higher radiance temperature than their own. Reflected ambient radiance can be as large or even larger than the target's thermal self-emission. An interesting situation occurs when the ambient irradiance is isotropic and its radiance temperature is equal to the target temperature. In that case the target appears as if it were a black body (Appendix 1). In general, however, the furnace is hotter than the target and one must separate the thermal target radiance from the reflected furnace radiation because only the former is associated with the target temperature. There is a family of active pyrometers that is designed for this application. These pyrometers have provisions to measure the average ambient radiance as well as the target reflectance. A microcomputer then subtracts the target radiance from the total radiance and then calculates the temperature from the former.

PRACTICAL DESIGNS

The following is a description of the pyrometer types that are commercially available at present. Total radiation and optical pyrometers are either being phased out or used for special applications only. Narrow-wavelength and dual-wavelength systems dominate the market. Active pyrometers, a newer type of

Figure 3. Passive single-wavelength system. D , detector; F , filter; L , objective lens; PA , pinhole aperture; A , amplifier; C , computer.

instrument, are gaining acceptance where accurate temperature measurements are required.

Narrow-Wavelength Pyrometers

The simplest pyrometer design, illustrated in Fig. 3, employs a lens (L), a pinhole aperture (PA), an optical filter (F), and a detector (D), with an output signal that is amplified by circuit (A) and then applied to microcomputer (C), which calculates the temperature from L and a manual input for the emissivity E via the Planck equation (1).

The temperature is then displayed in digital form (DS). One counterintuitive, but, nevertheless, valid feature of that design is that the radiance signal yielded by the detector is independent of the target distance. In other words, if the target moves out of focus, the detector signal remains the same. This very important feature is proven in Appendix 2. More advanced instruments are of the focusing type in which the lens (L) is adjustable to image the target surface onto the detector plane. An additional refinement is to reimagine the pinhole onto the detector with an auxiliary optical system (7). This latter design reduces stray radiation on the detector and thereby yields the highest degree of angular selectivity.

The dependence of temperature error on emissivity uncertainty can be analyzed by differentiating Eq. (1) with respect to E :

$$dT/T = (wT/c_2)dE/E \quad (2)$$

Equation (2) shows that for any given uncertainty in radiance or emissivity, the corresponding temperature error is smaller by the factor wT/c_2 ; that is, the shorter the wavelength, the smaller the temperature error, with all thing being equal. Of course, at shorter wavelengths the signal falls off exponentially. This puts a lower limit on the choice of wavelength for any given temperature. There are about a dozen companies that offer a complete assortment of narrowband pyrometers to cover the range of industrially important applications.

Dual-Wavelength Pyrometers

Figure 4 illustrates the design of one version of a dual-color system. A dichroic beam splitter M is placed in the optical path to separate the two wavelength components. One uses two filter-detector-amplifier systems $F1-D1-A1$ and $F2-D2-A2$ to measure the respective radiances. Both signals are applied to the microcomputer (C), which calculates the target temperature from the

Figure 4. Passive dual-wavelength system. D_1 , detector for wavelength 1; D_2 , detector for wavelength 2; F_1 , filter for wavelength 1; F_2 , filter for wavelength 2; M , dichroic mirror; PA_1 , pinhole aperture for wavelength 1; PA_2 , amplifier for wavelength 2.

formula

$$T = [(c_2/T)(1/w_2 - 1/w_1)] / [\ln(L_1/L_2)(E_2/E_1)(w_2/w_1)^5] \quad (3)$$

with a manual input for emissivity ratio E_1/E_2 . The dual-wavelength systems on the market employ wavelength combinations in the near- and mid-infrared regions: 0.7/0.9, 0.9/1.55, and 3.2/3.7 μm (8).

Active Pyrometers

By adding a reflectometer function, an ordinary pyrometer is transformed into an active instrument illustrated in Fig. 5, where the beam of a pulsed light source (LA), such as a laser, is superimposed onto the pyrometer's optical axis by a beam combiner (M_2). To normalize the outgoing radiation pulse, a beam splitter (M_1) diverts a small portion of the outgoing radiation onto a second, reference detector (D_1), whose output, after amplification, V_2 , is applied to a microcomputer (C). The radiance received by detector D consists of a dc component V_0 associated with the thermal target radiance and a superimposed pulsed component of height V_1 , which is associated with the reflected pulsed radiation. Timing signals (TR), synchronously generated with the outgoing pulsed radiation, are used by the amplifiers (A) and (A_r) to separate the pulses from the dc component. Finally, a signal V_3 associated with the target distance d is also applied to the computer. When the lens (L) is carefully focused

Figure 5. Active single-wavelength system. D , detector; D_r , reference detector for laser output; F , filter; A , signal amplifier; A_r , reference signal amplifier; L_1 , laser collimating lens; M_1 , beam splitter for the laser beam; L_2 , diverging lens; L_3 , objective lens; M_2 , mirror; PA , pinhole aperture; C , computer; EN , distance encoder.

onto the target, the position of this lens relative to its infinity focus location is a measure of the target distance from the lens. Thus, by indexing this relative lens position, monitored by the distance encoder EN , one generates signal V_3 to determine the value of d . This is then used in the following formula to calculate the in situ target emissivity:

$$E = 1 - c_{23}(V_1/V_2)/d^2 \quad (4)$$

The radiance component is proportional to V_0 ,

$$L = c_{20}V_0 \quad (5)$$

where c_{23} and c_{20} are instrument constants. After determining d from V_3 , the computer calculates the temperature T from V_0 , V_1 , and V_2 via Eqs. (4), (5), and (1).

FIBER-OPTIC SYSTEMS

All pyrometers of the preceding type can in principle be designed as fiber-optic models. The main advantage of fiber systems is their optical flexibility. While large-lens-type pyrometers require a straight, large-aperture line of sight, fiber systems make pyrometer measurements possible for very restricted and indirect optical access. Ordinary fiber cables have no imaging property; they simply collect over the acceptance angle of the fiber (about 20° for a typical clad quartz system). Also, normal fiber cables use polyvinyl chloride (PVC) jackets and must, therefore, stand off from a hot target. Hence the target spot would grow quickly with distance. One therefore places either a sapphire light pipe or a lens system in front of the fiber cable. A sapphire light pipe is extremely heat resistant and can be placed very close to a hot surface in order to make the target spot small. Another method is to stand off from a hot surface and use a lens to image the desired target spot onto the fiber end face. The other end of the fiber cable is placed close to a photodetection system, which sends its output to a signal-processing system. A schematic drawing of a fiber-optic pyrometer is shown in Fig. 6. Fiber-optic cables have wavelength restrictions. If we take 1 dB/m attenuation as a somewhat arbitrary spectral cutoff criterion, water-free quartz fibers transmit from about 0.5 μm to about 2.5 μm (9). Sapphire fibers transmit from 0.5 μm to 4 μm (10), and chalcogenide (As-Se-Te) fibers transmit from 3.0 μm to 9.5 μm (11). Together, these three fiber types cover the most important

Figure 6. Typical fiber-optic pyrometer.

spectral ranges of pyrometry. In principle, therefore, all these types of pyrometers can be designed as fiber-optic models.

NEW DEVELOPMENTS

Active Dual-Wavelength Pyrometers

Active pyrometry operating at one wavelength has been making very accurate temperature measurements when the target surfaces are diffuse. But there are many more applications for which the surface scattering is somewhere between specular and diffuse, and for which single-wavelength active pyrometry will therefore not work. For these cases the dual-wavelength active technique was developed (12,13).

If one assumes that the polar scattering of a target surface is wavelength independent, one can prove that a measurement of the radiances at two wavelengths and the *ratio* of retroreflectances yields the target emissivity E_1 . Since only the ratio of reflectances is needed, the method works for any polar scattering pattern. The formula for E_1 developed in Ref. 13 has the form

$$E_1 = 1 - R + RB(E_1)^n \quad (6)$$

where

$$B = [L_2(w_2)^5/c_1]/[L_1(w_1)^5/c_1]^n \quad (7)$$

$$n = w_1/w_2 \quad (8)$$

Equation (6) can be solved by successive iteration. From E_1 and L_1 follows the temperature T via the Planck equation (1).

Figure 7 shows a system demonstrated in Ref. 13. A bifurcated optical fiber is used to superimpose the illuminating and optical receiver systems. The lamp radiation is mechanically chopped and the reflected energy is synchronously amplified by a lock-in circuit so as to distinguish it from the dc radiance photo signal. The optical receiver uses a di-chroic prism beam splitter to separate the two wavelength components. Additional spectral selection is provided by filters 1 and 2, located in front of detectors D_1 , D_2 , respectively. Reflection and thermal

emission signals for both wavelengths are digitized by an ADC and applied to a PC for calculation of emissivity and temperature via equations (6), (7), and (1).

Ripple Pyrometry

Ripple pyrometry, another interesting technique is used to measure and control the temperature of silicon wafers heated by quartz-halogen lamps in various rapid thermal processors (14). The ripple method dynamically determines emittances by sensing time-dependent components in radiation from the lamps and radiation reflected by the wafer surfaces; see Fig. 8. A sapphire light probe (S_1) is used to detect radiation from a region on the wafer surface. A second sapphire light probe (S_2) is directed towards the heating lamps and measures the radiation incident on the wafer surface, including secondary reflected radiation. The radiation from sapphire probes S_1 and S_2 is coupled via optical fibers to separate photodetectors. The quartz-halogen lamps are ac powered and therefore exhibit a 120 Hz ripple on top of a dc radiance component, which gives rise to ac photosignals dI_1 and dI_2 , as well as dc photosignals I_1 and I_2 . According to Ref. 14 the wafer radiance L_w and its reflectivity r_w are related to the ac and dc signals as follows:

$$L_w/(1 - r_w) = (s_1^{-1}I_1 - s_2^{-1}RI_2)/(1 - R) \quad (9)$$

where the effective emittance $1 - R$ and reflectance R are defined in terms of the ratio of the ac components in the two detector signals, according to

$$R = (s_1/s_2)(dI_1/dI_2) \quad (10)$$

Here s_1 and s_2 are instrument constants. The left-hand side term of Eq. (9) is the blackbody temperature associated with the true wafer temperature and thus yields that temperature. This method has been used to measure wafer temperatures during rapid thermal annealing, an important technique in manufacturing microelectronic devices. Wafer annealing at a temperature of 660°C was monitored with an accuracy of better than 3°C at 1 standard deviation (15).

There are two other types of pyrometer designs which aim to eliminate the emissivity error, multiwavelength pyrometer (16) and the polaradiometer (17), which works best for specular, metallic targets. Multiwavelength systems match the radiance

Figure 7. Two-color active pyrometer. ADC, analog-to-digital converter; D_1 , D_2 , photodetectors.

Figure 8. Schematic cross-sectional view of an RTP furnace showing wafer (W), lamps (L), quartz isolation tube (Q), and optical-fiber probes for the wafer (S_1) and the lamps (S_2). Arrows indicate the directions of the radiances in the model of Eq. (1).

at three or more wavelengths to the Planck formula with some assumption about the spectral emissivity characteristic of the target surface.

The polaradiometer illuminates a specular target spot from 45° off normal with radiation from a black body while observing, from the mirror image direction, the sum of reflected and thermally emitted radiance with a polarization-analyzing optical receiver. The radiation emitted into an angle far off normal by a hot metal is such that the dominant component of polarization is E_1 (in the plane of incidence) with a lesser component E_2 (perpendicular to the plane of incidence). Since Kirchhoff's law holds for each component, the originally unpolarized black body radiation, when reflected, has R_2 as the dominant component of reflection, the lesser component R_1 . One varies the temperature of the black body illuminator, until the combined intensity of emitted and reflected radiation is the same for the two principal polarizations. At that point the temperature of the target is equal to that of the black body.

Both the multiwavelength and the polarization-compensating pyrometers are limited to very special applications, and are not really commercial at this point.

APPENDIX A. BLACKBODY CONDITIONS IN FURNACES

When making temperature measurements of objects inside furnaces, the influence of reflected radiation must be taken into account in order to determine the correct target temperature. One way to do this is to define an effective emissivity E_{eff} . Consider a hollow enclosure of arbitrary shape with a small opening (Fig. 9).

Assume now that the inside surface is at uniform, elevated temperature. We call L_{bb} the black body radiance of the surface, r the surface reflectivity, and the physical emissivity is E is unity, where once again $E = 1 - r$. Radiation from any point A on the inside surface is the sum of the thermal emission at that point, EL_{bb} , and reflected energy $r(1 - r)L_{\text{bb}}$ emanation from all other points on the internal surface. That radiation itself is of course also the sum of thermal self-emission and reflected radiation from other points on the surface, and so forth at infinitum.

The observed radiance therefore is equal to the infinite sum:

$$L_{\text{obs}} = L_{\text{bb}}(1 - r) + L_{\text{bb}}(1 - r)r + L_{\text{bb}}(1 - r)r^2 + L_{\text{bb}}(1 - r)r^3 + \dots \quad (\text{A.1})$$

Figure 9. Hollow blackbody. L , surface radiance; r , surface reflectance. The enclosure at uniform temperature emits like a blackbody independent of the physical emissivity of the inside wall material.

This equation can be written in the form

$$L_{\text{obs}} = L_{\text{bb}}(1 - r)(1 + r + r^2 + r^3 + \dots) \quad (2)$$

Noting that the sum of the infinite series inside the curly bracket equals $1/(1 - r)$, one obtains

$$L_{\text{obs}} = L_{\text{bb}}(1 - r)[1/(1 - r)] = L_{\text{bb}} \quad (3)$$

which means the total radiance emanating from the small opening is that of a black body at the temperature of the internal wall, independent of the reflectivity (emissivity) of the wall. Note that this analysis ignores the effect of radiation escaping through the opening. This is permitted if the area of the opening is small compared to the total internal wall area of the hollow space.

APPENDIX B. OUT-OF-FOCUS TARGETS

Most on-line pyrometers have a fixed focus. In general one tries to select the optics such that the target is in focus. But in many practical cases, the target ends up somewhat out-of-focus because the installation procedure is not precise. Sometimes the target distance changes such as for objects on a conveyer belt. When the instrument is calibrated by focusing at the opening of a blackbody furnace and is used in the field against a target that is out of focus, the question arises: How does this affect the calibration? Not at all! In the following we will verify by analysis this experimental fact.

If the optics is focused at distance a_1 , but the target is located at distance a_3 , the power impinging on the detector can be calculated with the help of a ray optics construction illustrated in Fig. 10. A circular detector aperture of diameter d_1 , located at image distance b_1 from the lens, corresponds to a circular target area at object distance a_1 of diameter M_1 on the other side of the lens. The object and image distances are related as

$$1/a_1 + 1/b_1 = 1/f \quad (\text{B.1})$$

where f is the focal length of the lens. The diameter M_1 is given by

$$M_1 = d_1(a_1/b_1) \quad (2)$$

The optical power passing through the detector aperture is

Figure 10. Spot diameters versus object distance. The edge ray construction is used to calculate the changes in target spot diameter and etendu.

proportional to the etendue:

$$(M_1)^2(D/a_1)^2 \quad (3)$$

where the term in the second set of parentheses represents the solid angle subtended by the lens as seen from the object plane. Imagine now that the target is moved to a new location at distance a_3 from the lens. By geometric analysis of the rays running from the edges of the lens to the edges of the target spot at a_1 , one can show that the spot diameter at distance a_3 is

$$M_3 = (a_3/a_1)(M_1 - D) + D \quad (4)$$

where D is the diameter of the lens.

Consider then a radiating disk of diameter M_3 at distance a_3 from the lens. The associated image distance b_3 on the other side of the lens is determined from

$$1/a_3 + 1/b_3 = 1/f \quad (5)$$

The image diameter

$$d_3 = d_1 + e \quad (6)$$

is larger than the detector aperture d_1 . Thus only a certain fraction of the imaged radiation passes through the aperture. A first-order approximation is to set the fraction of transmitted energy equal to

$$(d_1/d_3)^2 = [d_1/(d_1 + e)]^2 \quad (7)$$

where

$$e = (D/b_3)(b_3 - b_1) = Db_1(1/b_1 - 1/b_3) \quad (8)$$

Hence, the power passing through the aperture is proportional to

$$(M_3)^2(D/a_3)^2[d_1/(d_1 + e)]^2 \quad (9)$$

which is the etendue for an out-of-focus target.

In the following we will prove that the etendues (and hence the photosignals) for in-focus and out-of-focus targets are identical. For this purpose we may consider just the square roots of the respective etendues. Then, we normalize the aperture diameter $d_1 = 1$ in Eq. (B.9) without loss of generality. Next, we substitute e from Eq. (B.8), and M_3 from Eq. (B.4) into Eq. (B.9) and arrive at the expression:

$$D[1/a_3][(a_3/a_1)(M_1 - D) + D]/[1 + Db_1(1/b_1 - 1/b_3)] \quad (10)$$

The two rectangular brackets in the numerator of Eq. (B.10) can be consolidated and written as

$$M_1/a_1 + D(1/a_3 - 1/a_1) \quad (11)$$

From Eqs. (B.1) and (B.5) follow

$$1/a_3 - 1/a_1 = 1/b_1 - 1/b_3 \quad (12)$$

We substituted Eq. (B.12) in (B.11) and (B.10) to arrive at

$$D[M_1/a_1 + D(1/b_1 - 1/b_3)]/[1 + Db_1(1/b_1 - 1/b_3)] \quad (13)$$

In Eq. (B.13) we substitute $b_1 = a_1/M_1$ once, namely in the second square bracket before the parentheses. This results in the following expression:

$$D[M_1/a_1 + D(1/b_1 - 1/b_3)]/(a_1/M_1)[M_1/a_1 + D(1/b_1 - 1/b_3)] \quad (14)$$

Note that the terms in square brackets in the numerator and in the denominator of Eq. (B.14) cancel each other, leaving the expression $M_1(D/a_1)$. Hence, the etendue (and therefore the photosignal) for out-of-focus targets is equal to the etendue for in-focus targets. This approximation applies to cases for which the defocusing is moderate, that is where $b_3 - b_1 \ll f$.

For targets placed beyond the focal plane, the target diameter is given by

$$M_2 = (a_2/a_1)(M_1 + D) - D \quad (15)$$

A similar geometrical analysis as given in the preceding shows again that the signal for out-of-focus targets is the same as for in-focus targets. This very important feature of pyrometers is key to their use in factory application.

ACOUSTIC VARIABLES MEASUREMENT

The science and technology of acoustics encompass sound, ultrasound, and infrasound in all media. There are many specialties in acoustics as well as interrelations to other branches of engineering, physics, and chemistry. Consequently, the list of quantities and their corresponding units is rather extensive (1), including both fundamental (e.g., mass) and derived (e.g., force) physical quantities as well as measures of level (e.g., sound pressure level). This article concentrates on the measurement of variables that are peculiar to acoustics.

Acoustical variables have evolved from two general disciplines: wave theory and circuit theory. Because of this, many acoustical variables have their counterparts or analogs in electromagnetic theory, electrical-network theory, mechanics, and heat—a convenience that must be used with care. Naturally, as in other branches of engineering and physical science, variables applicable to acoustics only have been introduced. As an exact science, acoustics is relatively young; hence, its quantitative development has been primarily in terms of the metric system, which accounts for the almost exclusive use of the SI units.

MEASURABLE ATTRIBUTES OF SOUND

Sound pressure is the most important quantity in acoustics, probably because it is the attribute of sound measurable by all hearing mechanisms. The term sound pressure (or acoustic pressure) refers to the increment over ambient pressure, or excess pressure, produced by a disturbance of the medium, not to the total ambient pressure (2). Similarly, acoustic displacement refers to the net motion of the molecules of the medium, in response to the disturbing force and not to the random motion of particles when the medium is “at rest.” Another measurable quantity is the density, which has the usual definition of mass per unit volume. When a sound wave is propagated in the medium, the ambient value of density changes in proportion to the changes in pressure. Particle velocity and acceleration have the same meaning as in any mechanical system, their magnitude depending on the strength of the disturbance. Particle velocity is not to be confused with the speed of propagation of the acoustic wave, which depends entirely on the properties of the medium and environmental parameters, such as temperature. Since by their nature all of the above quantities are alternating, frequency (or period) is one of their most basic parameters. In modern acoustical practice, frequency is measured by a frequency counter or signal analyzer after the acoustic signal has been converted into electrical. The unit of frequency is the hertz, Hz. The quantities already listed are of a fundamental nature because other quantities can be derived from them. The derived quantities include intensity, impedance, and a variety of coefficients and ratios, some of which are too specialized and, hence, outside the scope of this work, and others are discussed in separate articles.

Sound Pressure and Sound Pressure Level

The American National Standard (3) defines instantaneous sound pressure as the difference between total pressure and the atmospheric static pressure that exists at a given point in space, at a particular instant of time, in a stated frequency

band. The SI unit is the pascal, Pa, which results from a 1 newton force uniformly applied over an area of 1 m². In acoustical practice, the term sound pressure or effective sound pressure is the root mean square of the instantaneous sound pressures determined over a specified time interval, at a point in space. Because of the wide range of pressures attending acoustic phenomena (from micro- to kilo-pascals), it is frequently more convenient to compare a sound pressure to some reference value, rather than state its magnitude in pascals. This ratio, converted to the logarithmic scale, is called sound pressure level in dB. It is defined as follows:

$$SPL = 10 \log \left(\frac{p}{p_{\text{ref}}} \right)^2 = 20 \log \frac{p}{p_{\text{ref}}} \quad (1)$$

The reference pressure, p_{ref} , must always be specified. The standard value for gases is 20 μPa ; for other media, $p_{\text{ref}} = 1 \mu\text{Pa}$, unless otherwise specified.

Particle Displacement, Velocity, and Acceleration

In the acoustics of fluids, the number of applications requiring a direct measurement of variables describing particle motion is very small. For instance, in the case of a loudspeaker it is the motion of the vibrating diaphragm rather than the displacement of the air particles that one measures. When particle displacement is required, it can usually be calculated from pressure measurements and the properties of the acoustic medium, especially since no simple instruments are available to perform this task. The opposite is true for solid media, where vibratory displacement, velocity, and acceleration are measured routinely by a variety of sensors and instrumentation. In terms of their relative usage in vibration measurements, accelerometers have considerable advantages over displacement and velocity sensors (4).

There are two measures of velocity of an acoustic medium: the particle velocity and the volume velocity. The particle velocity, defined at a point in the medium, is the velocity of a portion of the medium small enough that the variations of acoustic parameters within the volume of the portion can be considered infinitesimal. It is measured in m/s. The volume velocity is the volume of the medium displaced per unit time through a specified area. Thus, it is equal to the integral of the particle velocity over the area, and its unit is the cubic meter per second (5). Particle acceleration has the usual meaning of the rate of change of velocity, and is measured in m·s⁻². In the United States, acceleration is also expressed in units of g_n , the standard acceleration of free fall, equal to 9.80665 m·s⁻², and acceleration levels are often stated with reference to 1 μg . As in the case of acoustic pressure, when working with these variables, one must distinguish between instantaneous and effective root-mean-square (rms) values, which have the same meaning as for the electrical variables (6).

Measures of the Strength of an Acoustic Signal

The sound strength depends on the amount of energy carried by the wave. Two measures of this property are commonly used: the acoustic energy density flux and acoustic intensity. The energy transported by acoustic waves through a fluid medium comprises two components: the kinetic energy associated with particle motion, and the potential energy stored during compression and rarefaction of successive fluid elements. The

energy density is measured in joules per cubic meter. Because the instantaneous particle velocity and acoustic pressure are functions of both position and time, the instantaneous energy density, ϵ , is not constant throughout the fluid. Its time average, $\bar{\epsilon}$, at any point in the fluid can be expressed by a simple formula only if the relationship between particle velocity, u , and pressure, p , is known. For example, in a plane simple harmonic wave,

$$p = \rho_0 c u \quad (2)$$

hence

$$\bar{\epsilon} = \frac{1}{T} \int_0^T \epsilon dt = \frac{1}{2} \rho_0 U^2 = \frac{1}{2} \frac{P^2}{\rho_0 c^2} \quad (3)$$

where ρ_0 is the medium density, c is the speed of wave propagation, and P and U are the amplitudes of the acoustic pressure and particle velocity respectively (7). In sound fields where such relationships do not apply, pressure and velocity have to be measured by sampling over the area or volume of interest and appropriately summed. Investigation of jet noise is a good example (8).

Acoustic intensity, I , of a sound wave is defined as the mean rate of flow of energy through a unit area normal to the direction of propagation (5). Consequently, it represents the power of a sound wave incident on a unit area of a detector. However, unlike their optical counterparts, the simple acoustical detectors do not directly respond to intensity, but rather to pressure, displacement, velocity, or acceleration. But, since energy, and hence intensity, varies as the square of these quantities, one needs only to find the factor of proportionality. For example, basic acoustical theory shows that for a plane free progressive wave the intensity, I , and acoustic pressure, p , are related by the following equation:

$$I = \frac{1}{\rho_0 c} p^2 \quad (4)$$

The unit of intensity is the watt per square meter. For the calculation of intensity levels, $10^{-12} \text{ W} \cdot \text{m}^{-2}$ is often taken as the reference intensity. Measurements of acoustic intensity and acoustic energy-density flux are the subject of a separate article.

Frequency Response Functions

Acoustic variables, individually or in combination, depend on various parameters, frequency being the most common. Since most variables by their nature are phasors, they are representable by complex quantities having a real and an imaginary part or, alternately, magnitude (also called amplitude) and phase. Magnitude information is sought more often than phase; however, the dependence of both magnitude and phase on frequency are both very important characteristics of an acoustic or electro-acoustic system. Typically the magnitude is expressed in normalized form based on some convenient reference, which must be stated. Moreover, the ratio can be expressed in decibels instead of a fraction when the quantities can be related to energy or power, as was done for sound pressure level in Eq. (1). For phase, a common reference value is the phase at a specified frequency. In Fig. 1 the theoretical amplitude and phase response of a Bruel & Kjaer microphone is compared to

Figure 1. Example of a frequency-response function: relative amplitude and phase response of B&K type 4146 microphone. Solid lines: theoretical; symbols: experimental. See Ref. 9.

the measured response (9). It should also be noted that not all frequency-response functions represent ratios of the same denomination: they can, for example, be pressure-to-velocity ratios considered in the next section.

DESCRIPTIVE PARAMETERS AND FUNCTIONS

The behavior of acoustic systems is described not only by the basic variables discussed in the preceding section, but also by a collection of quantities derived from them. For a complete treatment of these parameters and functions the reader is referred to the rather extensive specialized literature, Ref. 10 being a good starting point, while in this article we consider only those deemed most important and commonly used.

Impedance

The concept of impedance was introduced into acoustics by A.G. Webster in 1919 by analogy with electrical circuits (11). Webster saw the value of extending the significance of the concept of impedance to the case of mechanical oscillations and acoustic wave propagation. The concept has been found to be of great value in both theoretical acoustics and applications. Impedance is a very useful quantity connecting the excitation and response of a system (see Fig. 2). Electrical impedance is defined as the ratio of the phasor representing an alternating voltage to the phasor representing a corresponding current (6). As such, it is a complex quantity having magnitude and phase angle (or, alternatively, a real and an imaginary part), is time invariant, but generally frequency dependent. Impedance, therefore, is one of the frequency-response functions listed in Table 1 which are used to describe the behavior of a linear system.

Before proceeding, it is proper to warn the reader of the dichotomy in choosing the sign of the reactance. It arises from the

Figure 2. Block diagram of a single input/single output system for defining frequency-response functions of Table 1. The complex function of frequency, given by the output-to-input ratio, characterizes the system.

Table 1. Frequency-Response Functions in Common Use

different representations of a traveling wave used in physics and engineering. A simple illustration readily makes this clear. Consider, for example, a plane wave of acoustic pressure, p , traveling in the direction of the x -axis. The physicist usually represents it by

$$p = P_+ e^{-i(\omega t - kx)} + P_- e^{-i(\omega t + kx)} \quad (5)$$

where P_+ and P_- are the amplitudes of the forward and backward traveling waves respectively, k is the wave number, and ω is the angular frequency of the alternating pressure. The electrical engineer prefers the following notation:

$$p = P_+ e^{j(\omega t - kx)} + P_- e^{j(\omega t + kx)} \quad (6)$$

The reason for these choices is that the physicist likes to think of the forward wave as traveling in the positive- x direction, while the engineer focuses on the phasor representation $P_+ e^{j\omega t}$. Elementary analysis (12) readily shows that the former choice ($-i$) leads to a negative sign for mass reactance and a positive sign for compliant reactance. In order to make the results of electrical circuit theory directly applicable to acoustics, the latter ($+j$) choice is followed in this article.

Types of Impedance Used in Acoustics. In accord with national and international standards, impedance of acoustic systems is specified in three different ways; hence, the type of impedance selected by the user must be carefully stated. The first of these, Z_a , is called acoustic impedance and is defined as the quotient of the sound pressure, p , on a given surface, S , divided by the volume velocity, U , through the surface:

$$Z_a = \frac{p}{Su} = \frac{p}{U} \quad (7)$$

where u is the particle velocity and S is the area. Its unit is the acoustic ohm, which has the dimensions of $\text{Pa} \cdot \text{s} \cdot \text{m}^{-3}$.

The second type of impedance is the specific acoustic impedance, Z_s , defined as the quotient of the sound pressure and the particle velocity:

$$Z_s = \frac{p}{u} \quad (8)$$

The unit is the rayl, equal to $\text{Pa} \cdot \text{s} \cdot \text{m}^{-1}$.

The third type of impedance, called the mechanical impedance, Z_m , is defined as the quotient of the force exerted on a given area and the resulting particle velocity:

$$Z_m = \frac{pS}{u} \quad (9)$$

The unit of Z_m is the mechanical ohm, equal to $\text{N} \cdot \text{s} / \text{m}$.

Each type of impedance has certain advantages in the solution of specific problems. For instance: the acoustic impedance does not vary with changes in cross section of a conduit down which a sound wave is traveling; specific acoustic impedance in a plane progressive wave is nearly the same at all points; mechanical impedance may be used directly in equivalent circuits. Moreover, like its electrical counterpart, acoustic impedance can be realized in either lumped or distributed form. When one or more dimensions of an acoustic system are not small as compared to the wavelength of sound, it is no longer possible to describe the system by lumped parameters.

Acoustic Compliance. Acoustic compliance is that parameter of an acoustical circuit which accounts for volume displacement without acceleration (5). The physical law governing the compression of a volume of acoustic medium is

$$p(t) = \frac{1}{C_a} \int U(t) dt \quad (10)$$

where $p(t)$ is the instantaneous pressure acting to compress the volume of the medium, $U(t)$ is the instantaneous volume velocity of the medium flowing into the volume, and C_a is the acoustic compliance. In the steady state of an acoustic pressure varying sinusoidally at an angular frequency ω ,

$$P = \frac{U}{j\omega C_a} \quad (11)$$

where P and U are complex rms quantities. It is evident from Eq. (11) that acoustic compliance has the units of $\text{m}^5 \cdot \text{N}^{-1}$. Note also that the acoustic impedance of a purely compliant element is

$$Z_a = -j \frac{1}{\omega C_a} \quad (12)$$

As a circuit element, acoustic compliance is a two-terminal device, but one of its terminals must always be at "ground potential," that is, one terminal is the outside of the enclosure containing the compressed medium. The reciprocal of compliance, called stiffness, is equally prevalent, the choice being a matter of convenience. Moreover, the adjective *dynamic* is sometimes used with the terms compliance and stiffness, especially in situations where the values of the static and dynamic parameters are substantially different.

Acoustic Inertia. The acoustic mass or inertance, m_a , is a quantity associated with a mass of an acoustic medium accelerated by a net force which acts to displace the medium without appreciably compressing it:

$$p(t) = m_a \frac{dU(t)}{dt} \quad (13)$$

As a consequence of this definition, the dimensions of acoustic mass are $\text{kg}\cdot\text{m}^{-4}$. In the sinusoidal steady state, the value of the parameter m_a multiplied by ω yields the magnitude of the imaginary part of the acoustic impedance resulting from the inertia or effective mass of the medium:

$$p = j\omega m_a U \quad (14)$$

As an acoustic-circuit element, acoustic mass can be realized as a tube open at both ends. The tube must have rigid walls and be short enough so that the medium in it moves as a whole without appreciable compression. Furthermore, the assumption of zero pressure at the ends requires that the tube diameter be small relative to the wavelength of sound in order to reduce its radiation impedance. The effect of the radiation impedance is to increase slightly the apparent length of the tube. One end of an acoustic mass is usually driven by a source, while the other end can be terminated in a boundless medium, a larger cavity, or a damping element.

Acoustic Resistance. Resistance may be contributed to an acoustic system by a number of different causes, but it is always associated with dissipative losses. The physical law defining acoustic resistance is

$$p(t) = R_a U(t) \quad (15)$$

Being the real part of acoustic impedance, Z_a , acoustic resistance has the same unit dimensions, $\text{Pa}\cdot\text{s}\cdot\text{m}^{-3}$, also called the acoustic ohm. In lumped form it can be realized by having the sound go through short capillary tubes or a fine-mesh screen.

The Helmholtz Resonator. A very instructive example of an acoustic system containing the three basic elements (compliance, inertance, and resistance) is provided by the Helmholtz resonator, shown in Fig. 3 alongside its electrical analog, the series RLC circuit. The lumped-parameter values can readily be calculated in terms of its dimensions and properties of the acoustic medium, as is done in Ref. 13 and other textbooks on acoustics. Thus,

$$C_a = \frac{V}{\rho_0 c^2}, \quad m_a = \frac{\rho_0 L}{S}, \quad R_a = \frac{R_r}{S^2} + R_{eq} \quad (16)$$

where R_r is the radiation resistance of the neck opening, and R_{eq} represents the effect of all damping present in the system, and all other quantities have the previously defined meaning.

Figure 3. A Helmholtz resonator consisting of acoustic compliance, mass, damping, and radiation resistance (a), and a schematic representation of its electrical equivalent (b).

Acoustic Absorption

When sound traverses matter, be it solid, liquid, or gaseous, the acoustic intensity decreases with distance. This fact is a consequence of the properties of the wave itself and the medium through which it travels. In the absence of boundaries this propagation loss is attributable mainly to spreading (e.g., the so-called inverse r^2 loss), scattering, and absorption by the medium. When boundaries are present, any diminution of intensity upon reflection from them is governed by the nature of the reflecting surfaces which in addition to presenting an impedance mismatch and absorbing acoustic energy can diffuse the acoustic field by virtue of their roughness. Absorption is a consequence, primarily, of the viscosity of the medium, and is usually accounted for by a complex value of the propagation velocity. Accordingly, the wave number must be complex also. In a boundless medium, this is accounted for by an extra factor in the spreading-loss expression. Likewise, when sound is reflected from a medium which has absorption, the transmitted and reflected waves are affected: inhomogeneous waves are produced along the boundary, and total internal reflection cannot take place (14).

Absorption Coefficient. The simplest theory of absorption yields the following expression for the acoustic pressure of a wave propagating in a viscous medium:

$$p = p_0 e^{-\alpha x} e^{j(\omega t - kx)} \quad (17)$$

where α is the absorption coefficient, x is the distance traveled by the wave, ω is the angular frequency, and k is the wave number. Accordingly, one of the standard methods of measuring sound absorption coefficient is the classical impedance-tube method (15). Yet even in this simple model, the absorption coefficient is a function of not only viscosity, but also of frequency and the speed of sound. To obtain good agreement between predicted and measured values of α , other processes may have to be built into the theoretical model. For example, in air, humidity becomes important, while in sea-water, chemical relaxation measurably affects the results at low frequencies.

An alternate definition of the sound absorption coefficient is as the fraction of the sound energy incident on a surface which is absorbed or dissipated. A convenient measure of the effectiveness of any absorptive treatment is, quite naturally, the reverberation time, that is, the time interval during which the sound is audible after its source has been turned off. Quantitatively, the reverberation time is defined as the time required for the level of the sound to drop by 60 dB.

The preceding discussion considered the effect of absorption on the propagation of sound in a definite direction. There are, however, many situations where sound is not expected to travel from one specified point to another, but rather to fill a volume of space with a uniform intensity. Such a sound field is called diffuse or reverberant, and is usually produced by multiple reflections. This process lends itself to straightforward analysis, which was originally performed by Sabine and can be found in one of several variants in most books on acoustics, for example in chapter 6 of Ref. 7. The analysis is based on a few realistic assumptions and involves the room dimensions as well as properties of the absorbers. When the average absorption coefficient, $\bar{\alpha}$, for the room is small, the Sabine formula in metric

units reads:

$$T = 0.161 \frac{V}{S\bar{\alpha}} \quad (18)$$

where T is the reverberation time, V is the room volume, and S is the area of the bounding surfaces. This formula can also be used to measure the average absorption coefficient of the room, and in turn the absorption coefficient of an individual absorber. Since

$$\bar{\alpha} = \frac{S_1\alpha_1 + S_2\alpha_2 + \cdots + S_n\alpha_n}{S_1 + S_2 + \cdots + S_n} \quad (19)$$

where S_i and α_i are corresponding areas and absorption coefficients, any α_i can be calculated if all the others are known and $\bar{\alpha}$ is measured. This is the basis of a standard method of measuring the absorption coefficient of materials.

DATA ACQUISITION, VALIDATION, AND ANALYSIS

Some of the most important measurement activities should take place before data are acquired. Planning for data acquisition and analysis should address several issues: the selection of transducers, evaluation of instruments to be used in the measurement system, measurement location and duration, and protocol for estimating uncertainties in the measurement. This is particularly important if a new method of measurement is contemplated or the procedure of a standard method is not adequately documented. Prior to data acquisition, the measurement system must undergo a complete calibration of all components as well as an end-to-end calibration of the system. The lack of a proper end-to-end electrical calibration is probably the most important source of errors in dynamic data measurements. Modern instruments, though fast and versatile, still require their user to be fully conversant with the different types of averaging, sampling rate, filtering, and statistical analysis that are available.

It is of paramount importance to carry out a reliable validation procedure prior to the analysis of data. Validation in this context means ensuring that the recorded signal correctly represents the measurand of the variable required for subsequent analysis. Signal clipping, excessive background noise, inadequate bandwidth of instrumentation, undesirable coupling, spurious signal pickup all make validation an essential component of the measurement procedure. Poor coherence between the input calibration signal and the output at the relevant channels of the data acquisition system can readily invalidate seemingly good results. The coherence function should have a value in excess of 0.99 at all frequencies of interest (16). If the practice is to record the measured signals on either analog or digital storage devices for later analysis, the signals can be validated prior to analysis. When data are acquired and analyzed on-line, complete validation prior to analysis may be impracticable; however, many of the desired data validation operations can be automated by knowledge-based computer programs, resulting in substantial reduction in time and labor (17).

Characterization of Measuring Instruments

In its elemental form, an instrument for measuring an acoustic variable is a transducer which converts acoustical energy into

another form, usually electrical. Since both the input and output measurands are phasor quantities, it is very convenient to describe performance of the transducer by its transfer function, that is the ratio of the output to the input. This function is called the sensitivity of the transducer and, like any complex quantity, may be expressed in terms of magnitude and phase, as in Fig. 1. Each of these components exhibits a definite dependence on frequency and, to a lesser extent, on environmental parameters, such as temperature, humidity, static pressure, magnetic field, and so on. For a specific application consider first the microphone, probably the most important instrument in acoustical metrology.

Measurement of Microphone Response. When a microphone is placed in a sound field, the field will be disturbed. The disturbance results in the sound pressure on the diaphragm being different from that of the undisturbed field. This pressure deviation is accounted for by the so-called free-field correction, which depends on the dimensions of the microphone, the shape (including any protective grid), and the angle of incidence of the sound. When sound arrives from many directions, the free-field response must be averaged over all directions to yield the correction necessary to compensate for the disturbing influence of the microphone. This is known as the random-incidence correction, required in situations such as machine shops and reverberation chambers. See Fig. 17.9 of Ref. 18.

There are two methods for expressing microphone frequency response: the free-field sensitivity and the pressure sensitivity. The free-field sensitivity is defined as the ratio of the microphone's electrical output to pressure applied on the diaphragm when the applied pressure is that which would exist at the microphone location in the absence of the microphone. The pressure sensitivity of a microphone is defined as the ratio of the electrical output to pressure at the diaphragm when the pressure is uniform and in phase over the entire sensing surface of the microphone. Thus, the actual response of a microphone in a sound field can be represented by the sum of its pressure response and the applicable free-field correction. The free-field and pressure responses of a microphone are identical at low frequencies, but begin to diverge at frequencies where the sound wavelength becomes comparable to the dimensions of the microphone. This information can be presented in absolute terms or relative to the value at some reference frequency.

The free-field response data is the most applicable description of microphone sensitivity as a function of frequency when the microphone is operated in an open space, several wavelengths removed from a sound source and any reflecting boundaries. The free-field correction curves are relevant only when the sound field is diffracted or reflected by the microphone body. When the microphone forms part of a natural boundary, the pressure response for sound normally incident upon the diaphragm should be used. For example, when measuring the sound pressure acting on an aircraft wing, the microphone should ideally be mounted so that its diaphragm is flush with the surface of the wing. As long as the diaphragm's input impedance is large compared with the radiation impedance loading the diaphragm, the microphone will not disturb the field, and the pressure response will adequately represent the microphone's performance. There exist standard methods of calibrating microphones, based on the above definitions, as well as the so-called pistonphone calibrator which is easier to use, but less accurate. The pistonphone calibration is most

suitable for use at frequencies where the wavelengths are very long compared with the dimensions of both the microphone and the volume of air entrapped within the pistonphone. Recently the pistonphone technique has been adapted to phase-response measurements (Chapter 9 of Ref. 18).

Regardless of the method employed the microphone response is typically displayed in two plots: amplitude vs. frequency, and phase vs. frequency, as illustrated in Fig. 1. Until the 1980s users were interested mostly in the magnitude of the microphone sensitivity, but in recent years the demand for phase response information has greatly increased, primarily because of its importance to sound intensity measurements. What is needed in practice is the relative phase response of two microphone systems, that is, the phase difference between them. Methods involving phase angles of microphone response are the subject of active research (19).

Sound-Level Meter. Although the availability of a calibrated microphone together with an amplifier and indicating meter is all that is required to construct an instrument for measuring sound pressure, such instruments have not come into common use. Instead, a related instrument with increased capabilities has evolved. It is the sound level meter, which has become the basic instrument for all sound- and noise-level measurements, particularly those made in the field. Figure 4 shows a photograph of a representative sound level meter. These instruments come in different shapes and sizes as well as signal-processing capabilities, but all comprise a microphone, an amplifier, frequency weighting networks, and an output-indicating meter, and are constructed according to national and international standards (20). The sound level meter measures the weighted sound pressure level, defined as follows:

$$SL = 10 \log \frac{(p)_{av}^2}{(p)_{ref}^2} \quad (20)$$

where p is the acoustic pressure being measured, and p_{ref} is a reference pressure, which must always be specified. Normally, for airborne sound $p_{ref} = 20 \mu\text{Pa}$, and for underwater sound, $p_{ref} = 1 \mu\text{Pa}$. Although the unit of the displayed quantity is the decibel, Eq. (20) will yield the same value as Eq. (1) only when no spectral weighting, resulting in a flat frequency response, is used. Usually, however, one of three or four (A, B, C, D) weighting characteristics is employed, which modifies the response at low frequencies, and consequently the indicated average reading. The precise dependence of these weighting networks on frequency has been standardized (20). (Originally they were intended to make the sound level meter respond approximately like the human ear to the loudness of the sounds being measured.) When reporting data in an isolated context, one should state not only the reference pressure, but also the weighting, for example: “the A-weighted $SL = 43 \text{ dB}$.”

Displacement Transducers. In acoustics it is the vibratory displacement of a surface, rather than the particle displacement of the acoustic medium, that is commonly measured. To accomplish this function a number of successful methods have been developed, using either contacting or noncontacting probes. The method of choice appears to be some type of optical interferometry, especially since the advent of affordable good-quality lasers. An interferometer, based on one of several

Figure 4. An example of the basic instrument for acoustical measurements, a sound level meter (courtesy of Brüel & Kjær Instruments, Inc.).

classical configurations, usually Michelson or Mach-Zehnder, can be custom built from off-the-shelf components, is easy to set-up, and offers the user the assurance of accuracy traceable to the wavelength of the laser light. Many systems are available commercially, and some are designed to respond to either displacement or velocity. In principle, the behavior of an interferometer does not depend on frequency, but practical instruments do have limitations on dynamic range as a function of frequency.

Velocity Transducers. Faraday's law of electromagnetic induction is the principle of the moving-coil transducer, an intrinsically velocity transducer that finds application in both microphones and vibration pickups. The voltage induced in the coil is, therefore, proportional to the relative velocity of the coil motion. An instrument that has gained great popularity in recent years is usually referred to as the laser vibrometer, marketed by manufacturers worldwide for both laboratory and field use. It operates on the Doppler principle whereby light reflected from the vibrating surface experiences a frequency shift which is proportional to the instantaneous velocity of the vibration. In the fiber-optic version the lens probe is decoupled

Figure 5. Components of a laser Doppler vibrometer, a versatile vibration measuring instrument: (a) sensor and optical fiber probes; (b) positioning stage for x , y , z , tip, and tilt adjustment (courtesy of Polytec PI, Inc.).

from the interferometer system by an optical fiber probe allowing the experimenter to reach locations not accessible otherwise. Figure 5 shows one of several commercially available laser vibrometers.

Accelerometers. Transducers that directly sense particle acceleration and that are employed to measure vibrations of solid surfaces are by far more common than those which directly sense their velocity or displacement. There exist several general types of accelerometers with many specialized implementations of each type. The piezoelectric accelerometer usually is the optimum choice because of its very wide frequency and dynamic ranges. For specific information the reader is referred to publications on vibration measurements (21,22) and product literature.

Mechanical-Impedance Heads. In the measurement of mechanical impedance, a force transducer and a velocity transducer must be used simultaneously. Some manufacturers supply devices containing a force transducer and an accelerometer, in which case the output of the latter must first pass through an integrator. Like all joint measurements, mechanical impedance measurements present special problems. The force and

velocity transducers must be much closer together than the shortest wavelength of interest in order for the two transducers to be considered as a single transduction system. Moreover, because of the complex nature of impedance, both amplitude and phase responses of each transducer must be accurately known. Mechanical resonances of structures other than the one whose impedance is measured can also affect the results.

Application of Correlation Techniques

Correlation methods originally were used to obtain statistical measures of randomly varying signals, for example to characterize the sound field in an enclosure. However, it soon became apparent that because of their inherent advantages, methods based on measuring auto- and cross-correlation of acoustic signals could rival many measurements traditionally using deterministic signals. The chief among these advantages is the ability to discriminate against noise, the latter being defined as the unwanted part of a signal. This is particularly important in situations of low signal-to-noise ratio. Another is the opportunity to design pseudo-random test signals which can generate the desired results more rapidly than measurements using deterministic signals. To illustrate we present two specific applications, particularly relevant to this article: measurements of the speed of sound and of transmission loss.

The feasibility of measuring the speed of sound follows from the form of the cross-correlation function of the same signal recorded at two points along the path of propagation. If the separation between the microphones is d , the maximum of the correlation function $R_{12}(\tau)$ occurs when the time delay $\tau = d/c$. Knowing the separation and noting the value of time delay, the speed of propagation, c , is readily obtained (23). In this respect the correlation method resembles the pulse method. They differ primarily in the nature of the test signal, which should be random and broadband for the correlation method, but for the pulse method it usually takes the form of a pulse-modulated sine wave. This method is particularly convenient for measurements in solids or liquid-filled tubes, where more than one mode may simultaneously be excited (24). As an example, consider the measurement of the speed of propagation of breathing waves in a tube with soft walls (25).

As a second example, consider the problem of measuring sound isolation and damping (23,24). The experimental set-up, shown schematically in Fig. 6, consists of a loudspeaker driven by a noise generator and power amplifier, a microphone with

Figure 6. Equipment layout diagram for the measurement of sound transmission loss of an absorptive panel by a correlation method: (1) random noise generator and amplifier; (2) loudspeaker; (3) microphones; (4) signal conditioners; (5) test panel; (6) correlator and data recorder.

signal conditioner, and a correlator. The microphone picks up the direct sound plus any reflected and diffracted sounds. All those signals have different arrival times and, consequently, the maxima of their correlation with the source signal are appropriately delayed. The transmission loss, TL, equals the difference between the first maxima of the correlation functions, $R_0(\tau)$ and $R_p(\tau)$, corresponding respectively to the direct paths in the absence and presence of the test panel. (The delay in the signal that has passed through the panel is caused by the sound speed in the panel material being slower than in air.)

$$TL = 20 \log \frac{R_0(\tau_1)}{R_p(\tau_1)} + 20 \log \frac{K_0}{K_p} \text{ dB} \quad (21)$$

where K_0 and K_p are the respective microphone-channel gains.

For accurate results it is important that the level of the transmitted sound greatly exceed the ambient noise level. The constraint on the sound source is that it have sufficient bandwidth.

Slight variations of the technique just described can be used to measure the reflection coefficient of a wall and the absorption coefficient of a reverberant room (24). It should also be noted that the correlation measurements here described, as well as all others, have their counterparts in the frequency domain and can be measured in terms of spectral functions.

ELECTROMAGNETIC-ACOUSTICAL ANALOGIES

There exist well-defined analogies between acoustical and electrical systems. Researchers familiar with electromagnetism and circuit theory can readily transfer much useful information to acoustics by a judicious application of a few rules and by keeping in mind the fundamental distinctions between sound and electromagnetic waves, particularly with regard to the variables in each system. For example, the most often measured quantity of an acoustic field, the sound pressure, is a scalar satisfying the Helmholtz equation, while the electromagnetic field quantities are vectors satisfying Maxwell's equations. These differences notwithstanding, the results of most boundary-value problems are mathematically analogous (26).

As an illustration consider the two-dimensional reflection problem. The acoustic pressure, p , can be shown (27) to be analogous to the tangential component of the electric field, E_y , and the normal component of particle velocity, u_z , to be analogous to the magnetic field, H_x , as evidenced by the following relationships:

$$u_z = \frac{1}{j\omega\rho} \cdot \frac{\partial p}{\partial z} \quad \text{and} \quad H_x = \frac{c}{j\omega\mu} \cdot \frac{\partial E_y}{\partial z} \quad (22)$$

Consequently, the reflection coefficients in the two cases differ only by their constant factors, which themselves have similar physical meaning, if one recalls that ρc and $\sqrt{\epsilon/\mu}$ characterize the wave impedance of the respective media.

The same analogy can generate other important results. For example, the well-known Snell's and Brewster's laws have identical forms in both systems. However, in three-dimensional problems, it is usually not possible to find acoustical counterparts to a general solution of Maxwell's equations, except for the so-called geometrical optics case, when Kirchhoff's approximation holds (27). It is because under that condition it is

Table 2. Electroacoustical Analogies

Acoustical	Electrical
Sound pressure	Potential difference (voltage)
Volume velocity	Electric current
Volume displacement	Electric charge
Acoustic mass (inertance)	Inductance
Acoustic compliance	Capacitance
Acoustic resistance	Resistance
Acoustic impedance	Electric impedance

permissible to treat the electromagnetic-field quantities as scalars.

The analogies extend beyond the variables describing the behavior of systems in terms of field quantities. Individual elements of electromagnetic and acoustic circuits are characterized by analogous parameters that preserve the same frequency and space dependence, for example, when mechanical impedance is represented by its electrical analog. This can be especially useful in transferring results of electric-circuit theory to the design of acoustical and vibration measurements. The formulation of circuit-theory analogies follows definite rules, discussed by Olson (28), Kurtze (29), and many others. Table 2 shows some commonly employed analogies between acoustical and electrical variables and parameters.

As an illustration consider the task of calculating the transmission loss provided by a rigid wall whose area mass density is m . This basic problem of sound transmission between two media can also be solved by the application of Thevenin's theorem, resulting in the circuit of Fig. 7(b), where acoustic pressure is the analog of voltage, and particle velocity is the analog of current (30). Accordingly,

$$u = \frac{2p_1}{2\rho c + j\omega m} \quad \text{and} \quad p_2 = p_1 \frac{2\rho c}{2\rho c + j\omega m} \quad (23)$$

Hence, the transmission loss, in decibels, becomes

$$TL = 20 \log \left| \frac{p_1}{p_2} \right| = 20 \log \sqrt{1 + \left(\frac{\omega m}{2\rho c} \right)^2} = 10 \log \left[1 + \left(\frac{\omega m}{2\rho c} \right)^2 \right] \quad (24)$$

Figure 7. Derivation of an expression for the sound transmission loss by the application of Thevenin's theorem to an equivalent electrical circuit: (a) an acoustic panel of area mass density m , placed in a medium of specific acoustic impedance ρc ; (b) an analogous electrical circuit.

While the answer originally sought is correct, the reader is cautioned not to regard the two parts of Fig. 7 as equivalent in every respect. To understand this warning, consider, for example, the particle velocities on both sides of the partition. Clearly, they are in the same ratio as the pressures since the acoustic impedances on both sides are equal to ρc , but according to the schematic diagram the same particle velocity “flows” on either side of the wall.

It likewise follows that the matrix equations representing acoustical and electric systems are analogous. This is very fortuitous because the elegant and easily understood theory of multiports can serve as the foundation for important analytical and experimental investigations. For example, two- and three-port models of microphones and accelerometers facilitate the development and implementation of methods for calibrating them. When two microphones are coupled by an acoustic medium, the system can be represented by a four-port model, which provides the basis for a reciprocity calibration of standard microphones, elucidated in chapter 4 of Ref. 18.

TIME, FREQUENCY, AND PHASE

FREQUENCY AND TIME INTERVAL METERS

Frequency and time interval meters are broadly applied to measure frequency, period, and other time-related waveform parameters, including pulse duration, rise and fall times, duty cycle, frequency or period ratio, and also the time relationships between two different signals. The most popular meters, digital meters, measure frequency and time by comparing an unknown quantity to a reference. The reference sources of these meters are usually either built-in or externally applied to control the gate which passes the signal to the counters. The reference sources can work independently of the source of absolute time reference, or they can be synchronized with the absolute time reference to measure the actual time (1). The meters with references provide very accurate readings of frequencies or time intervals, including periods. Less accurate meters with calibrated tuned circuits or frequency-to-voltage converters are applied when less precise frequency or time measurements are required.

The detailed descriptions of the frequency and time standards, frequency stability, frequency transfer, clocks, oscillators, frequency synthesis, time and frequency measurements are included in the following articles of this encyclopedia: FREQUENCY STANDARDS, CHARACTERIZATION; FREQUENCY STABILITY; CLOCKS IN TELECOMMUNICATIONS; MEASUREMENT OF FREQUENCY, PHASE NOISE AND AMPLITUDE NOISE.

The frequency and time interval measurements are interrelated, and for higher frequencies, it is more convenient and more accurate to measure frequency and calculate time parameters. For lower frequencies, the period measurements are more reliable and the frequency is then calculated.

FREQUENCY METERS

Frequency represents the count of the number of events of a repetitive waveform occurring per unit of time. The accepted unit of frequency is hertz (Hz), corresponding to the number of cycles per second. Other, larger units are kilohertz (kHz or 10^3 hertz), megahertz (MHz or 10^6 hertz), gigahertz (GHz or 10^9 hertz), and terahertz (THz or 10^{12} hertz). Smaller units are millihertz (mHz or 10^{-3} hertz) and microhertz (μ Hz or 10^{-6} hertz).

The simplest frequency meters are passive or active absorption meters, which are applied for periodic signals whose frequencies are within the radio frequencies and also within microwave frequency ranges. As shown in Fig. 1, the meter is composed of an LC resonance circuit, a diode detector, and a meter indicating the maximum reading when the circuit is tuned to the frequency of the radiating source. The frequency ranges are selected by changing the coils. The variable capacitor used to tune the LC circuit is calibrated in frequency or wavelength units. The microwave absorption meters have their resonance circuits constructed as resonating cavities with tunable dimensions.

The other absorption meters, called dip oscillators (2), involve processes of energy absorption from external sources in

order to mix them with the internally generated sine wave signals (Fig. 2). When the oscillator frequency is the same as the source frequency, the meter indicates the minimum indication since the differential frequency component is a direct current (dc) signal, which does not pass through the circuit capacitor.

Frequency and time interval measurements can be performed applying an oscilloscope. The distance considered as a period of an observed wave is computed either visually or by a built-in digital counter. The visual reading leads to large errors reaching several percent. The built-in digital meters do not differ from classical frequency counters, which are described later in this text.

The block diagram of a single-channel, low-frequency (below several hundred megahertz) counter is depicted in Fig. 3, and the typical waveforms are shown in Fig. 4. The unknown frequency signal after shaping is applied to the main gate operating like an AND logic gate, which is opened by the main gate control signal for a defined amount of time. The gate timing is selected according to the preferred setting of the time base controlled by the time base generator or clock. The unknown frequency, f_x , is then compared with a built-in standard. Through the open gate the input signal pulses are applied to the digital counter that accumulates the count and displays it according to the measurement cycles programmed in the measurement cycle control unit. The total count on n pulses refers to the main gate control pulse duration, T_{base} , so the unknown

Figure 1. Passive absorption wavemeter. (a) Capacitive-coupled. (b) Transformer-coupled.

Figure 2. Active absorption wavemeter (dip meter).

frequency is expressed as

$$f_x = \frac{n \text{ pulses}}{T_{\text{base}}} \quad (1)$$

Inaccuracy of Eq. (1) is caused by the discrete nature of pulse counting. The error involved is called ± 1 count quantization error (3). Additional errors are added due to short- and long-term instability of the time base oscillator (clock) and due to the input conditioning unit trigger uncertainty. This error can be reduced by accumulation of many measurements and averaging. The error is then reduced $\sqrt{N}$ times, where N is the number of measurement cycles.

Figure 3. Frequency mode of a counter.

Figure 4. Waves in a frequency counter.

TIME INTERVAL MEASUREMENT

To achieve time interval measurement, we change the frequency counter configuration by swapping the function of the time base with the function of the input signal. The input signal opens the main gate for the pulses applied from the time base oscillator through the time base dividers, as shown in Figs. 5 and 6. The count accumulated in the counter register multiplied by the time base period yields the unknown time interval duration:

$$T_x = nT_{\text{clk}} \quad (2)$$

The basic errors are similar to the ones discussed before. More discussion of errors is included later in the article.

Figure 5. Period measurement mode of a counter.

Figure 6. Waves in period meter.

A two-channel, start-stop, time interval meter can measure the time between two independent events or it can measure the period or the pulse width of one waveform. When two events are separately measured, the two signals are applied independently to two inputs, A and B. When a single signal is investigated, the inputs of the meter are connected together or the same signal is applied to both inputs. One input conditioning system is set to one signal slope, and the other system is set to the other slope. The process is carried out the way the previous meter operates (Figs. 7 and 8).

RATIO MEASUREMENT MODE

Two input counter shown in Fig. 9 can be used to find the ratio of two frequencies. One signal is applied to one channel and the other channel is used to gate the first signal. In all cases when the frequencies of the two channels are different, the smaller frequency signal gates the higher frequency signal. The accuracy of measurement is very critical when both frequencies are close one to each other. The effect of ± 1 count becomes then more significant and has to be reduced by averaging.

Figure 8. Waves in the time interval meter.

Figure 7. Time interval measurement mode.

RECIPROCAL COUNTER

The reciprocal counter measures the period and calculates the frequency from the period. At lower frequencies, the period measurements show smaller effect of the ± 1 count error than the frequency measurements. When the signal frequency exceeds the clock frequency, the frequency measurement is more accurate. Some reciprocal counters switch their mode from period to frequency measurement (3).

In the following sections the two major digital counter components are described. The first of them is the input conditioning unit, and the second is the time base oscillator.

INPUT CONDITIONING CIRCUIT

A block diagram of an input conditioning circuit is shown in Fig. 10 and its more detailed version of it in Fig. 11. The

Figure 9. Ratio measurement mode of a counter.

major function of the circuit is to convert a periodic input signal into a standardized rectangular pulse wave whose pulses can be counted during gating time when the frequency is measured. When the period or the time interval is measured, the pulses from the gating signals are counted during the interval defined by the input signal. The input conditioning circuit, especially the trigger amplifier and the comparator with hysteresis, provides proper shaping of the input signals of various amplitudes, shapes, and speeds in order to drive digital circuits of the meter. At the same time, the effects of the input signal impurities, noise, and interference are also minimized by the trigger and comparator circuits. An amplitude limiter and sometimes an additional fuse protect the internal circuits when the input signal levels exceed the dynamic capability of the circuit.

DIGITAL CIRCUITS OF THE COUNTERS

Typical digital parts of a modern frequency or time interval meter include specialized integrated circuits. Each of them has a high frequency oscillator, main gate, time base counter, multidecade data counter, latches, seven-segment decoders, digit multiplexers, and multidigit multiplexed LED-display drivers. The circuits require very few external components, like crystal, several resistors, capacitors, display, switches, and power supply to operate. Circuits like these are capable of measuring frequency, period, and time interval, counting pulses, and determining frequency ratio. Maximum frequency range for

Figure 10. Block diagram of an input circuit.

direct count does not exceed several tenths of MHz. Additional prescaler circuits can extend the range of operation to several hundred MHz or even above 1 GHz. Some of these circuits, like UPB582, MC12009, and CD4017, are available on the market; some are custom designed.

The details of design and analysis of various circuits, including flip-flops, counters, analog and digital comparators, analog and digital phase-locked-loop circuits, and others are given in other articles of this encyclopedia. The related articles are: ASYNCHRONOUS CIRCUITS; ASYNCHRONOUS SEQUENTIAL CIRCUITS; COMPARATOR CIRCUITS; COUNTING CIRCUITS; PHASE-LOCKED LOOPS; SEQUENTIAL CIRCUITS; and MULTIVIBRATORS.

TIME BASE OSCILLATORS

The standard oscillators are discussed in FREQUENCY STABILITY. Here, only a short introduction is included to review the limitations. The time base oscillators are usually high-stability, high-accuracy crystal oscillators. In more expensive and complex solution, the crystal oscillator is mounted in an oven to maintain constant temperature during regular operation so the temperature effects on the oscillator frequency can be minimized. This guarantees relative inaccuracies close to 1×10^{-8} while nonstabilized oscillators, even if they are temperature-compensated [temperature-controlled crystal oscillators (TCXO)], show errors at least two orders of magnitude higher. The rubidium frequency reference oscillators have much better accuracy expressed as an error close to 10^{-10} (4). Much more expensive, cesium beam frequency standards have their inaccuracies on the order of 10^{-11} . The most complex, maser oscillators, mostly used as frequency standards, reach the level of error close to 10^{-15} . The accuracy figures cited here are related to one-year change (5). Due to the cost and weight, the majority of counters employ various crystal oscillators. Many of them have temperature-stabilized ovens for better stability [oven-controlled crystal oscillators (OCXO)]. The most popular frequencies of the time base oscillators are 1 MHz and 10 MHz, which allows for establishing very convenient meter frequency ranges. High precision crystals can be produced for fundamental mode of operation up to about 300 MHz (9). Two examples of block diagrams of the crystal oscillators are shown in Fig. 12. In the first circuit [Fig. 12(a)] the quartz operates as an inductor with a high-quality factor that maintains very good frequency stability. The second circuit [Fig. 12(b)] oscillates when the quartz impedance reaches its minimum, which occurs at the frequency of series resonance. The transistor solutions are shown in Fig. 13. Lower frequency signals necessary to control the counter main gate are obtained from the frequency dividers. A typical time base divider unit is shown in Fig. 14 for both modes of operation, frequency measurement and time interval (or period) measurement.

ERRORS IN DIGITAL FREQUENCY AND TIME INTERVAL METERS

An electronic counter measuring frequency or time interval involves (1) a reference oscillator or a clock and (2) a discrete counting of pulses within a certain amount of time defined by the gating process. The types of measurement errors include the following:

Figure 11. Input circuit of the HP 5315 counter.

Figure 12. Block diagrams of crystal oscillators. (a) Collpits oscillator. (b) Crystal oscillator with quartz coupling two stages.

- Time base errors result from inaccuracy and from short-term and long-term instability of the time base oscillator.
- Trigger error, of random character, is caused by the noise. The error is a result of random instability of the gate pulse width caused by the noise of different thresholds.
- The systematic error, affecting only time interval measurements, originates in any differences between the start and stop trigger levels caused by hysteresis of the internal comparator, differences in delays, and the signal slew rate (3,6).
- The ± 1 count error is due to lack of synchronization of the gating pulses and the counted pulses.

The numerical values of different error components strongly depend upon the quality of the reference oscillator. The inaccuracies of the various clock circuits are between 10^{-8} and 10^{-6} .

The trigger error, important in the period and the time measurements, can be expressed in terms of the noise voltage levels and the triggering signal speed as follows (3):

$$e_t = \frac{\sqrt{2(e_i^2 + e_m^2)}}{dV_{in}/dT} \quad (3)$$

where

e_i is the root mean square (rms) voltage noise of the instrument input circuits,
 e_m is the rms voltage noise of the signal source limited by the counter bandwidth,
 dV_{in}/dT is the slew rate of the input signal at the trigger point.

Figure 13. Circuit implementation of crystal oscillators. (a) Collpits oscillator. (b) Crystal oscillator circuit with quartz coupling two stages.

The level of the noise component can reach several hundred microvolts. The slew rates of the pulses vary from several volts per nanosecond to several volts per microsecond or less, which leads to the error values between 1 ps and 1 ns.

The systematic error, which strongly depends on the differences in delays the trigger level settings, affects the time interval measurements when short pulses are measured. This error is usually minimized through careful design and calibration.

The ± 1 count error, which is random in nature, becomes critical when a small number of pulses is counted within the frame of the gating pulse. Then a missing or additional pulse counted creates a relative error of great significance. These error effects can be summarized as follows:

$$\frac{\Delta f}{f} = \pm \frac{1}{f_{in} T_{GATE}} \quad (4)$$

for frequency measurements and

$$\frac{\Delta T}{T} = \pm T_{clk} / T_{in} \quad (5)$$

Figure 14. Time base divider unit.

for period measurements, where f_{in} and T_{in} are frequency and period of the signal under test, T_{clk} is the time base period, and T_{GATE} is the length of the counter gating pulse.

If $f_{clk} = 10$ MHz and $f_{in} = 10$ kHz, then the frequency error equals $\pm 10^{-7}$ and $\Delta T/T = \pm 10^{-3}$ for 1 s gating pulse.

HIGH-FREQUENCY METERS

Direct measurement of frequency is now available to the frequencies close to 1 GHz. Higher-frequency measurements above 1 GHz are achieved by means of frequency down-conversion using prescaling with frequency dividers (Fig. 15), transfer oscillators (Fig. 16), and frequency translation by mixing (Figs. 17 and 18). The frequency prescaling involves a process of frequency division in the fast digital counters. Then a classical low-frequency counter measures the input signal frequency. Typical division ratios are 2 to 16. The maximum frequency divided in a stable manner can reach several gigahertz (HP 5386A). Frequencies of signals reaching 25 GHz can be measured with help of transfer oscillators. The down-conversion, which is based on the heterodyne conversion, is applied to provide measurements within the frequency ranges comparable with the previous method, although the harmonic conversion extends the frequency to millimeter wave region.

In the following sections, the transfer oscillator and frequency translation methods are discussed.

TRANSFER OSCILLATOR

The transfer oscillator provides the down-conversion to extend the frequency measurement range by means of phase locking a

Figure 15. High-frequency counter with down conversion.

low-frequency oscillator to the high-frequency repetitive input wave. The high-frequency signal of the frequency f_x is sampled every n th period at a rate adjusted by the low-frequency oscillator of the frequency f_1 , as in coherent sampling scopes. The low frequency and the number n are computed to find the high frequency (3).

Figure 16 shows the block diagram and basic waves illustrating operation of a transfer oscillator. The upper part includes the phase-locked-loop system composed of a voltage-controlled oscillator, VCO_u , producing narrow sampling pulses; sampling gate; video amplifier, acting as a low-pass filter; phase detector, comparing phases of a reference oscillator signal with a signal filtered by the video amplifier. The lower part has the same sampling gate and video amplifier as the upper channel. Additionally, the channel includes a frequency mixer with a filter, and a low-frequency counter measuring frequency and frequency ratio.

When the loop is in lock, the input signal of frequency f_x is sampled by the narrow pulses at frequency f_1 established by the voltage-controlled oscillator VCO_u . The frequency f_1 is much lower than f_x , and is adjusted automatically in the loop. The output signal of the sampler is composed of the train of samples whose amplitudes vary like the input signal amplitude but at a much lower rate (f_{u1}). This signal, filtered by the video amplifier, has the frequency close to the reference frequency oscillator f_{ur} . The signal frequencies in the lock-in conditions follow the equation

$$f_x = nf_1 - f_{ur} = nf_1 - f_{ur} \quad (6)$$

where f_1 is the sampling pulse frequency, f_x is the unknown frequency, f_{ur} is the reference frequency, which in lock equals f_{uf} , n is an integer number. Typically, $f_{ur} \ll nf_1$, so nf_1 is close to f_x . The upper channel sends the signal of frequency f_1 to the low-frequency counter shown at the bottom of Fig. 16. The counter also determines the frequency transfer coefficient, n , and finally the product of n and f_1 . The lower channel involves the same sampling processes as the upper channel but the sampling frequency is offset to $f_1 + f_0$, where f_0 is a constant frequency much lower than f_1 . By offsetting the frequency f_1 , the unknown integer number n is transferred to the frequency f_0 . The rate of the signal variations after sampling and filtering by the lower channel video amplifier is determined by the frequency f_{lf} . The frequency relations for the lower channel are as follows:

$$f_{lf} = n(f_1 + f_0) - f_x \quad (7)$$

Figure 16. Transfer oscillator. (a) Block diagram. (b) Time waves in the upper part of the circuit.

since

$$f_2 = f_1 + f_0 \quad (8)$$

hence

$$f_{1f} = nf_0 + f_{uf} = nf_0 + f_{ur} \quad (9)$$

The signal of frequency f_{1f} is mixed with the signal of frequency f_{ur} and later filtered to pass only the signal of frequency nf_0 . The low frequency counter measures the frequency ratio of nf_0 and f_0 to determine the number n , and this number determines the length of the time base to measure the frequency nf_1 . In this way all components are available to find the frequency f_x , which is expressed as

$$f_x = nf_1 - f_{ur} \quad (10)$$

In practice, $f_{ur} \ll nf_1$ and $f_x = nf_1$.

FREQUENCY TRANSLATION

Frequency translation or heterodyne down-conversion system is shown in Fig. 17. The conversion involves mixing the input signal of unknown frequency with a harmonic of the reference source. The harmonic number, k , is adjusted automatically by the processor, which registers the signal from the signal detector and tunes the YIG/PIN switch filter until harmonic frequency of f_1 from the comb generator (generator of many harmonic signals) produces a noticeable detector signal. The comb generator is controlled through the frequency by the clock reference signal of high stability. The multiplier output signal frequency is typically 100 MHz to 500 MHz. The flowchart of Fig. 18 illustrates the system operation.

A combination of both previously described methods is applied in harmonic heterodyne counters to extend the measurement range to millimeter and submillimeter waves.

Similar techniques are used in optical measurements, although all operations are performed on optical signals.

LOW-FREQUENCY METERS

A classical digital frequency counter can measure signal frequencies by determining periods. The frequencies are then computed from the periods. Another method to measure low frequencies is applied in the counters, which have frequency multipliers. Figure 19 shows the frequency multiplier with the phase-locked-loop system. The loop is in lock when the subharmonic frequency of the voltage-controlled oscillator is adjusted to satisfy the phase condition imposed by the phase detector. The phase difference between the detector input signals must be confined between 0° and 180° , with the center of 90° ; or for some detectors the range of 180° is centered at 0° in order to produce a stable dc output to control the voltage-controlled oscillator. When the frequencies are not correctly aligned, the loop is not in lock, and the output voltage of the low-pass filter oscillates. If both frequencies are closer together, the oscillating frequency falls within the low-pass filter bandwidth, and the loop "captures" the input signal to lock it. The voltage-controlled

Figure 17. High-frequency counter with frequency translation (heterodyning).

oscillator is tuned automatically by the negative feedback loop of the system.

Another interesting method is applied in low-frequency measurements of rotating objects. This method is called a stroboscopic method. The low-frequency stroboscopic method involves high-intensity flashes of light, whose frequency can be controlled by a source of very stable but adjustable frequency signals. The light is directed on the mark on the rotating object whose frequency is to be measured. For the proper frequency of the flashlight, full synchronization of the light pulses

with a rotating object produces a single motionless image of the marker. The synchronization can be also achieved at the rotational speeds, which are multiples or submultiples of the actual speed of the rotating object. Figure 20 shows the basic measuring configuration with a stroboscopic device and the most basic patterns observed for various speeds. More complex synchronization patterns are described in Ref. 7.

The high-frequency stroboscopic method is applied in sampling oscilloscopes described in OSCILLOSCOPES. The sampling scopes were also called the stroboscopic oscilloscopes during very early stages of the development of this technique.

Figure 18. Flowchart illustrating operation of a high-frequency counter with frequency translation.

EXAMPLES OF CALIBRATION OF FREQUENCY AND TIME INTERVAL METERS

The processes of calibration are usually done by comparison of time or frequency of the internal time bases of the meters with available, more accurate standards whose parameters are traceable to national or international references. The standard

Figure 19. Frequency multiplier applied in low-frequency counters.

Figure 20. A stroboscope. (a) Measurement setup. (b) Stroboscopic patterns.

frequencies and time standards are accessible directly through radio, TV, and satellite signals, including GPS (1). The inaccuracy of atomic standards used to deliver reference signals reaches the level of 10^{-13} . Commercially available built-in standards (4) have their accuracy close to 10^{-10} . The external sources serve to either introduce automatic frequency corrections or establish the error bands. The frequency comparison can be done by means of the vector voltmeters, the linear phase comparators, oscilloscopes, and frequency counters measuring the differential frequency. Figures 21 through 23 show a few examples of the measurement setups in which the frequency of the counter time base are compared with the applied reference. The oscilloscope Lissajous patterns are described in OSCILLOSCOPES. Figure 21 illustrates another oscilloscope method that registers the frequency drift of an oscillator under test in relation to the oscillator of high stability. The rate of movement of the observed wave indicates the drift. If the wave displayed on the

Figure 21. Oscilloscope tests of the frequency drift.

Figure 22. Frequency comparison testing circuit with a vector voltmeter or a phase comparator.

screen moves to the left, the tested frequency is higher than the frequency of the standard. If the wave moves right, the counter frequency is lower. Frequency error can be calculated from the speed of motion of the wave. If a 1 MHz wave is displayed using a 100 kHz reference signal for triggering and the observed drift is one full cycle per 10 s, then the frequency error 0.1 cycle per second related to 1 MHz gives 10^{-7} relative error due to the drift. The vector voltmeter method is illustrated in Fig. 22. The phases of the reference and tested signals are compared instead of frequencies. Frequency difference is calculated from the phase change $\Delta\Phi$ over a predetermined amount of time Δt according to the definition of the frequency:

$$\frac{\Delta f}{f} = \frac{\Delta\Phi}{2\pi\Delta t_f} \quad (11)$$

where. The factor 2 can be replaced with 360° when the phase is expressed in degrees.

In Fig. 23, the frequency counter is used to compare the frequency of the unit under test and the standard source frequency. The standard source clocks the frequency counter that measures the frequency counter under test.

Precision time and frequency transfer procedure at a remote site by means of the GPS system is described in (8). A site clock can be compared with universal time coordinated (UTC at NIST) anywhere in common view of a GPS satellite with NIST branch located in Boulder, Colorado.

FREQUENCY STANDARDS, CHARACTERIZATION

In this article we describe the characterization of frequency standards following the general definitions accepted by the IEEE, the International Telecommunication Union-Radiocommunications (ITU-R), and International Radio

Consultative Committee (CCIR) (1–3). In using the term “frequency standard” we imply that changes in the frequency $\Delta\nu$ of the device are small compared to its nominal frequency ν_0 and that therefore the frequency would be about the same if we were to remeasure it. This permits us to treat the variations in fractional frequency $\Delta\nu/\nu_0$ as small compared to 1, and this greatly simplifies the mathematics of the characterization. We describe what is meant by accuracy and frequency stability of a frequency standard. The variations in frequency (which define the frequency stability) can be classified into two basic types, random and systematic. To characterize the random variations in frequency the systematic effects must be removed from the data. Special statistical techniques other than the standard variance must then be used to quantify the random variations in frequency, because some of the noise processes are not stationary. By this we mean that the mean of the frequency noise changes slowly with time. As part of the statistical treatment we describe how to determine the confidence intervals for the estimates of the various types of random frequency noise.

ACCURACY

Frequency standards generate a periodic voltage signal, whose ideal frequency is defined as a specific number of oscillations per second. The second is the agreed unit of time, based on the energy difference between two energy levels of the unperturbed cesium atom (4), and it is this definition that allows the specification of accuracy of a frequency standard. Generally there will be offsets or biases in the actual frequency of a standard when compared to the ideal or defined value (according to the definition of the second) due to systematic and random effects (5–7). The *accuracy* of a frequency standard, more recently described as an uncertainty, is a measure of the confidence relative to a physical model of the standard and the evaluation process. To evaluate the accuracy of a frequency standard, a list of known sources of frequency offsets is made, and the offset or bias due to each source and its uncertainty are carefully measured or computed. The uncertainty is a proper summation of the estimates of various systematic offsets and random noise (8). For example, a frequency standard with an output frequency of 10 MHz and an uncertainty of 10^{-8} has an frequency error of $\leq \pm 0.1$ Hz.

STABILITY

Figure 1 shows the output voltage signal of an ideal *frequency standard* as a function of time. The maximum value V_0 is the nominal amplitude of the signal. The time required for the signal to repeat itself is the period T of the signal. The nominal frequency ν_0 of the signal is the reciprocal of the period, $1/T$. This voltage signal can be represented mathematically by a sine function,

$$v(t) = V_0 \sin \theta = V_0 \sin(2\pi \nu_0 t) \quad (1)$$

where the argument $\theta = 2\pi \nu_0 t$ of the sine function is the nominal phase of the signal. The time derivative of the phase θ is $2\pi \nu_0$ and is called the nominal angular frequency ω_0 . In the frequency domain, this ideal signal is represented by a delta

Figure 1. Ideal output voltage of a frequency standard.

function located at the frequency of oscillation. Since this signal is ideal, there are no known sources that cause frequency shifts, and thus its frequency is *totally* accurate and its uncertainty is 0. Furthermore, its frequency, phase, and amplitude are constant; therefore the signal is also stable in frequency, phase, and amplitude.

In real situations, the output signal of an oscillator (source) or frequency standard has noise. Such a *noisy signal* is illustrated in Fig. 2. In this example we have depicted a case where the noise power is much less than the signal power. Frequency instability is the result of fluctuations in the period of the signal. Amplitude instability is the result of fluctuations in the peak values of the voltage. Phase instability is the result of fluctuations in the zero crossings. Since the period (and thus the frequency) of the signal is related to its phase, frequency instability and phase instability are directly related.

Figure 3 shows the *power spectrum of a noisy signal* (power as a function of frequency) as measured by a spectrum analyzer. Although the maximum power occurs at the frequency of oscillation, other peaks are observed at frequencies of $2\nu_0$, $3\nu_0$, $\dots$, $n\nu_0$, where n is a positive integer. These frequencies are called *harmonics* of the fundamental frequency ν_0 ; $2\nu_0$ is the second harmonic, $3\nu_0$ is the third harmonic, and so on. The power at these harmonic frequencies will depend on the design of the source. The spectrum around the fundamental frequency displays power sidebands at frequencies above the carrier (upper sideband) and at frequencies below the carrier (lower sideband). These power sidebands are the result of phase fluctuations and amplitude fluctuations in the signal.

Figure 2. Output voltage of a noisy signal.

Figure 3. Power spectrum of a noisy signal.

While the power spectrum gives an idea of the total noise of a signal, it does not give information about the relative magnitude of its phase instabilities and amplitude instabilities. Furthermore, at frequencies close to ν_0 it is difficult to separate the noise power from the power of the fundamental frequency. Therefore, special measurement techniques are needed to measure phase instabilities and amplitude instabilities in sources.

A *noisy signal* can be mathematically represented by

$$v(t) = [V_0 + \epsilon(t)] \sin[2\pi\nu_0 t + \phi(t)] \quad (2)$$

where $\epsilon(t)$ represents amplitude fluctuations (amplitude deviation from the nominal amplitude V_0) and $\phi(t)$ represents phase fluctuations (phase deviation from the nominal phase $2\pi\nu_0 t$). (1). The instantaneous frequency of this signal is defined as

$$\nu(t) = \frac{1}{2\pi} \frac{d}{dt} (\text{phase}) = \nu_0 + \frac{1}{2\pi} \frac{d}{dt} \phi(t) \quad (3)$$

Frequency fluctuations refer to the deviation $\nu(t) - \nu_0$ of the instantaneous frequency from the nominal frequency. Fractional frequency fluctuations, denoted as $y(t)$, refer to frequency fluctuations normalized to ν_0 ; that is,

$$y(t) = \frac{\nu(t) - \nu_0}{\nu_0} = \frac{1}{2\pi\nu_0} \frac{d}{dt} \phi(t) \quad (4)$$

Equation (4) indicates that there is a direct relation between phase fluctuations and fractional frequency fluctuations. Therefore, if a signal exhibits a certain amount of phase fluctuation, it also exhibits frequency fluctuation given by Eq. (4). The *time deviation* $x(t)$ of a signal is the integral of $y(t)$ from 0 to t . Thus one can write

$$y(t) = \frac{d}{dt} x(t) \quad (5)$$

The frequency stability of a frequency standard is affected by random noise processes and by systematic, deterministic changes. Systematic effects often dominate the frequency stability in nonlaboratory environments. The sensitivity of the standard to temperature, humidity, atmospheric pressure, magnetic field, and radiation may play a role (9–11). Generally, frequency (and thus phase) stability is divided into three regions: short-term, medium-term, and

long-term stability. (Though the term frequency stability is used throughout most of the literature, the term actually refers to instabilities in the frequency.)

Short-term frequency stability refers to the random, nonsystematic fluctuations that are related to the signal-to-noise ratio of the device. In quartz crystal resonators this refers to the region dominated by white phase noise, where the time between observed frequencies (sample time) is less than a second. In atomic frequency standards the short-term stability also includes white frequency noise and extends to sampling times of several minutes.

Medium-term frequency stability refers to the region where flicker noise dominates. The sampling time characteristic of this region is a function of the type of frequency standard. Short-term and medium-term frequency stability can be characterized either in the frequency domain or in the time domain, after known systematic effects have been removed. Frequency-domain characterization and measurements are generally used when the sample time of interest is less than a second. For sampling times longer than a second, time-domain measurements are used to characterize frequency stability.

Long-term frequency stability includes random-walk frequency-noise processes in addition to systematic, deterministic changes in frequency observed when the sampling time is long. The long-term, systematic frequency change is called *frequency drift* (2,12). Drift includes frequency changes due to changes in the components of the source in addition to those due to external parameters such as temperature, humidity, pressure, magnetic field, and radiation (9–11). *Frequency aging*, on the other hand, refers to the long-term systematic frequency change due to changes in the components of the source, independent of parameters external to the source (2,12).

Frequency-Domain Characterization

Phase fluctuations in the frequency domain, or *phase modulation* (PM) noise, are characterized by the power spectral density (PSD) of the phase fluctuations, given by (13)

$$S_\phi(f) = \mathcal{F}[\mathcal{R}_\phi(\tau)] = \int_{-\infty}^{\infty} \mathcal{R}_\phi(\tau) e^{-j\omega\tau} d\tau \quad (6)$$

where $\mathcal{F}[\]$ is the Fourier transformation and $\mathcal{R}_\phi(\tau)$ is the autocorrelation function of the phase fluctuations, given by

$$\mathcal{R}_\phi(\tau) = \langle \phi(\tau)\phi(t-\tau) \rangle \quad (7)$$

A more practical definition of $\text{PSD}[\phi(t)]$ is

$$S_\phi(f) = \text{PSD}[\phi(t)] = [\phi(f)]^2 \frac{1}{\text{BW}} \quad (8)$$

where $[\phi(f)]^2$ is the mean squared phase deviation at an offset frequency f from the frequency ν_0 (called the carrier in this context), and BW is the bandwidth of the measurement system (1,13–15). The offset frequency f is also called the Fourier frequency. The units for $S_\phi(f)$ are rad^2/Hz . Equation (8) is defined for $0 < f < \infty$; nevertheless it includes fluctuations from the upper and lower sidebands and thus is a double-sideband measure.

The PM noise measure recommended by the IEEE (1,14,15) is $\mathcal{L}(f)$, defined as

$$\mathcal{L}(f) \equiv \frac{S_\phi(f)}{2} \quad (9)$$

At Fourier frequencies far from the carrier frequency, where the integrated PM noise from ∞ to f (the Fourier frequency) is less than 0.1 rad^2 , $\mathcal{L}(f)$ is equal to the single-sideband phase noise. The units for $\mathcal{L}(f)$ are decibels below the carrier in a 1 Hz bandwidth (dBc/Hz).

Frequency fluctuations in the frequency domain, or *frequency modulation* (FM) noise, are characterized by the power spectral density of the fractional frequency fluctuations, given by

$$S_y(f) = \text{PSD}[y(t)] = [y(f)]^2 \frac{1}{\text{BW}} \quad (10)$$

where $y(f)^2$ represents the mean squared fractional frequency deviation at an offset (Fourier) frequency f from the carrier (1,13–15). $S_y(f)$ is defined for Fourier frequencies $0 < f < \infty$, and its units are inverse hertz.

The conversion between $S_y(f)$ and $S_\phi(f)$ can be obtained from Eq. (4). Applying the Fourier transformation to both sides of Eq. (4), squaring, and dividing by the measurement bandwidth results in

$$S_y(f) = \left(\frac{1}{2\pi\nu_0} \right)^2 (2\pi f)^2 S_\phi(f) = \left(\frac{f}{\nu_0} \right)^2 S_\phi(f) \quad (11)$$

Amplitude fluctuations in the frequency domain, or *amplitude modulation* (AM) noise, are characterized by the power spectral density of the fractional amplitude fluctuations, given by

$$S_a(f) = \text{PSD} \left[\frac{\epsilon(t)}{V_0} \right] = \left(\frac{\epsilon(f)}{V_0} \right)^2 \frac{1}{\text{BW}} \quad (12)$$

where $\epsilon(f)^2$ represents the mean squared amplitude deviation at an offset frequency f from the carrier (1). $S_a(f)$ is defined for Fourier frequencies $0 < f < \infty$, and its units are inverse hertz.

In free-running sources, the FM noise is usually modeled by the sum of five different power laws or noise types as

$$S_y(f) = \sum_{\gamma=-2}^2 h_\gamma f^\gamma = h_{-2} f^{-2} + h_{-1} f^{-1} + h_0 f^0 + h_1 f^1 + h_2 f^2 \quad (13)$$

where $h_{-2} f^{-2}$ represents random-walk frequency noise, $h_{-1} f^{-1}$ represents flicker frequency noise, $h_0 f^0$ represents white frequency noise, $h_1 f^1$ represents flicker phase noise, and $h_2 f^2$ represents white phase noise. Similarly, the PM noise can be modeled by

$$S_\phi(f) = \sum_{\beta=-4}^0 k_\beta f^\beta = k_{-4} f^{-4} + k_{-3} f^{-3} + k_{-2} f^{-2} + k_{-1} f^{-1} + k_0 f^0 \quad (14)$$

Figure 4. PM and FM noise characteristics of a source.

where $k_{-4}f^{-4}$ represents the random-walk frequency noise, $k_{-3}f^{-3}$ represents flicker frequency noise, $k_{-2}f^{-2}$ represents white frequency noise, $k_{-1}f^{-1}$ represents flicker phase noise, and k_0f^0 represents white phase noise. Notice that $S_\phi(f)$ and $S_y(f)$ have different slopes for a specific type of noise, as implied by Eq. (11). Equation (11) can be used to obtain the conversion between the $S_\phi(f)$ and $S_y(f)$ coefficients, yielding

$$k_\beta = v_o^2 h_\gamma \quad \text{for} \quad \beta = \gamma - 2 \quad (15)$$

Figure 4 shows the common noise types characteristic of the PM noise and the FM noise of a source (1,14–17). Usually a source exhibits two or three of the noise types shown in the plots (17).

The AM noise of a source can typically be modeled by the sum of three different power laws or noise types:

$$S_a(f) = \sum_{\gamma=-2}^0 h_\gamma f^\gamma = h_{-2}f^{-2} + h_{-1}f^{-1} + h_0f^0 \quad (16)$$

where $h_{-2}f^{-2}$ represents random-walk amplitude noise, $h_{-1}f^{-1}$ represents flicker noise, and h_0f^0 represents white amplitude

Figure 5. AM noise characteristics of a source.

noise (18). Figure 5 shows the common noise types characteristic of the AM noise of a source.

Upper and lower PM sidebands are always equal and 100% correlated. Likewise the upper and lower AM sidebands are always equal and 100% correlated. This is true even when the RF spectrum is not symmetric about the carrier (18a). The phase between AM and PM noise varies randomly with time for broadband additive noise (18a).

Time-Domain Characterization

In the time domain, the *fractional frequency stability* of a signal is usually characterized by the Allan variance, a type of two-sample frequency variance given by (1,13–15)

$$\sigma_y^2(\tau) = \frac{1}{2} (\bar{y}_{i+1} - \bar{y}_i) \quad (17)$$

where $\bar{y}_i$ is the average fractional frequency of interval i given by

$$\bar{y}_i = \frac{1}{\tau} \int_{t_i}^{t_i+\tau} y(t) dt = \frac{1}{\tau} [x(t_i + \tau) - x(t_i)] = \frac{1}{\tau} (x_{i+1} - x_i) \quad (18)$$

In practical situations only a finite number of fractional frequency samples are available, and the Allan variance is approximated by

$$\sigma_y^2(\tau) \approx \frac{1}{2(M-1)} \sum_{i=1}^{M-1} (\bar{y}_{i+1} - \bar{y}_i)^2 \quad (19)$$

where $M = N - 1$ is the number of frequency samples (N is the number of time samples) (1,14,15). The Allan variance can also be expressed in terms of time samples using $\bar{y}_i = (x_{i+1} - x_i)/\tau$:

$$\sigma_y^2(\tau) \approx \frac{1}{2(N-2)\tau^2} \sum_{i=1}^{N-2} (x_{i+2} - 2x_{i+1} + x_i)^2 \quad (20)$$

The square root of the Allan variance is called the Allan deviation, $\sigma_y(\tau)$.

When time samples are taken every τ_0 seconds, the Allan variance can be computed for several sampling times $\tau = n\tau_0$ where $n > 0$. For $n > 1$, overlapped samples can be used to compute σ_y^2 as shown in Fig. 6, providing better confidence

Figure 6. Computation of $\{\bar{y}_i\}$ for the overlapped Allan variance and $n = 2$.

intervals (1,19). An expression for the fully overlapped Allan variance can be derived using Fig. 6 and Eq. (19). For $\tau = n\tau_0$ Eq. (19) becomes

$$\sigma_y^2(\tau) \approx \frac{1}{2(M-2n)} \sum_{i=1}^{M-2n} (\bar{y}_{i+n} - \bar{y}_i)^2 \quad (21)$$

which can also be expressed in terms of time-domain data by substituting $\bar{y}_i$ for $(x_{i+n} - x_i)/n\tau_0$:

$$\sigma_y^2(\tau) \approx \frac{1}{2(N-2n)\tau^2} \sum_{i=1}^{N-2n} (x_{i+2n} - 2x_{i+n} + x_i)^2 \quad (22)$$

Figure 7(a) shows a log-log plot of the Allan variance as a function of the sampling time τ for a source that exhibits all five common noise types. The slopes of the white PM noise and the flicker PM noise are the same; therefore these two noise types cannot be separated using this plot. The Allan variance can often be modeled by the sum of four different power laws:

$$\sigma_y^2(\tau) = \sum_{\mu=-2}^1 p_\mu \tau^\mu = p_{-2}\tau^{-2} + p_{-1}\tau^{-1} + p_0\tau^0 + p_1\tau^1 \quad (23)$$

where $p_{-2}\tau^{-2}$ represents white phase and flicker phase noise, $p_{-1}\tau^{-1}$ represents white frequency noise, $p_0\tau^0$ represents flicker frequency noise, and $p_1\tau^1$ represents random walk frequency noise.

When the dominant noise type in the short term is flicker PM or white PM, the modified Allan variance can be used to improve the estimate of the underlying frequency stability of the sources (1,14,20). Here a new series $\{\bar{x}_i\}$ is created by averaging n adjacent phase (time) measurements of duration τ_0 . The average fractional frequencies are computed from the $\{\bar{x}_i\}$, as illustrated in Fig. 8. For N time samples and $\tau = n\tau_0$, the resulting modified Allan variance is

$$\text{Mod } \sigma_y^2(\tau) \approx \frac{1}{2(N-3n+1)} \sum_{i=1}^{N-3n+1} (\bar{y}'_{i+n} - \bar{y}'_i)^2 \quad (24)$$

Equation (24) can also be expressed in terms of the initial time-domain data $\{x_k\}$:

$$\begin{aligned} \text{Mod } \sigma_y^2(\tau) &\approx \frac{1}{2\tau^2 n^2 (N-3n+1)} \sum_{j=1}^{N-3n+1} \left[\sum_{i=j}^{n+j-1} (x_{i+2n} - 2x_{i+n} + x_i) \right]^2 \\ &\quad (25) \end{aligned}$$

(a)

(b)

Figure 7. $\sigma_y^2(\tau)$ and $\text{Mod } \sigma_y^2(\tau)$ for the five noise types.

where

$$\bar{y}'_i = \frac{\bar{x}_{i+n} - \bar{x}_i}{\tau} \quad (26)$$

and

$$\bar{x}_i = \frac{\sum_{k=0}^{n-1} x_{i+k}}{n} \quad (27)$$

$$\bar{x}_i = x_{i+2} + x_{i+1} + x_i$$

Figure 8. Computation of $\{\bar{x}_i\}$ and $\{\bar{y}'_i\}$ for the Modified Allan variance and $n = 3$.

Figure 9. Ratio of the modified Allan variance to the Allan variance, $R(n) = [\text{Mod } \sigma_y^2(\tau)]/\sigma_y^2(\tau)$, as a function of n (15). $\tau = n\tau_0$.

Here $\bar{x}_i$ is the phase (time) averaged over n adjacent measurements of duration τ_0 . Thus $\text{Mod } \sigma_y(\tau)$ is proportional to the second difference of the phase averaged over a time $n\tau_0$. Viewed from the frequency domain, $\text{Mod } \sigma_y(\tau)$ is proportional to the first difference of the frequency averaged over n adjacent samples. The square root of the modified Allan variance is called the modified Allan deviation $\text{Mod } \sigma_y(\tau)$.

Figure 9 shows the ratio $R(n) = [\text{Mod } \sigma_y^2(\tau)]/\sigma_y^2(\tau)$ as a function of n for all five types of noise processes (15). For random-walk FM, flicker FM, and white FM the ratio is constant for $n \geq 5$. Therefore, $\text{Mod } \sigma_y^2(\tau)$ and $\sigma_y^2(\tau)$ have the same slope for these noise types. For white PM noise ($\alpha = 2$), the slope is $-1/n$; therefore the slope of $\text{Mod } \sigma_y^2(\tau)$ is equal to the slope of $\sigma_y^2(\tau)$ divided by τ . Finally, for flicker PM noise the ratio asymptotically reaches $3.37/(1.04 + 3 \ln \omega_h \tau)$. In this case and for $n > 10$, the slope of $\text{Mod } \sigma_y^2(\tau)$ is approximately τ^{-1} . Figure 9 also shows that $\text{Mod } \sigma_y^2(\tau)$ is considerably smaller than $\sigma_y^2(\tau)$ for white PM and flicker PM noise. Not only does $\text{Mod } \sigma_y^2(\tau)$ provide a different slope for white PM noise and flicker PM noise, allowing the separation of the two noise processes (see Fig. 7b); it can also speed the stability measurements. If a system is limited by white and flicker PM noise at short average times, using $\text{Mod } \sigma_y^2(\tau)$ reduces the measurement time required to observe white FM, flicker FM, and random-walk FM at longer averaging times, in comparison with that required when using $\sigma_y^2(\tau)$ (15).

At long averaging times when the ratio $N\tau_0/(2n\tau_0)$ is close to 1, the Allan variance has a bias related to its insensitivity to odd noise processes in the phase (time) fluctuations (odd with respect to the midpoint). In these situations an extension of the Allan variance that removes this bias can be used to characterize the frequency stability of a source. This variance, $\sigma_{y,\text{TOTAL}}^2(\tau)$, is obtained by extending the $\{x_i\}$ in both directions and then computing the Allan variance from the new $\{x'_i\}$

sequence (21–23). Figure 10 illustrates this extension of $\{x_i\}$: on the left side the extension is the inverted mirror image of $\{x_i\}$ with respect to x_1 ; on the right side it is the inverted mirror image of $\{x_i\}$ with respect to x_N . How far this extension depends on the maximum value n_m of n . For N time data points, n_m is the integer part of $(N-1)/2$. The far-left data point is $x'_{2-n_m} = 2x_1 - x_{n_m}$; the far-right data point is $x'_{N+n_m} - 1 = 2x_N - x_{N-n_m} + 1$. Thus $\sigma_{y,\text{TOTAL}}^2(\tau)$ is given by

$$\hat{\sigma}_{y,\text{TOTAL}}^2(\tau) = \frac{1}{2(N-2)} \sum_{i=2}^{N-1} (\bar{y}_i - \bar{y}_{i-n})^2 \quad (28)$$

Equation (28) can be expressed in terms of $\{x'_i\}$ using $\bar{y}'_i = (x'_{i+n} - x'_i)/\tau$ as

$$\hat{\sigma}_{y,\text{TOTAL}}^2(\tau) = \frac{1}{2\tau^2(N-2)} \sum_{i=2}^{N-1} (x'_{i-n} - 2x'_i + x'_{i+n})^2 \quad (29)$$

For a detailed description of $\sigma_{y,\text{TOTAL}}^2(\tau)$ see Refs. 21–23.

Figure 10. Extension of $\{x_i\}$ for $\sigma_y^2(\tau)$.

CONVERSION BETWEEN TIME-DOMAIN MEASURES AND FREQUENCY-DOMAIN MEASURES

Frequency-domain data $S_\phi(f)$ can be converted to time-domain data $\sigma_y^2(\tau)$ using the relation (1,24)

$$\sigma_y^2(\tau) = \frac{2}{(\pi \nu_0 \tau)^2} \int_0^{f_h} S_\phi(f) \sin^4(\pi f \tau) df \quad (30)$$

Equation (30) is derived by expressing both $S_\phi(f)$ and $\sigma_y^2(\tau)$ in terms of the autocorrelation function $\mathcal{R}_\phi(\tau)$ of the random process $\phi(t)$ and then combining the two expressions to cancel $\mathcal{R}_\phi(\tau)$ (13). Similarly,

$$\sigma_y^2(\tau) = \frac{2}{(\pi \tau)^2} \int_0^{f_h} S_y(f) \frac{\sin^4(\pi f \tau)}{f^2} df \quad (31)$$

Expressions for $\text{Mod } \sigma_y^2(\tau)$ (15,24), obtained using a similar procedure, are

$$\text{Mod } \sigma_y^2(\tau) = \frac{2}{n^4(\pi \nu_0 \tau_0)^2} \int_0^{f_h} \frac{S_\phi(f) \sin^6(\pi \tau f)}{\sin^2(\pi \tau_0 f)} df \quad (32)$$

$$\text{Mod } \sigma_y^2(\tau) = \frac{2}{n^4(\pi \tau_0)^2} \int_0^{f_h} \frac{S_y(f) \sin^6(\pi \tau f)}{f^2 \sin^2(\pi \tau_0 f)} df \quad (33)$$

The inclusion of f_h as the upper limit of the integral assumes that the term inside the integral is multiplied or “filtered” by an infinitely sharp low-pass filter with cutoff frequency f_h . Table 1 shows the results of Eqs. (31) and (33) for the five types of noise for $2\pi f_h \tau \gg 1$ (1,14–16,24). The results will depend on the type of filter assumed. While an infinitely sharp filter was assumed in Eqs. (30)–(33), actual measurement systems have different filter response.

Expressions have also been derived for a single-pole filter (15,25,26). These expressions, along with those in Table 1, constitute the boundaries for $\sigma_y^2(\tau)$ and $\text{Mod } \sigma_y^2(\tau)$, given a specific PSD of phase fluctuations (15). For this reason it is important to specify the filter frequency response, including the high cutoff frequency, when specifying the Allan and modified Allan variances of a source.

Generally, conversion from $\sigma_y^2(\tau)$ or $\text{Mod } \sigma_y^2(\tau)$ to the frequency domain is not possible, unless specific information about the noise characteristics is known. Greenhall demonstrated that several different spectral densities of random processes can have the same Allan variance (27). However, in the case where the spectral density follows the noise model in Eqs. (13)–

(14), a one-to-one correspondence between $S_\phi(f)$ and $\sigma_y^2(\tau)$ and $\text{Mod } \sigma_y^2(\tau)$ is found, except that for white PM and flicker PM noise $\sigma_y^2(\tau)$ exhibits the same slope, corresponding to τ^{-2} . Often, uniqueness fails more generally. Some sources have internal phase-locked loops, and their noise spectra deviates from the model in Eqs. (13)–(14) (28); others exhibit 60 Hz and other peaks that will affect $\sigma_y^2(\tau)$ (16,29). Generally, multivariate analysis should be used to obtain frequency-domain coefficients for each type of noise from time-domain data (30).

CONFIDENCE INTERVALS FOR $\sigma_y^2(\tau)$ AND $\text{Mod } \sigma_y^2(\tau)$

The Allan variance is defined as the first difference of average fractional frequencies, averaged over an infinite time. Since only a finite number M of frequency samples can be taken, we can only estimate the Allan variance and deviation, and the confidence of this estimate depends on the number of samples.

A simple method to obtain confidence intervals is to use the chi-squared distribution function. The Allan variance has a chi-squared distribution function given by

$$\chi^2 = \text{df} \frac{\hat{\sigma}_y^2(\tau)}{\sigma_y^2(\tau)} \quad (34)$$

where df is the number of degrees of freedom (16). The Allan variance is the sum of the squares of the first differences of adjacent fractional frequency values. If all the first-difference values were independent, then the number of degrees of freedom would be equal to the number of first difference values. This is not the case, and thus other procedures have been used to compute the number of degrees of freedom for $\sigma_y^2(\tau)$ (16). Table 2 shows analytical (empirical) equations that approximate the number of degrees of freedom for the fully overlapped Allan variance (16). The equation depends on the noise type. For nonoverlapped estimates, n in Table 2 is equal to 1, and N refers to the *equivalent* number of time samples for $\tau = n\tau_0$ given by $\text{Int}((N-1)/n) + 1$, where $\text{Int}(\)$ refers to the integer part.

Usually a $(p \times 100)\%$ confidence interval is computed, where p is the probability that the true Allan variance or Allan deviation is within the computed confidence interval. The $(p \times 100)\%$ confidence interval for the overlapped Allan

Table 1. Conversion Factors for $\sigma_y^2(f)$ and $\text{Mod } \sigma_y^2(f)$ (1, 14–16, 24)

Noise Type	$S_y(f)$	$\sigma_y^2(f)$	$\text{Mod } \sigma_y^2(f)$
Random walk frequency	$h_{-2}f^{-2}$	$(2\pi^2\tau/3)h_{-2}$	$5.42h_{-2}\tau$
Flicker frequency	$h_{-1}f^{-1}$	$(2 \ln 2)h_{-1}$	$0.936h_{-1}$
White frequency	h_0f^0	$h_0/2\tau$	$h_0/4\tau$
Flicker phase	h_1f^1	$\frac{1.038 + 3 \ln(\omega_0\tau)}{4\pi^2} h_1 \frac{1}{\tau^2}$	$\frac{3.37}{4\pi^2} h_1 \frac{1}{\tau^2}$
White phase	h_2f^2	$\frac{3f_h}{4\pi^2} h_2 \frac{1}{\tau^2}$	$\frac{3f_h}{4\pi^2} h_2 \frac{1}{n\tau^2}$

Table 2. Empirical Equations for the Number of Degrees of Freedom When Computing Confidence Intervals for the Overlapped Allan Variance (16)

Noise Type	α	No. of Degrees of Freedom
White phase	-2	$\frac{(N+1)(N-2n)}{2(N-n)}$
Flicker phase	-1	$\exp \left[\ln \left(\frac{N-1}{2n} \right) \ln \left(\frac{(2n+1)(N-1)}{4} \right) \right]^{1/2}$
White frequency	0	$\left(\frac{3(N-1)}{2n} - \frac{2(N-2)}{N} \right) \frac{4n^2}{4n^2+5}$
Flicker frequency	+1	$\frac{2(N-2)^2}{2.3N-4.9}$ for $n=1$ $\frac{5N^2}{4n(N+3n)}$ for $n \geq 2$
Random-walk frequency	+2	$\frac{N-2}{n} \frac{(N-1)^2 - 3n(N-1) + 4n^2}{(N-3)^2}$

Table 3. Confidence Intervals for the Nonoverlapped and Fully Overlapped $\sigma_y(\tau)$ (16) and for the Fully Overlapped Mod $\sigma_y(\tau)$ (31–33)^a

n	Noise Type	Confidence Interval (%)					
		Nonoverlapped $\sigma_y(\tau)$		Fullyoverlapped $\sigma_y(\tau)$		Fullyoverlapped Mod $\sigma_y(\tau)$	
		–	+	–	+	–	+
2	White PM	4.1	4.8	2.9	3.2	3.1	3.4
8		7.7	10.1	2.9	3.2	5.2	6.1
32		13.6	23.1	3.0	3.4	9.7	14
2	Flicker PM	3.7	4.3	2.9	3.1	3.0	3.3
8		7.1	9.0	3.6	4.0	5.7	6.8
32		12.7	20.7	5.2	6.1	11	16
2	White FM	3.6	4.0	2.8	3.0	3.0	3.2
8		6.8	8.6	4.8	5.6	5.8	7.0
32		12.5	20.1	8.8	12	11	16
2	Flicker FM	3.2	3.5	2.6	3.0	2.9	3.2
8		6.1	7.4	5.1	6.0	5.8	7.1
32		11.1	16.8	9.9	14	11	16
2	Random-walk FM	3.0	3.3	3.0	3.3	3.2	3.5
8		5.7	6.8	5.7	7.0	6.4	8.0
32		10.4	15.2	11	16	12	19

^a Confidence intervals for the nonoverlapped $\sigma_y(\tau)$ were obtained using df in Table 2 (16). The degrees of freedom used for the fully overlapped $\sigma_y(\tau)$ were computed using numerical methods and are approximately equal to those obtained using Table 2 (16, 19). Confidence intervals for the fully overlapped Mod $\sigma_y(\tau)$ were obtained from Ref. 33. $N = 1025$.

variance is given by

$$\chi^2 \left(\frac{1-p}{2} \right) < df \frac{\hat{\sigma}_y^2(\tau)}{\sigma_y^2(\tau)} < \chi^2 \left(p + \frac{1-p}{2} \right) \quad (35)$$

$$\frac{df}{\chi^2 \left(p + \frac{1-p}{2} \right)} \hat{\sigma}_y^2(\tau) < \sigma_y^2(\tau) < \frac{df}{\chi^2 \left(\frac{1-p}{2} \right)} \hat{\sigma}_y^2(\tau) \quad (36)$$

where the chi-squared value $\chi^2(C)$ for $(p \times 100)\%$ confidence can be obtained from chi-squared distribution tables or from several computer programs. The $(p \times 100)\%$ confidence interval for the Allan deviation is

$$\sqrt{\frac{df}{\chi^2 \left(p + \frac{1-p}{2} \right)}} \hat{\sigma}_y(\tau) < \sigma_y(\tau) < \sqrt{\frac{df}{\chi^2 \left(\frac{1-p}{2} \right)}} \hat{\sigma}_y(\tau) \quad (37)$$

The chi-squared distribution can also be used to find the confidence intervals for Mod $\sigma_y^2(\tau)$.

Walter (31) and Greenhall (32) have derived expressions for the number of degrees of freedom of Mod $\sigma_y^2(\tau)$ using different procedures. These expressions are complicated and will not be presented here. The two methods yield similar results (33). Table 3 shows the confidence intervals for $\sigma_y(\tau)$ with no overlap and full overlap (16,19), and for Mod $\sigma_y(\tau)$ (31–33) for the five noise types. In general, the confidence intervals for the fully overlapped $\sigma_y(\tau)$ are smaller than those for the nonoverlapped $\sigma_y(\tau)$. For random-walk FM noise, the confidence intervals for the nonoverlapped and the fully overlapped $\sigma_y(\tau)$ are approximately the same, although Table 3 shows a small degradation when using fully overlapped estimates. This degradation is due to the approximations used in the analytical expressions. Table 3 also shows that the confidence intervals for the fully overlapped Allan deviation are smaller than the ones for the fully overlapped modified Allan deviation. Nevertheless, the modified deviation is generally smaller than the Allan deviation, and thus the absolute confidence intervals for the two are similar.

FREQUENCY STABILITY

Stable and spectrally pure signal generators have been widely employed in various fields of science and technology such as physics, high precision frequency standards, fundamental metrology, telecommunication systems, space missions, radars, and broadcasting. In addition to the inherent fluctuations in the output signal, almost all signal generators are influenced to some extent by their environment, such as changes in ambient temperature, supply voltage, magnetic field, barometric pressure, humidity, and mechanical vibration. These perturbations manifest themselves as noise in frequency or phase of the output signals and become the limiting factor in various applications. Therefore, it is of fundamental importance to characterize the frequency fluctuations in the output signal using a common measure as well as to reduce these fluctuations to an acceptable level.

Extensive research efforts have been devoted to the establishment of a general and common measure of frequency stability in the past 40 years. Tremendous progress has been achieved since 1955 through the development of high precision frequency standards, such as cesium beam clocks, optically pumped rubidium clocks, hydrogen masers, and quartz crystal oscillators. In the early 1960s the needs were clearly recognized for common parameters characterizing the frequency stability and for related measurement techniques. These parameters were required for at least two main purposes: The first purpose is to allow for meaningful comparisons between similar devices developed by different laboratories or between different devices in a given application; and the second one is to access application performance in terms of the measured oscillator frequency stability.

In 1964 a special symposium on frequency stability was organized by the National Aeronautics and Space Administration (NASA) and the Institute of Electrical and Electronics Engineers (IEEE) as an attempt to improve the situation (1). After this symposium, a Subcommittee on Frequency Stability was formed as a part of the Technical Committee on Frequency and Time of the IEEE Professional Group on Instrumentation and Measurement. In 1966 several members of this subcommittee contributed an original paper to a special issue of the *Proceedings of the IEEE* (2). In 1970 a report on the characterization of frequency stability was issued by the above mentioned subcommittee (3). Proposed definitions for the measure of frequency stability are the power spectral density in the frequency domain and the Allan variance in the time domain. Since then the concepts and methods proposed in this report have been widely accepted by many researchers and engineers in the field of time and frequency measurement.

In this article, a definition and a estimation procedure will be presented on the measure of frequency stability commonly employed. For more extensive and complete discussion, refer to the textbook and reviews on this subject (4,5).

BACKGROUND AND DEFINITION

Consider a sinusoidal signal generator whose instantaneous output voltage $u(t)$ may be written as

$$u(t) = [U_0 + \epsilon(t)] \sin[2\pi \nu_0 t + \phi(t)] \quad (1)$$

where U_0 and ν_0 are the nominal values of the amplitude and frequency, respectively. Throughout this article the Greek letter ν is used to stand for the signal frequency, while the Latin symbol f is used to denote the Fourier frequency in the representation of spectral densities. The parameter $\epsilon(t)$ and $\phi(t)$ in Eq. (1) represent the instantaneous amplitude and phase fluctuations, respectively. The instantaneous frequency $\nu(t)$ of the sinusoidal voltage is then expressed as the sum of a constant value ν_0 and variable term $\nu_v(t)$:

$$\nu(t) = \nu_0 + \frac{1}{2\pi} \frac{d\phi(t)}{dt} = \nu_0 + \nu_v(t) \quad (2)$$

Since we are dealing with stable oscillators, it is assumed that the magnitude of these fluctuations are much smaller than the nominal values; that is,

$$|\epsilon(t)| \ll U_0 \quad (3)$$

and

$$|\nu_v(t)| \ll \nu_0 \quad (4)$$

for substantially all time t . Oscillators with large frequency deviation are a subject of frequency modulation theory which is not treated in this article. Various types of oscillators are used in scientific and engineering fields, and their nominal frequencies cover a wide range of the spectrum—that is, from several hertz to several hundred terahertz (lightwave). For a general discussion of oscillators having a wide range of frequencies, it is useful to introduce normalization. The normalized frequency offset $y(t)$ from the nominal value is defined as

$$y(t) = \frac{\nu_v(t)}{\nu_0} = \frac{1}{2\pi \nu_0} \frac{d\phi(t)}{dt} \quad (5)$$

The quantity $y(t)$ is called the *fractional frequency offset*. Another useful quantity is the time integral of $y(t)$:

$$x(t) = \int_0^t y(t) dt = \frac{\phi(t)}{2\pi \nu_0} \quad (6)$$

and

$$y(t) = \frac{dx(t)}{dt} \quad (7)$$

The parameter $x(t)$ has the dimension of time and is proportional to instantaneous phase. This quantity was called the *phase-time* (Phasenzeit) by Becker (6).

From the definition of $y(t)$ given by Eq. (5), it is natural to assume that $y(t)$ should have a zero mean over the time of

observation, whereas this will not be the case for $x(t)$. However, most actual oscillators exhibit frequency drift with time as well as random variations. In performing a series of measurements over a long period of time, it is always possible to subtract the drift and the initial offset from the data.

There are two aspects in the analysis of measured results of $y(t)$, namely, time-domain analysis and frequency-domain analysis.

FREQUENCY DOMAIN

The behavior of $y(t)$ in the frequency domain is described by its power spectral density $S_y(f)$, which is defined as the Fourier transform of the autocorrelation function $R_y(\tau)$ given by

$$R_y(\tau) = \lim_{T \rightarrow \infty} \int_0^T y(t') y(t' + \tau) dt' \quad (8)$$

From the Wiener–Khinchine theorem, the power spectral density is obtained from the autocorrelation function as

$$S_y(f) = 4 \int_0^\infty R_y(\tau) \cos 2\pi f \tau d\tau \quad (9)$$

and inversely

$$R_y(\tau) = \int_0^\infty S_y(f) \cos 2\pi f \tau df \quad (10)$$

The power spectral density represents the fluctuation power of the fractional frequency offset $y(t)$ contained in a unit bandwidth as a function of the Fourier frequency. Its dimension is Hz^{-1} , since $y(t)$ and $R_y(\tau)$ are dimensionless.

The relations between the power spectral densities of various quantities are shown below.

Absolute frequency offset: $\delta\nu = \nu(t) - \nu_0 [\text{Hz}]$

$$S_{\delta\nu}(f) = \nu_0^2 S_y(f) [\text{Hz}] \quad (11)$$

Phase: $\phi(t)$ [radian]

$$S_\phi(f) = \frac{\nu_0^2}{f^2} S_y(f) [(\text{radian})^2/\text{Hz}] \quad (12)$$

Phase-time: $x(t) = \int_0^t y(t) dt$ [s]

$$S_x(f) = \frac{1}{(2\pi f)^2} S_y(f) [(\text{radian})^{-2}/\text{Hz}] \quad (13)$$

Angular frequency: $\omega = \dot{\phi} = d\phi/dt$ [radian/s]

$$S_\omega(f) = (2\pi \nu_0)^2 S_y(f) [(\text{radian})^2/\text{Hz}] \quad (14)$$

The above relations are very useful for converting measured data and for translating formula between various measures.

TIME DOMAIN

The measure of frequency stability in the time domain is based on the sample variance of the fractional frequency fluctuations. In actual measurements it is difficult to obtain the

Figure 1. Measurement process for the calculation of sample variances. Here T and τ represent the repetition interval and duration of the measurement, respectively.

instantaneous sample of the fractional frequency offset $y(t)$. The results of frequency measurement are always in the form of sampled data of $\bar{y}_k$ of $y(t)$ averaged over a finite time interval τ , which is given by

$$\bar{y}_k(t_k, \tau) \equiv \frac{1}{\tau} \int_{t_k}^{t_k+\tau} y(t) dt = \frac{\phi(t_k + \tau) - \phi(t_k)}{2\pi \nu_0 \tau} \quad (15)$$

where $t_{k+1} = t_k + T$, $k = 0, 1, 2, \dots$, T represents the repetition interval for measurements of duration τ , and t_0 is arbitrary. The dead time between measurements is given by $T - \tau$. Figure 1 shows the measurement process for the sampled data $\bar{y}_k$.

The measure of frequency stability in the time domain is then defined in analogy to the sample variance by the relation

$$\sigma_y^2(N, T, \tau) \equiv \left\langle \frac{1}{N-1} \sum_{n=1}^N \left(\bar{y}_n - \frac{1}{N} \sum_{k=1}^N \bar{y}_k \right)^2 \right\rangle \quad (16)$$

where $\langle \rangle$ denotes the infinite time average. The quantity in Eq. (16) is called the *Allan variance* (7) and is dimensionless.

In many situations it is not correct to assume that the variance (16) converges to a meaningful limit as $N \rightarrow \infty$. In practice one cannot let N approach infinity, and it is known that some actual noise processes contain substantial fractions of the total noise power in the extremely low Fourier frequency range. Therefore it is important to specify particular N and T in order to improve the comparability of data.

The recommended definition of frequency stability is choosing $N = 2$ and $T = \tau$, which means no dead time between measurements. Expressing $\langle \sigma_y^2(N = 2, T = \tau, \tau) \rangle$ as $\sigma_y^2(\tau)$, the Allan variance may be written as

$$\sigma_y^2(\tau) = \left\langle \frac{(\bar{y}_{k+1} - \bar{y}_k)^2}{2} \right\rangle \quad (17)$$

In the practical situation, the true time average is not realizable and the estimate of $\sigma_y^2(\tau)$ should be obtained from a finite number of samples. It has been shown that when $\sigma_y^2(\tau)$ is estimated from the ensemble average of $\sigma_y^2(2, \tau, \tau)$, the average converges with increasing number of data even for noise processes that do not converge for $\langle \sigma_y^2(N, \tau, \tau) \rangle$ as $N \rightarrow \infty$. Therefore, $\sigma_y^2(\tau)$ has greater utility than $\langle \sigma_y^2(\infty, \tau, \tau) \rangle$ even though both involve an assumption of an infinite average. A widely used formula for

estimating $\sigma_y^2(\tau)$ experimentally is

$$\sigma_y^2(\tau, m) = \frac{1}{2(m-1)} \sum_{k=1}^{m-1} (\bar{y}_{k+1} - \bar{y}_k)^2 \quad (18)$$

where m represents the number of samples. The another advantage of the Allan variance with $N = 2$ and $T = \tau$ is the simplicity of computation from the measured data as shown by Eq. (18). In any case one should specify the number of samples used for estimation in order to avoid ambiguity and to allow for meaningful comparisons.

TRANSLATIONS BETWEEN MEASURES (FREQUENCY DOMAIN TO TIME DOMAIN)

The relation between the Allan variance and the power spectral density $S_y(f)$ was derived by Cutler and co-workers (3) and is expressed as

$$\langle \sigma_y^2(N, T, \tau) \rangle = \frac{N}{N-1} \int_0^\infty S_y(f) |H(f)|^2 df \quad (19)$$

where

$$|H(f)|^2 = \frac{\sin^2 \pi f \tau}{(\pi f \tau)^2} \left(1 - \frac{\sin^2 \pi r f \tau N}{N^2 \sin^2 \pi r f \tau} \right) \quad (20)$$

and

$$r = T/\tau \quad (21)$$

The parameter r represents the ratio of the time interval between successive measurements to the duration of the averaging periods. Equation (19) allows one to estimate the time-domain stability $\langle \sigma_y^2(N, T, \tau) \rangle$ from the frequency domain stability $S_y(f)$. Two assumptions were made in deriving Eq. (19). The first one is that $R_y(t_1 - t_2) = \langle y(t_1)y(t_2) \rangle$ exists; that is, $y(t)$ is stationary in the covariance sense. The second assumption is that

$$\langle y^2(t) \rangle = R_y(0) = \int_0^\infty S_y(f) df \quad (22)$$

exists. To satisfy the second assumption it is sufficient to assume that $S_y(f)$ is finite in the frequency interval $f_l < f < f_h$ and zero outside this interval; that is, there are lower and higher cutoff frequencies in the device and the measuring equipment. This condition is always satisfied in practical situations.

In the limit of $N \rightarrow \infty$, Eq. (19) reduces to

$$\lim_{N \rightarrow \infty} \langle \sigma_y^2(N, T, \tau) \rangle = \frac{1}{\pi \tau} \int_0^\infty S_y\left(\frac{u}{\pi \tau}\right) \frac{\sin^2 u}{u^2} du \quad (23)$$

$$u = \pi f \tau \quad (24)$$

In the special case of $N = 2$, Eq. (19) is written by

$$\langle \sigma_y^2(2, T, \tau) \rangle = \frac{2}{\pi \tau} \int_0^\infty S_y\left(\frac{u}{\pi \tau}\right) \frac{\sin^2 u \sin^2 ru}{u^2} du \quad (25)$$

By comparing Eqs. (23) and (24), it can be seen that the convergence on the lower limit is better for $N = 2$ because of the additional factor of $\sin^2 ru$. For the Allan variance with $N = 2$ and $T = \tau$, the translation is expressed as

$$\sigma_y^2(\tau) = 2 \int_0^\infty S_y(f) \frac{\sin^4 \pi f \tau}{(\pi f \tau)^2} df \quad (26)$$

TRANSLATIONS BETWEEN MEASURES (TIME DOMAIN TO FREQUENCY DOMAIN)

For general $\langle \sigma_y^2(N, T, \tau) \rangle$ no simple prescription is available for translation into the time domain. For this reason, $S_y(f)$ is preferred as a general measure of frequency stability, especially for theoretical work. For specific types of noise process discussed below, the Allan variance $\sigma_y^2(\tau)$ can be translated into the power spectral density $S_y(f)$.

OSCILLATOR NOISE MODEL

The types of noise observed on the output signal of actual oscillators can be suitably represented by the spectral density $S_y(f)$. It has been known empirically that a simple power-law model of the form

$$S_y(f) = h_{-2} f^{-2} + h_{-1} f^{-1} + h_0 + h_1 f + h_2 f^2 = \sum_{\alpha=-2}^2 h_\alpha f^\alpha \quad (27)$$

$$S_y(f) = 0 \quad \text{for} \quad f > f_h$$

can cover all actually known types of oscillators in the limit of drift elimination. In the above equation, h_α ($\alpha = -2, -1, 0, 1, 2$) is a constant. It is assumed that the measuring system has an ideally sharp upper cutoff frequency f_h . The individual terms have been identified by common names given in Table 1. Figure 2 shows the power spectral density $S_y(f)$ for five noise processes in Eq. (27). It can be seen that each noise process is clearly distinguishable from the slope.

It is easy to show the relationship between $S_y(f)$ defined above and $\sigma_y^2(\tau)$ by using the translation of Eq. (26). For every term of the form $h_\alpha f^\alpha$ ($\alpha = -2, -1, 0, 1, 2$) we have

$$\sigma_y^2(\tau) = \frac{2h_\alpha}{(\pi\tau)^{\alpha+1}} \int_0^{\pi\tau f_h} u^{\alpha-2} \sin^4 u du \quad (28)$$

where $u = \pi f \tau$. This relation may be expressed as

$$\sigma_y^2(\tau) = K_\alpha \tau^\mu \quad (29)$$

$$\mu = -\alpha - 1 \quad (30)$$

$$K_\alpha = \frac{2h_\alpha}{(\pi\tau)^{\alpha+1}} \int_0^{\pi\tau f_h} u^{\alpha-2} \sin^4 u du \quad (31)$$

Table 1. Common Names of Various Noise Terms

Random walk y	$\alpha = -2$	$\mu = 1$
Flicker y	$\alpha = -1$	$\mu = 0$
White y		
Random walk x	$\alpha = 0$	$\mu = -1$
Flicker x	$\alpha = 1$	$\mu = -2$
White x	$\alpha = 2$	$\mu = -3$

Figure 2. Power spectral density $S_y(f)$ for five noise terms in Eq. (27). A sharp upper cutoff frequency of $f_h = 20$ Hz is assumed. (a) Random walk frequency noise, (b) flicker frequency noise, (c) white frequency noise, (d) flicker phase noise, (e) white phase noise. $h_{-2} = h_{-1} = h_0 = h_1 = h_2 = 10^{-24}$.

For $\alpha < 1$ and $2\pi\tau f_h \gg 1$, K_α is independent of f_h and τ and becomes a constant due to the very rapid convergence of the integral. For $\alpha = 1$ and 2, the value of integral depends on f_h as well as on τ . The relations for general N and r are shown in Table 2. Figure 3 shows the dependence of $\sigma_y(\tau)$ on averaging time τ for five noise processes in the limit of $2\pi\tau f_h \gg 1$. It can be seen that the noise processes with $\alpha = 0, -1, -2$ are clearly distinguished from the slope of $\sigma_y(\tau)$. However, the slope of $\sigma_y(\tau)$ is almost the same for $\alpha = 1$ and $\alpha = 2$. As a consequence, the Allan variance $\sigma_y(\tau)$ is not useful for distinguishing flicker and white noise processes. For both types of noise, the dominant contribution to $\sigma_y(\tau)$ is frequency fluctuations at $f = f_h$ even for long measurement time. Therefore the determination of $\sigma_y(\tau)$ for some types of noise is dependent on the noise bandwidth and on the type of low-pass filter used in the measurement. The power expansion law of Eq. (27) has some physical meaning. Any practical oscillator contains a frequency-determining element (resonant circuit, quartz crystal resonator, atomic resonator, optical resonator) and a feedback loop. Any sources of noise have influences on the frequency or on the phase of the generated signal. Therefore, it is also useful to treat the noise in terms of phase fluctuations. Using Eq. (13) to transform Eq. (27) we can define the power spectral density of the phase-time fluctuations:

$$S_x(f) = \frac{1}{4\pi^2} \sum_{\alpha=-2}^2 h_\alpha f^{\alpha-2} \quad (32)$$

$$= \frac{1}{4\pi^2} (h_{-2} f^{-4} + h_{-1} f^{-3} + h_0 f^{-2} + h_1 f^{-1} + h_2)$$

The various types of noise characterized by α terms in Eqs. (27) and (32) usually dominate over some frequency range; in most cases, not all five terms are significant. The individual terms have been identified by common names given in Table 1.

Table 2. Stability Measure Conversion Chart

Frequency Domain (Power Spectral Densities)	$\sigma_y^2(\tau)$ [$N = 2, r = 1$]	Time Domain (Allan Variances) $\langle \sigma_y^2(N, T = \tau, \tau, f_h) \rangle$ [$r = 1$]	$\{\sigma_y^2(N, T, \tau, f_h)\}$
White x $S_y(f) = h_2 f^2$ $S_x(f) = h_2 / (2\pi)^2$ $2\pi f_h \tau \gg 1$	$h_2 \cdot \frac{3f_h}{(2\pi)^2 \tau^2}$	$h_2 \cdot \frac{N+1}{N(2\pi)^2} \cdot \frac{2f_h}{\tau^2}$	$h_2 \cdot \frac{N + \delta_k(r-1)}{N(2\pi)^2} \cdot \frac{2f_h}{\tau^2}$ $\delta_k(r-1) = 1, r = 1$ $= 0, \text{otherwise}$
Flicker x $S_y(f) = h_1 f$ $S_x(f) = h_1 / (2\pi)^2 f$ $2\pi f_h \tau \gg 1, 2\pi f_h T \gg 1$	$h_1 \cdot \frac{\frac{9}{2} + 3 \ln(2\pi f_h \tau) - \ln 2}{(2\pi)^2 \tau^2}$	$h_1 \cdot \frac{2(N+1)}{N\tau^2(2\pi)^2} \left[\frac{3}{2} + \ln(2\pi f_h \tau) - \frac{\ln N}{N^2 - 1} \right]$	$h_1 \cdot \frac{2}{(2\pi \tau)^2} \left\{ \frac{3}{2} + \ln(2\pi f_h \tau) + \frac{1}{N(N-1)} \times \sum_{n=1}^{N-1} (N-n) \cdot \ln \left[\frac{n^2 r^2}{n^2 r^2 - 1} \right] \right\}, r \gg 1$
White y (random walk x) $S_y(f) = h_0$ $S_x(f) = h_0 / (2\pi)^2 f^2$	$h_0 \cdot \frac{1}{2} \tau^{-1}$	$h_0 \cdot \frac{1}{2} \tau^{-1}$	$h_0 \cdot \frac{1}{2} \tau^{-1}, r \geq 1$ $h_0 \cdot \frac{1}{6} r(N+1) \tau^{-1}, Nr \leq 1$
Flicker y $S_y(f) = \frac{h_{-1}}{f}$ $S_x(f) = h_{-1} / (2\pi)^2 f^3$	$h_{-1} \cdot 2 \ln 2$	$h_{-1} \cdot \frac{N \ln N}{N-1}$	$h_{-1} \cdot \frac{1}{N(N-1)} \sum_{n=1}^{N-1} (n-n) [-2(nr)^2 \ln(nr) + (nr+1)^2 \ln(nr+1) + (nr-1)^2 \ln nr-1]$
Random walk y $S_y(f) = \frac{h_{-2}}{f^2}$ $S_x(f) = h_{-2} / (2\pi)^2 f^4$	$h_{-2} \cdot \frac{(2\pi)^2 \tau}{6}$	$h_{-2} \cdot \frac{(2\pi)^2 \tau}{12} \cdot N$	$h_{-2} \cdot \frac{(2\pi)^2 \tau}{12} [r(N+1) - 1], r \geq 1$

The types of noise commonly observed in oscillators are as follows:

1. *Additive Noise.* Thermal noise in amplifier is simply added to the signal. This type of noise appears as phase noise and is usually white with high cutoff frequency.
2. *Perturbing Noise.* Thermal and shot noise acting within the feedback loop appears as white frequency noise (random walk in phase).
3. *Modulating Noise.* This type of noise is caused by random variations of reactive parameters such as semiconductor

junction capacitors, frequency-determining parameters of resonators, and so on. These fluctuations are either inherent in the devices or due to environmental effect. Flicker x and y usually belong to this class.

MODIFIED ALLAN VARIANCE

To improve the relatively poor discrimination of the Allan variance $\sigma_y(\tau)$ against flicker ($\alpha = 1$) and flicker ($\alpha = 2$) phase noise, the modified Allan variance was introduced in 1981. The definition is based on (a) the algorithm developed by Snyder (8) for increasing the resolution of frequency meters and (b) the detailed consideration of Allan and Barnes (9).

It consists in dividing a time interval τ into n cycles of period τ_0 such that

$$\tau = n\tau_0. \quad (33)$$

As depicted in Fig. 4, for a given observation time interval of duration 2τ , there are n overlapping time intervals of duration

Figure 3. Square root of the Allan variance $\sigma_y(\tau)$ for five noise processes in Eq. (27) in the limit of $2\pi\tau f_h \gg 1$, where f_h represents the sharp upper cutoff frequency. (a) Random walk frequency noise $S_y(f) = h_{-2}f^{-2}$, (b) flicker frequency noise $S_y(f) = h_{-1}f^{-1}$, (c) white frequency noise $S_y(f) = h_0$, (d) flicker phase noise $S_y(f) = h_1f^{-1}$ with $f_h = 20$ Hz, (e) white phase noise $S_y(f) = h_2f^{-2}$ with $f_h = 20$ Hz. $h_{-2} = h_{-1} = h_0 = h_1 = h_2 = 10^{-24}$.

Figure 4. Measurement process for the calculation of the modified Allan variance.

τ . Allan and Barnes introduced the modified Allan variance such that

$$\text{Mod } \sigma_y^2(\tau) = \frac{1}{2\tau^2} \left\langle \left[\frac{1}{n} \sum_{k=1}^n \left\{ \int_{t_0+(k+n)\tau_0}^{t_0+(k+2n)\tau_0} y(t) dt - \int_{t_0+k\tau_0}^{t_0+(k+n)\tau_0} y(t) dt \right\} \right]^2 \right\rangle \quad (34)$$

It can be seen from the above equation that the calculation of each statistical sample involved in the definition of $\text{Mod } \sigma_y^2(\tau)$ requires a signal observation of duration 3τ .

For $n=1$, the Allan variance and the modified one are equal.

$$\text{Mod } \sigma_y^2(\tau) = \sigma_y^2(\tau) \quad (35)$$

The power spectral density $S_y(f)$ is translated into the modified Allan variance $\text{Mod } \sigma_y^2(\tau)$ by the following relation:

$$\text{Mod } \sigma_y^2(\tau) = \frac{2}{n^2 \pi^2 \tau^2} \left[n \int_0^\infty \frac{S_y(f)}{f^2} \sin^4(\pi f n \tau_0) df + 2 \sum_{k=1}^{n-1} (n-k) \int_0^\infty \frac{S_y(f)}{f^2} \cos(2\pi f k \tau_0) \sin^4(\pi f n \tau_0) df \right] \quad (36)$$

The analytical expressions of the modified Allan variance for each noise term in Eq. (27) can be directly calculated by the above equation. These relations are summarized in Table 3 in the limit of $2\pi \tau f_h \gg 1$ (10).

Figure 5. Dependence of the ratio $R(n)$ on n for (a) flicker and (b) white phase noise processes under the condition $2\pi \tau f_h \gg 1$.

It is useful for comparing the Allan variance with the modified one to define the ratio $R(n)$ as

$$R(n) = \frac{\text{Mod } \sigma_y^2(\tau)}{\sigma_y^2(\tau)} \quad (37)$$

Figure 5 depicts the variation of the ratio $R(n)$ with n , for flicker and white phase noise processes. It can be seen that for a large value of n , flicker and white phase noise processes have different dependencies. This property can be used to distinguish these two types of noise processes.

EXAMPLE OF THE ALLAN VARIANCE

Sinusoidal Frequency Modulation

Consider a frequency-modulated (FM) signal with the modulation frequency of f_m and maximum frequency deviation of $\Delta\nu_0$.

Table 3. Conversion Chart for the Modified Allan Variance

Frequency Domain (Power Spectral Densities)	Time Domain (Allan Variances) $\text{Mod } \sigma_y^2(\tau)$
White x $S_y(f) = h_2 f^2$ $S_x(f) = h_2 / (2\pi)^2$ $2\pi f_h \tau \gg 1$	$h_2 \cdot \frac{3f_h}{8\pi n \tau^2}$
Flicker x $S_y(f) = h_1 f$ $S_x(f) = h_1 / (2\pi)^2 f$ $2\pi f_h \tau \gg 1, 2\pi f_h T \gg 1$	$h_1 \cdot \frac{1}{4\pi^2 n^2 \tau^2} \left[3n \ln(2\pi f_h \tau) + \sum_{k=1}^{n-1} (n-k) \left\{ 4 \ln \left(\frac{n^2}{k^2} - 1 \right) - \ln \left(\frac{4n^2}{k^2} - 1 \right) \right\} \right]$
White y (random walk x) $S_y(f) = h_0$ $S_x(f) = h_0 / (2\pi)^2 f^2$	$h_0 \cdot \frac{n^2 + 1}{4n^2 \tau^2}$
Flicker y $S_y(f) = \frac{h_{-1}}{f}$ $S_x(f) = h_{-1} / (2\pi)^2 f^3$	$h_{-1} \cdot \frac{2 \ln 2}{n^2} \left[\frac{4n^2 - 3n + 1}{n^2} + \frac{1}{n^2 \ln 2} \sum_{k=1}^{n-1} (n-k) \left\{ \frac{n}{2} [(k+2n) \ln(k+2n) - (k-2n) \ln(2n-k)] + \frac{1}{2} (k+n)(k=2n) \ln(k+n) + \frac{1}{2} (k-n)(k+2n) \ln k-n + 3k^2 \ln k - k \left[(n+2k) \ln \left(k + \frac{n}{2} \right) - (n-2k) \ln \left k - \frac{n}{2} \right \right] \right\} \right]$
Random walk y $S_y(f) = \frac{h_{-2}}{f^2}$ $S_x(f) = h_{-2} / (2\pi)^2 f^4$	$h_{-2} \cdot \frac{2\pi^2 \tau}{3} \left(\frac{33}{40} + \frac{1}{8n^2} + \frac{1}{20n^4} \right)$

The normalized frequency offset $y(t)$ is given by

$$y(t) = \frac{\Delta\nu_0}{\nu_0} \sin(2\pi f_m t) \quad (38)$$

The power spectral density for this signal is expressed as

$$S_y(f) = \frac{1}{2} \left(\frac{\Delta\nu_0}{\nu_0} \right)^2 \delta(f - f_m) \quad (39)$$

where δ is the Dirac delta function. Substitution of Eq. (39) into Eq. (26) and (36) yields

$$\sigma_y^2(\tau) = \left(\frac{\Delta\nu_0}{\nu_0} \right)^2 \frac{\sin^4(\pi f_m \tau)}{(\pi f_m \tau)^2} \quad (40)$$

and

$$\text{Mod } \sigma_y^2(\tau) = \left(\frac{\Delta\nu_0}{\nu_0} \right)^2 \frac{\sin^6(\pi f_m n \tau_0)}{n^2 (\pi f_m n \tau_0)^2 \sin^2(\pi f_m \tau_0)} \quad (41)$$

respectively. The effect of sinusoidal FM in both cases is 0 when τ equals the modulation period $T_m = f_m^{-1}$ or one of its multiples, since the modulating signal is completely averaged away. The largest value of $\text{Mod } \sigma_y(\tau)$ occurs when τ is $T_m/2$ or one of its odd multiples. $\text{Mod } \sigma_y(\tau)$ falls n times faster than $\sigma_y(\tau)$ for sinusoidal FM.

Linear Frequency Drift

When linear frequency drift exists (i.e., $y(t) = dt$), no tractable model exists for the power spectral density $S_y(f)$. Direct calculation in the time domain using Eqs. (17) and (34) yields

$$\sigma_y(\tau) = \frac{d}{\sqrt{2}} \tau \quad (42)$$

and

$$\text{Mod } \sigma_y(\tau) = \frac{d}{\sqrt{2}} \tau \quad (43)$$

respectively. Thus linear frequency drift yields τ^{+1} law for both $\sigma_y(\tau)$ and $\text{Mod } \sigma_y(\tau)$.

OTHER MEASURES OF FREQUENCY STABILITY

A number of other measures have been proposed and used during the past 25 years. Each measure has some advantages and limitations compared with the well-established power spectral density and the Allan variance. The Hadamard variance (11) has been developed for high-resolution spectral analysis of $y(t)$ from measurements of $\bar{y}_k$. The high-pass variance (12) has been proposed through the transfer function approach and is defined by

$$\sigma^2(\tau) = \int_0^\infty S_y(f) |H(f)|^2 df \quad (44)$$

It was shown that the Allan variance can be estimated by high-pass filtering the demodulated phase noise without using counting technique. A band-pass variance (12) has also been

proposed to distinguish white and flicker phase noise processes. A filtered Allan variance (13) has been used to separate various noise processes.

PHASE METERS

Phase meters measure a time-domain position of one periodic signal, including electromagnetic waves, with respect to another periodic signal of the same frequency, then relate the resulting time difference to the period to display it in terms of the phase angle.

Measurement techniques applied in phase meters depend upon the frequencies of the tested signals. In the range of lower frequencies, below several megahertz, the signals under test are acquired and directly processed to produce the phase reading. Analog or digital time-into-output reading conversion methods can be used.

Application of internally generated phase references improves measurement accuracy. With the recent development of fast real-time data acquisition systems, sampling methods are

used to compute wave parameters, like phase shift and magnitude, average value, and others.

In the higher frequency region, above several megahertz, the linear down-conversion of both tested signals is applied to reduce the operating frequency so lower frequency measurement techniques can be used. The frequency down-conversion employs sinusoidal heterodyning, persecuting or down counting, and coherent or periodic random sampling.

Besides stand-alone phase measuring devices, built-in phase meters are used as parts of impedance meters, power meters, frequency meters, network and waveform analyzers, as well as analog and digital oscilloscopes. Some high frequency wave analyzers and digital oscilloscopes use coherent or random sampling methods to reconstruct the wave images and display them on the screen before processing. Direct oscilloscope two-channel observation methods and indirect $x - y$ ellipsis display methods are discussed in Oscilloscopes.

Typical phase measurement is based on the assumptions that the investigated waves have the same periods and that they are sampled at the same points relative to the cycle start.

Many direct and indirect or conversion phase meters allow reduced random errors by accumulating many readings and computing average values.

Microwave six-port network analyzers (1,2) and homodyne four-port meters (3) are a separate group of phase meter related instruments which use scalar power or voltage readings to compute phase shift and other parameters of the networks.

REVIEW OF THE PHASE MEASUREMENT METHODS

In this section we review the basic methods of phase measurement which are applied in the majority of phase meters. The details related to the specific implementations are described in the later parts of the article.

As mentioned before, the oscilloscope $x - y$ method with Lissajous patterns is given in the article entitled Oscilloscopes in greater detail. The phase shift is determined from the following equation for signals of the same frequency

$$PH = \arcsin(A/B) \quad (1)$$

where PH is the phase shift, and A and B are as shown in Fig. 1.

Figure 1. Phase measurement using Lissajous pattern for two signals of the same frequency.

Figure 2. Phase measurement using sweep method.

The accuracy of this method is limited by the errors of the vertical and horizontal channels and by the error of reading from the oscilloscope screen. The total error may exceed 5%.

Another visual method, which could be digitized, is the sweep method. Two waves are displayed on the screen, as shown in Fig. 2. The phase reading involves measurements of the period and the time delay between the two waves. The following expression is used to determine the phase

$$PH = 360 \deg T_0/T \quad (2)$$

where T_0 is the delay between the waves and T is the period.

The visual method leads to the error which could be much more than several percent when the phase between the waves is small. Additional error is introduced due to channel misalignment and vertical wave offset. Some analog and digital oscilloscopes have digital signal processing packages which automate the measurement process, so the error of reading from the screen can be significantly reduced.

The wave offset error is compensated in some analog and digital phase meters by the proper technique described in (15). The phase measurement involves the process of conversion of the input waves into standardized rectangular signals, as shown in Fig. 3. The time shift preserved in the front edge differential signal is related to the entire period thus resulting in the phase shift.

The same differential signal, V_{DD} of Fig. 3 can be averaged to provide direct information about the phase shift. Proper calibration of the averaging device provides correct readings. The lead or lag information is indicated by additional logic circuitry described later in this paper.

Many waveform analyzers, including more complex digital oscilloscopes, accumulate the signal samples from the investigated signals and process them in order to determine various signal parameters. Among them, the phase shift is obtained from the computations.

GENERAL BLOCK DIAGRAMS OF DIRECT PHASE METERS

Figure 4 is a general block diagram of a direct phase meter system measuring phase without frequency down-conversion. Two input waves are applied to the inputs A and B. The waves are converted into trains of pulses of the same lengths and delivered to the processor, which determines the phase difference

Figure 3. Phase measurement using wave amplitude standardization (for both analog and digital measurements).

in an analog or digital fashion. Connection of the frequency down-converters to both inputs greatly expands the frequency range of operation.

The heart of the direct phase meter is a phase-to-output variable converter whose major function is translating the phase difference of the investigated signals into a quantity like voltage, time ratio, or frequency. Figure 5 illustrates the first type of converter that changes input signal phase difference into

output voltage. The output voltage can be measured directly by a voltmeter or converted again into current and measurement by an ammeter. Analog-to-digital conversion process added to the converter of Fig. 5 changes it into a simple digital phase meter. The way the results are displayed depends upon the type of applied phase detector. Phase meters with two-quadrant, digital or unipolar type of a phase detector produce the results in terms of phase magnitude and lead/lag indication. Meters with a four-quadrant phase detector deliver bipolar readings thus indicating negative or positive phase shift when the positions of both waves are shifted more or less than 90° . Figure 6(a) shows a two-quadrant phase detector with Exclusive-NOR gate whose inputs are controlled by two binary signals formed from the input tested signal and reference signal. The gate output signal is filtered to yield the dc level proportional to the phase shift. The static transfer characteristic of Fig. 6(b) illustrates the relationship between the output voltage level and the phase difference between the input signals. The detector registers only the phase magnitude. Additional circuitry is necessary to indicate the phase polarity.

The four-quadrant phase detector of Fig. 7(a) includes two clocked D flip-flops. The binary input signals shifted in phase are applied to the clock inputs while the D inputs are high. The two output signals from the flip-flops are subtracted in a bipolar analog subtractor and then filtered by a low-pass filter. The detector exhibits inconsistent readings near -180° and 180° which is shown as sudden changes in the transfer characteristic of Fig. 7(b).

Another four-quadrant product detector and its static transfer characteristic are shown in Fig. 8. This type of a detector is often used in phase-lock-loop systems.

A classical digital meter shown in Fig. 9 uses two channel time interval measurement that combines the time shift between the waves and the period measurements. The reading is given as a ratio of these two. The meter could be a stand-alone unit or it could be a part of a frequency counter or an oscilloscope.

In some digital meters, the time shift between the waves can be initially converted into gate pulses whose duration is measured by a single channel time interval meter. The reading related to the period constitutes the measure of the phase shift (4). Figure 10 shows a phase-to-output variable converter in which an internal counter locks in to the input signal frequency producing a multiple frequency of that of the external signal. An internal counter counts the multiple-frequency pulses, and if the multiplication factor is 360 with a resolution of one degree, the phase shift is given directly in degrees. Larger multiplication factors, like 3600, offer better resolution. Application of the high-frequency clock whose frequency is much greater

Figure 4. General block diagram of a phase meter.

Figure 5. Phase-to-output variable converter with phase detectors.

than the input signal repetition frequency requires compatible high-frequency counters (5).

Real-time sampling technique which is applied in modern data acquisition systems allows computations of the phase shift between two signals. The two signals are applied to the samplers through anti-aliasing filters. The sampled signals are then converted by analog-to-digital converters and stored in processor memory for further processing. The phase shift is calculated from the samples located near zero-crossings for both signals. Basic phase error is related to uncertainty of these samples (6).

Complex impedance bridges and complex transmission coefficient bridges also measure phase shift with the help of precision phase shifters. In the impedance meters phase measurements are accomplished with reference to the calibrated phase shifter by adjusting and comparing the phase shifter and system attenuator readings for a known and unknown impedance by setting the output of a video detector to null. In the transmission coefficient bridges the signal is applied to the device under test and to the variable phase shifter. A general block diagram of such a meter is shown in Fig. 11, and a simplified diagram of a millimeter wave transmission coefficient bridge is shown in Fig. 12 (7).

Figure 6. Two-quadrant phase detector. (a) Diagram. (b) Static transfer characteristic.

DOWN-CONVERSION TECHNIQUES USED IN PHASE METERS

Phase-to-Output Variable Converters previously described are limited in their operation frequency range by the speed of the input circuits, logic circuits in a counter, and circuits of a phase detector. Although the frequency counters can directly measure frequencies of signals reaching far more than several megahertz, time interval measurements are affected by large errors which reduce operating frequencies for phase measurements.

In order to extend the phase meter operating frequency range the following techniques are used:

1. Persecuting or down counting (8)
2. Sinusoidal heterodyne conversion (5,9)
3. Coherent sampling (10)
4. Random repetitive sampling (11,12,13)

All methods involve acquisition of many periods of the signal under test.

Application of the down-conversion technique in signal and network analyzers, impedance meters, and multichannel microwave receivers increases the frequency range of phase measurement to millimeter waves. The most critical issue in high-frequency tests related to wave separation is solved with the aid of directional couplers and hybrid-tee connectors.

Persecuting or Down Counting

Two input signals, the signal under test and the reference signal, are applied to two identical frequency dividers. As a result, lower frequency signals are measured in analog or digital circuits previously described. This method has found applications in high-speed frequency counters which also have the capability of time interval measurements leading to phase determination.

Sinusoidal Heterodyne Conversion

The heterodyne, single or double down-conversion process, reduces the frequency of the tested signals by mixing so they can be acquired and directly processed by lower frequency phase meters. The block diagram of a typical heterodyne phase meter is shown in Fig. 13. The system is designed to lock-in the voltage controlled oscillator to the incoming signal frequency of the reference channel so a signal of fixed intermediate frequency is produced. The voltage controlled oscillator also mixes with the other signal to reduce its frequency to the same intermediate frequency as that of the reference signal. Intermediate frequency signals are then processed by a classical low-frequency phase meter.

Coherent Sampling

The phase meter uses a fast sampling technique to down convert periodic high frequency signals to intermediate frequency signals. Initially, the internally generated sampling pulses are swept automatically until their frequency is locked to produce the intermediate frequency signals, as in Fig. 14. Two high-frequency input signals are sampled in the sampling gates which are switched on by very short sampling pulses. The samples are stored in analog memories (capacitors of

(a)

(b)

Figure 7. Four-quadrant phase detector. (a) Diagram. (b) Static transfer characteristic.

sample-and-hold circuits). The sampling rate is automatically adjusted so each sample occurs at an earlier relative point on the waves during a subsequent recurrence of the waves. The reconstructed waveforms after sampling resemble the original waves but they have much lower frequencies. The sampling pulse frequency is controlled by a phase-locked-loop system which maintains the desired intermediate frequency at the sampler output. The method is applied in vector voltmeters, network analyzers, and impedance meters to measure phase shift and the magnitude of two different signals.

Another solution, shown in Fig. 15, involves a regular subsequent process of sampling typically used in sampling wave analyzers and oscilloscopes. Two input signals are sampled in sampling gates by very narrow sampling pulses whose timing is coherently triggered by the waves of lower frequencies which are synchronous submultiples of the input signal frequencies. Subsequent samples are automatically delayed so the output waves look like time-transformed input signals. The sampling rates do not exceed several hundred kHz while the input signal frequencies could reach 20 GHz or more. The time-domain transformation factors are very high. For instance, if 10 GHz waves are tested and 1000 samples are taken to reconstruct a period, with the samples located 10 μ s apart, then the

time transformation factor is 10^8 . This allows us to determine the phase using a low frequency processor calculating signal parameters or a direct phase meter (14).

Random Repetitive Sampling

Random repetitive sampling is applied in modern digital scopes which can also measure time intervals and phase shifts. A typical block diagram of major parts of such a scope is shown in Fig. 16. Two analog signals applied to the inputs are converted into corresponding digital signals. The sampling process in analog-to-digital converters, including sample-and-hold blocks, is controlled by an acquisition processor. The analog signals are used to trigger the time base of the acquisition processor. The samples are not collected in a sequential order, and the processor determines their proper location in relation to the trigger signals synchronized with the input waves. The voltage and time coordinates of individual samples are stored in the processor memory. The waves can be displayed on the scope screen and all information about the waves is also available for further processing. The phase shift between the two tested signals is measured with measurement/storage modules, such as HP 54657A, HP 54658A, and HP 54659B.

Figure 8. Four-quadrant analog phase detector. (a) Diagram. (b) Static transfer characteristic.

The measurement requires the display of a minimum of one cycle of the reference signal. The data acquisition time necessary to capture one period is usually larger than in coherent sampling units. The internal computer, together with the measurement/storage unit, can produce the calculated result of the phase shift. In automatic measurement mode, the phase is referred to as 50% of the transition level. A wave processor, also shown in Fig. 16, reconstructs the waves and displays them at its own rate. Processes of acquisition and wave reconstruction take a long time, but the enhanced signal processing capability of the system allows us to automate the measurement of phase shifts and other signal parameters.

EXAMPLES OF PHASE METERS AND OTHER PHASE MEASUREMENT UNITS

In this section, several examples of commercial phase measuring devices are discussed. Two typical stand-alone phase meters, a phase meter of a more advanced network analyzer, and a phase meter applied in a high-frequency impedance meter are included.

Example of Low-Frequency Direct Phase Meters

The first two units shown in Figs. 17 and 18 are two classical stand-alone phase meters designed by Feedback Instruments, Inc. (UK) (15). Both analog and digital meters have the same analog signal processors. In the analog meter the processor output signal which is proportional to the phase shift between the

input signals under test is filtered and directly measured by a dc meter. In the digital meter, the processor output signal is converted into its digital equivalent form and displayed. The meters use a smart compensation technique to correct errors due to input comparator or input wave offsets which are critical when the input signals have different amplitudes. The mark/space ratio-adjusting circuit fulfills this function. The analog meter operates up to 1 MHz, with a resolution of 1° and inaccuracy less than 2° . The digital meter operating within the same frequency range has a resolution and mid-frequency error of 0.1° .

Example of a Phase Meter Applied in Network Analyzers

Figure 19 shows the simplified block diagram of a typical network analyzer. The analyzer measures magnitude and phase

Figure 9. Phase-to-output variable converter with time interval meter.

Figure 10. Counting phase-to-output variable converter with a frequency multiplier.

responses of high-frequency networks. The signals can be acquired by three receivers which have double frequency down conversion. After conversion the signals can be processed by analog quadrature detectors and split into real and imaginary parts to calculate phases and magnitudes after analog to digital conversion (Fig. 20). In some other solutions the signals can be sampled after frequency down-conversion, then converted from analog to their digital equivalents. The output signals of the analog-to-digital converters contain both amplitude and phase information. In the receivers, digital quadrature detectors are used to generate real and imaginary parts of the converted input signals. The signals are then filtered and processed by the fast math processor to yield magnitude and phase (Fig. 21). Such a solution is used in the HP 3577A Network Analyzer (9).

Example of Phase Meters Applied in Wave Analyzers

Many wave analyzers, including some modern digital oscilloscopes, combine features of coherent samplers and digital signal processors. Figure 22 shows a two-channel signal analyzer in which time transformed waves in an analog part of the analyzer are converted into digital signals and then processed in the digital processor. The results of processing, in terms of

wave parameters, like phase, magnitude, average value, or others are displayed. This type of circuit is used in the HP 71500A Microwave Transition Analyzer (16), and it is also applied in sampling digitizing oscilloscopes (13).

The details of another solution applied in wave analyzers and vector voltmeters involves the sampling technique and is described in Coherent Sampling in this article can be found in (10).

Example of a Phase Meter Applied in an Impedance Meter

Figure 23 shows a block diagram of a vector impedance meter. Two high-frequency signals, one proportional to the voltage across impedance, the other proportional to the current of the impedance, are converted to lower, intermediate frequency by means of coherent sampling. The coherent sampling process is controlled by a phase-locked-loop circuit supported by a search loop acting when the phase-locked-loop is not locked. The intermediate-frequency signals are processed by a low-frequency pulse phase detector to determine the phase. A voltage magnitude signal after demodulation defines the impedance magnitude.

ERRORS IN PHASE METERS

The errors affecting the accuracy of direct phase measurements originate in analog and digital parts of different phase measuring devices described before. The phase measuring devices have two or more channels. Misalignment of the channels, interference between adjacent channels, differences in delays, threshold levels, gains, differences in hysteresis loops of comparators, and noise introduce major errors. If analog readout is used the reading error is added to the previous errors. In digital time interval meter errors also involve the time base uncertainty and the count error (17,18,19). Frequency down-conversion introduces additional phase errors due to differences in converter channels. Low-frequency digital phase meters operating without built-in references can have their maximum errors below 0.1° maintaining very fine resolution, well below 0.1° (17).

Figure 23. Simplified block diagram of an impedance meter with a phase meter unit.

Calibration of low-frequency phase meters requires application of high precision, digitally synthesized variable phase generators whose estimated uncertainties do not exceed 20 millidegrees (20). In microwave and millimeter wave regions, air-filled transmission lines of calibrated lengths help achieve significant accuracy. The length of such lines can be measured with laser interferometers yielding errors below 0.01° (17).

TIME MEASUREMENT

The function of a time interval measurement device is to produce a quantitative measure of the length of a time interval at

the input of the device. Typically this interval is presented by short, logic level start and stop pulses that have a relation to some physical phenomena whose time behavior is to be studied by the device. Its output is given either by an analog quantity such as a voltage change in a capacitor or as a digital number, an output of a counter, for example (Fig. 1). Typically the final output of the device, independent of the method that is being used, is characterized by a number that gives the length of the time interval as a multiple of the least resolvable time interval of the device. This can be achieved by an analog-to-digital converter (ADC) in case of analog realizations, for example. The least resolvable time interval characterizing the measurement system being used can be considered the value of its least significant bit (LSB) analogically to ADCs. It defines the resolution of the device. Accordingly, a time-interval measurement device is often called a time-to-digital converter (TDC).

Time-to-digital converters have manifold applications. They are one of the critical components of a pulsed time-of-flight laser radar, for example, where the distance measurement accuracy is directly dependent on the time measurement accuracy. Pulsed time-of-flight laser radars can be used in geodesy and also in various industrial inspection applications (1,2).

Time interval counters can also be found in applications of time and frequency comparison. For example, each Global Positioning System (GPS) time transfer receiver uses a time interval counter to determine the time difference between the atomic clock on board a GPS satellite and a local clock. In frequency calibration applications, the time interval measurements obtained from an oscillator being tested and a reference oscillator are used to characterize the performance (such as the phase offset, frequency offset, and frequency drift of the oscillator being tested with respect to the reference oscillator (38,39,40).

Another application area for TDCs is found in nuclear science, for example, dE/E , time-of-flight, and positron annihilation studies (3,4). TDCs are also used in the calibration of test equipment for electronic circuits. Since in high-speed large-scale integration (LSI) circuit propagation delays are reduced to 100 ps or even below, high speed and accuracy are required in automatic test equipment systems (ATE). Test timing control with an accuracy to the order of tens of picoseconds is needed and, to maintain such timing performance, the calibration hardware requires even higher-performance TDCs with picosecond resolution and accuracy (5,6).

The most straightforward method to realize a time-to-digital converter is to have an electronic counter counting the pulses of an accurate oscillator during the start–stop time interval. The resolution of this method, as shown later, is defined by the period of the oscillator. This means that a resolution better than in the range of nanoseconds is difficult to achieve due to difficulties in the realization of high-frequency, high-performance oscillators. The purpose of this article is to describe this time-interval measurement method with its variations where its fundamental resolution limitation is overcome with some kind of

Figure 1. Input–output interfaces of a time-to-digital converter (TDC). LSB is the least significant bit, for example, 10 ps to 10 ns. $N \times \text{LSB}$ is the length of the start–stop interval.

interpolation and where accordingly picosecond-range time-interval measurement resolution can be achieved. Some of these interpolator structures, such as analog-to-digital converters or digital delay lines, can be used as stand-alone time-interval measurement units, too.

In the following sections, first some important performance parameters of a time-interval measurement device are given. Then the basic counting method is analyzed in more detail. After this, interpolation methods to increase the precision and accuracy of the counting method are described. Next the performance of one interpolation technique, the Nutt method, is analyzed in more detail. This method is selected as it is perhaps the most popular technique in high-performance time-to-digital conversion with many practical realizations. As part of the presentation some practical realization aspects are also discussed.

PERFORMANCE PARAMETERS IN TIME-INTERVAL MEASUREMENT

The main performance parameters used in connection with the time-interval measurement method are resolution, precision, and accuracy.

The term *resolution* is used for the smallest time interval that can theoretically be resolved by the TDC in a single measurement, that is, the quantization step (LSB). The term (single-shot) *precision* is used for the standard deviation (σ) of the measurement result distribution around the mean value (m) when a single time interval is measured repeatedly (Fig. 2). In a practical measurement, the single-shot precision is influenced, besides the quantization error, by nonidealities like jitter in timing signals and power-supply noise and can be used to estimate the smallest real time interval that can be resolved. Since precision is limited by quantization error and statistical error sources, it can usually be improved by averaging. (7).

While precision gives the statistical variation of the measurement result around a mean value, single-shot accuracy is affected both by this statistical variation and any systematic errors in the mean value. The statistical variation (σ) can be reduced by averaging but systematic errors cannot, that is, the precision of the average may be good but the accuracy may still be poor. Systematic errors include, for example, linearity and stability errors. Integral linearity error (INL) is the deviation of the input-output characteristics from the ideal, straight-line input-output characteristics (Fig. 2). Differential linearity

error (DNL) is the deviation of a single quantization step from the ideal value of 1 LSB. Stability of a TDC is defined as the sensitivity of its characteristics with temperature, supply voltage, time, and the like. Clearly, to measure the systematic errors reliably, the statistical variation should be reduced to a negligible level by averaging.

Other parameters that should be considered while choosing time-measurement techniques are, for example, the measurement range of a TDC and the conversion time. The range of the device defines the maximum time interval than can be measured or digitized. Conversion time is the time between the end mark of the input time interval and the moment when the measurement result is ready. Sometimes, especially with analog TDCs, a parameter called dead time that typically defines the period during which the system is incapable of accepting a new start after a registered start signal (conversion time plus possible recovery time) is also used. Dead time might be an important parameter especially in applications where the time intervals to be measured are randomly distributed, which often happens in nuclear measurements. For example, if the start detector efficiency is high and the stop efficiency low, respectively, a long dead time may result in reduced measurement efficiency since many of the start signals that trigger the time-interval measurement may not be followed by a valid stop signal. In this case it is important for the TDC to recover from the useless start pulse as quickly as possible (8).

COUNTING METHOD

Analysis of the Method

The counting method where clock pulses are counted during the input time interval is perhaps the most simple time measurement method (Fig. 3). Provided that the reference clock is accurate, a crystal oscillator, for example, the counter method has a wide linear range and good stability. In asynchronous measurement, that is, when the measurement begins in a random phase with respect to the clock, the maximum error in one measurement is $\pm T_{\text{clk}}$, where T_{clk} is the clock period. For each input interval the counter will measure either N or $N + 1$ counts, and for this binomial distribution it can be shown that for an input interval of $(Q + F) T_{\text{clk}}$, where Q is an integer and $0 \leq F < 1$, the expected value of the measurement result is $Q + F$ and the standard deviation is (9)

$$\sigma = \sqrt{F(1 - F)} \quad (1)$$

Thus, the measurement precision varies with the input interval and the worst case value for $F = 0.5$ is $0.5 T_{\text{clk}}$. For a 1 GHz clock, for example, the maximum single-shot error is ± 1 ns and the worst case value for σ is 500 ps.

To improve precision, averaging can be used in applications where several samples per measurement can be taken. In asynchronous measurement and for N_{av} samples the precision is (9)

$$\sigma = \frac{\sqrt{F(1 - F)}}{\sqrt{N_{\text{av}}}} \quad (2)$$

which is shown in Fig. 4.

In asynchronous measurement the phase of the input interval with respect to the clock is continuously distributed over

Figure 2. Performance parameters of a time-to-digital converter.

Figure 3. Basic counting method, where clock pulses are enabled to increment the counter during the input time interval. The gating logic of (b) is preferable to that in (a) because it allows only integral clock pulses to reach the counter. The method in (a) can produce short pulses that may or may not be detected by the counter.

the clock period or even several periods. Synchronous measurement is also possible. This can be realized if the start timing signal is repeated at a constant rate and if the oscillator of the system is locked to this rate. However, if the measurement is completely synchronous with respect to the clock, averaging does not improve precision. On the other hand, if the phase of the synchronous measurement can be controlled, it is possible to achieve a faster precision improvement rate than in asynchronous measurement. For example, if the phase of the start signal and oscillator has M discrete values evenly distributed within the clock period, the measurement precision can be improved in averaging with a rate proportional to $1/M$ (rather than to $1/\sqrt{M}$ as in synchronous measurement) but the improvement is limited by factor $1/M$. The synchronous method utilizing discrete phase steps is, however, more difficult to realize than the asynchronous method (9).

The basic counting method has good accuracy, since with a stable crystal oscillator reference the linearity and both the short-term and long-term stabilities are good. Measurement range can be increased simply by increasing the number of bits in the counter. With standard commercially available high-performance crystal oscillators the maximum frequency is limited to a few hundred megahertz, which corresponds to a single-shot resolution of several nanoseconds (10). With advanced clock-generation techniques single-shot resolutions of about 500 ps to 1 ns have been achieved. Here the idea typically is to multiply the clock frequency of a reference source by a

phase-locked loop which includes a divider and a voltage-controlled oscillator (VCO) in its loop. In integrated time-to-digital converter realizations a VCO based on a ring oscillator is especially attractive, since the measurement resolution can be further improved by utilizing all the clock phases of the ring oscillator (3,11).

Input Synchronization

In the counting method, the gating of the digitization clock may have a great impact on the measurement accuracy. If the input interval (asynchronous with respect to the clock) is directly used for gating the counter, short clock pulses appear frequently at the input of the counter [Fig (3a)]. These may or may not be long enough to increment the counter and cause an unpredictable error in the averaged result. Therefore, a synchronizer, with which the input interval is synchronized to the clock, is needed. An example is shown in Fig. 3(b), where only full-size clock pulses are allowed to the counter. It should be noted that even now there is a small possibility for a counting error if the setup time of the flip-flop is not fulfilled, which increases the propagation delay of the flip-flop and shortens the clock pulse. However, the probability to lose an entire clock pulse is small. More advanced synchronizing methods are presented in later sections.

Figure 4. Precision of the counting method as a function of the fractional part F (by which the length of a time interval exceeds an integral number of clock periods) and number of averaged samples N_{av} .

INCREASING PRECISION AND ACCURACY

The precision of the counting method can be improved by averaging but at the cost of measurement time. In some applications, however, averaging is not possible due to the single-shot nature of the measured phenomena. Typically this is the case in the experiments made in nuclear physics. The aim of this section is to discuss the variations of the basic counting method that enable one to achieve an improved single-shot precision with realistic clock rates. These methods typically utilize accurate clock generators in connection with other time-interval measurement techniques, which enable a resolution markedly better than the clock period to be achieved. In a way these methods digitize the basic clock period so that the resolution of this digitization (interpolation) defines the system resolution.

Figure 5. Principle of the vernier method in time measurement. Two oscillators with different periods are triggered by the timing pulses. The counting is terminated at coincidence. The time interval t_x is effectively digitized with a resolution defined by the period difference.

Vernier Method

In the vernier method (12), two startable oscillators with slightly different frequencies are used to achieve an LSB equal to the difference of the oscillator periods (dt in Fig. 5). The start mark of the input interval enables the oscillator with a lower frequency $f_1 = 1/T_{\text{clk}}$, and the stop mark enables the oscillator with a higher frequency $f_2 = 1/(T_{\text{clk}} - dt)$. A counter records the pulses from the oscillators until, since $f_1 < f_2$, at some point the two oscillators will be in phase. Then, from Fig. 5, $t_x = (N_1 - N_2) T_{\text{clk}} + N_2 dt$. If $t_x < T_{\text{clk}}$, $N_1 = N_2 = N$ and $t_x = Ndt$. The maximum value of N_2 is T_{clk}/dt so the maximum conversion time (time from the stop mark to the coincidence) is $(T_{\text{clk}}/dt)(T_{\text{clk}} - dt)$. To measure input intervals longer than T_{clk} , two counters recording both N_1 and N_2 are needed; see Ref. (12).

Functionally the vernier method can also be considered a time-interval multiplier where the multiplication factor is T_{clk}/dt . When the multiplied time interval is digitized with a clock having a period T_{clk} , the effective resolution is equal to dt . The accuracy and the resolution of this method can be high if f_1 and f_2 are stable and dt is made small (typically 1% of the period).

In the dual vernier method (Fig. 6), the startable start and stop oscillators have an equal frequency $f_0 = 1/(T_{\text{clk}} + dt)$, and their phase crossover points with a third, continuously running oscillator with a frequency $f_{\text{clk}} = 1/T_{\text{clk}}$ are detected (13). Similar to the basic vernier method of Fig. 5, the LSB of the measurement is dt and the maximum conversion time is $(T_{\text{clk}}/dt)(T_{\text{clk}} + dt)$. Using the three counter values N_c , N_1 , and N_2 , the input interval can be calculated from

$$t_x = N_c T_{\text{clk}} + N_1(T_{\text{clk}} + dt) - N_2(T_{\text{clk}} + dt) \quad (3)$$

Good single-shot resolution can be achieved with the vernier techniques. In Ref. 13 the LSB is 20 ps with a clock frequency of 200 MHz, and in Ref. 6 the measured standard deviation is

2.3 ps in a 2 ns range with a clock frequency of 500 MHz. The time-measurement circuitry in Ref. 13 is a discrete implementation for a commercial counter, while the TDC in Ref. 6 is an integrated implementation but the start and stop clock sources are external. This circuit is used for tester timing calibration, where the start input is the reference clock and the stop input is a tester output.

Nutt Method

Analysis of the Method. A powerful method for measuring time intervals is to combine an accurate digital clock and an analog or digital interpolation circuit as shown in Fig. 7 (14). The input time interval is roughly digitized by counting the reference clock periods during this interval. The counter is enabled at the first clock pulse following the start mark, and disabled at the first clock pulse following the stop mark. The resulting time interval T_{12} is synchronized to the clock and is, therefore, accurately measured. The fractions T_1 and T_2 are digitized separately with interpolators to improve single-shot resolution. For an n -bit interpolator the LSB of the measurement is equal to $T_{\text{clk}}/2^n$ and the input interval t_x can be calculated from the following equation:

$$t_x = T_{12} + T_1 - T_2 = N_c T_{\text{clk}} + N_1 T_{\text{clk}}/2^n - N_2 T_{\text{clk}}/2^n \quad (4)$$

Note that if the system clock is asynchronous with respect to the time intervals to be measured, the length of time fractions T_1 and T_2 change randomly in a repeated measurement although their difference has only two discrete values (dt if the main counter result is $N_c - 1$ or $dt - T_{\text{clk}}$ if the main counter result is N_c). This means that in the averaged results the nonlinearities of the interpolators are also averaged in a way so that the accuracy of the system is not limited by them. Note also that the drifts of the interpolators tend to cancel as it is the difference $T_1 - T_2$ that counts in the final result.

Figure 6. Principle of the dual vernier method in time measurement.

Figure 7. Block diagram and operating principle of a TDC based on the Nutt method. The start–stop time interval is digitized coarsely by the counter. In addition, time fractions from start and stop to the next following clock pulses, respectively, are digitized by interpolators.

The interpolators are generally based on analog time-to-voltage conversion or on digital delay lines. These structures can achieve good single-shot resolution in a limited dynamic range. Practically, they can be used for measuring time intervals from tens to some hundreds of nanoseconds with a resolution of 100 ps to 1 ns depending on the measurement range. The Nutt method can thus be considered a technique that combines the inherently good single-shot resolution of an analog time-interval measurement method such as time-to-amplitude conversion, for example, and the accuracy and wide linear range of the counting method.

Synchronization. For the Nutt method it is typical that the timing signals and the clock are deliberately asynchronous. This produces a synchronization problem in the generation of time intervals T_1 , T_{12} , and T_2 . In Fig. 8(a) is shown a simplified scheme of a control block of a TDC based on the Nutt method. The end mark of $T_1(T_2)$ is taken from the output of the flip-flop

Figure 9. Improved synchronization of start and stop inputs in a TDC based on the Nutt method. Here the setup time violation in D2 does not produce error in T_1 and T_2 .

D2a (D2b). However, in asynchronous measurement the start (stop) pulse arrives at a random phase with respect to the reference clock. When the setup time requirement of the flip-flop D2a or D2b is not fulfilled, the propagation delay of that flip-flop will increase [Fig. (8b)] and in the extreme case the flip-flop will enter a metastable state. Thus, if a start (stop) pulse occurs near the rising clock edge, an erroneous measurement is possible. Unlike in the basic counting method, even a small excess delay affects the measurement result directly through T_1 and T_2 .

The probability of a synchronization error can be reduced by waiting before sampling the output of flip-flop D2a (D2b). In the scheme of Fig. 9 the measurement will be accurate if the flip-flop D2a (D2b) settles in less time than T_{clk} (15). This method reduces the number of errors very effectively (for a detailed analysis, see, e.g., Ref. 16, pp. 533–538). However, the linear measurement range required from the interpolators is doubled as compared to the scheme of Fig. 8(a).

The synchronization scheme of Fig. 8(a) can be used if averaging is used to improve resolution, and it is possible to detect and reject a single incorrect measurement. The scheme of Fig. 9 increases the measurement range required of the interpolators, which is a disadvantage in digital interpolators, where the integral nonlinearity due to delay element mismatch increases. In time-to-voltage conversion, a short time offset is an advantage, since the nonlinear part of the characteristics due to switching effects is then not used for measurement.

Figure 8. (a) Synchronization of start and stop inputs in a TDC based on the Nutt method. Problems may occur when the clock edge and output of first flip-flops occur within the setup time of D2. (b) Simulated propagation delay of a 0.8 μm current mode logic flip-flop.

Figure 12. Delay line as a time-measurement unit. The output of the flip-flops is latched by the stop signal. The first flip-flop not set indicates the length of the start–stop interval.

Digital Interpolators. An example of a digital delay line is shown in Fig. 12. In a delay line, the time measurement unit is the propagation delay of a logic gate, usually of an inverter. In Fig. 12, the start mark of the input interval travels along the delay line. When the stop mark arrives, it stores the status of the delay line into the flip-flops. From these data, the input interval can be coded as a multiple of one gate delay. The delay of the element must be controllable to compensate for the effects of process variations and temperature and supply changes. As shown in Fig. 13, the control parameter can be the current (23,24) or the load of the element (5,25,26). The control voltages (p_{bias} , n_{bias} , bias) are commonly created in analog phase-locked loops or delay-locked control loops (23,25) but also digital control has been implemented (24,26).

However, if the propagation delay of a logic gate is directly used as the measurement unit, the achievable resolution is limited by the minimum gate delay, which, in turn, depends on the technology and operating temperature range. This limitation can be avoided by using the difference of two gate delays as the quantization step. The delay difference can be implemented with two delay lines having slightly different gate delays (27–30), but a more compact solution is the pulse-shrinking delay line presented in Ref. (31). In a pulse-shrinking delay line (Fig. 14) the time resolution depends on the difference between two delays of a single element. The input pulse t_{in} propagates in a chain of delay elements. The pulse shrinks by a constant amount in each element until it disappears entirely. The SR (set–reset) flip-flops are set by the propagating pulse until the pulse vanishes, after which the following flip-flops are left reset. The address of the first flip-flop not set is coded to the output. The propagation of the rising edge of the input pulse is slowed down by the current-starving transistor N_1 while the falling edge travels fast. Thus, in each element the pulse shrinks with an amount equal to the delay difference. The amount of

Figure 13. Controllable delay elements used in delay lines. In (a) the delay is controlled by adjusting the current of the inverter with the bias voltages n_{bias} and p_{bias} . In (b) the delay is controlled by varying the load seen by the inverter.

shrinking, that is, the LSB of the delay line is controlled by the bias voltage v_{bias} at the gate of the current starving transistor N_1 . V_{bias} is generated in the delay-locked loop, which stabilizes the length of the delay line to be equal to the reference clock period. Basically, the bias voltage is adjusted so that a pulse with a width of one clock period, which is equal to the maximum input time interval of the interpolator, just disappears in the last delay element.

Delay line interpolators based on inverter gates are easily implemented in a complementary metal oxide semiconductor (CMOS) process, have low power consumption, and can relatively easily be transferred to a low-supply-voltage environment (3,32). Also, the conversion time of a TDC based on delay-line interpolators is short, since the conversion time depends on the propagation delay of the delay element chain and the coding logic. The main factor limiting the performance is the nonlinearity caused by random mismatch, which determines the achievable single-shot resolution. LSB values below 100 ps are difficult to achieve. For example, with a clock frequency of 100 MHz, a 128-tap delay line is needed to achieve an LSB of 80 ps. The single-shot error due to the nonlinearity of the interpolators is then easily larger than 1 LSB, as can be seen from the measured nonlinearities in Refs. 3 and 33, which are 80 ps for a 32-tap delay line and 300 ps for a 100-tap delay line, respectively.

Note also that the delay-line method in which the difference of the two absolute delays defines the resolution is equivalent to the vernier method in which resolution was defined by the difference of the oscillator periods.

CHARACTERISTICS OF THE INTERPOLATION METHOD

Single-Shot Precision

Similarly to a counter, in asynchronous measurement (i.e., the start pulse arrives at a random phase with respect to the reference clock) the worst case single-shot precision of an ideal TDC based on the Nutt method is, according to Eq. (1), 0.5 LSB and the precision improves with averaging according to Eq. (2). The maximum single-shot quantization error is ± 1 LSB (if the interpolator results are truncated as is the case for delay lines and analog dual-slope converters) and the measurement result distribution is binomial (N or $N + 1$ counts). In practice, however, several error sources from the timing logic and interpolators deteriorate precision. In asynchronous measurement, the single-shot precision is often limited by gain error or, more generally, by the nonlinearity of the interpolators.

In Ref. 34 the effect of interpolator nonlinearity on the accuracy and precision of the TDC is analyzed. Assuming a general form $e(x)$ for the interpolator error (nonlinearity and/or gain error), using subscripts 1 and 2 for the start and stop interpolators, respectively, and by normalizing T_{clk} to 1, the TDC measurement error for input time interval $Q + F$ (Q is an integer and $0 \leq F < 1$) in a single measurement can be calculated as

$$\begin{aligned} e(x) &= e_1(x) - e_2(x + F), x + F < 1 \\ e(x) &= e_1(x) - e_2(x + F - 1), x + F \geq 1 \end{aligned} \quad (5)$$

The maximum single-shot measurement error is now equal to the maximum difference $e_1(x) - e_2(x)$, and the measurement result distribution is no longer binomial but more than two

Figure 14. Pulse-shrinking delay line and schematic of the delay element.

results are possible. Since in asynchronous measurement x varies randomly and with equal probability between $0 \leq x < 1$, the mean value of the TDC measurement error is

$$\begin{aligned} m &= \int_0^1 e(x) dx = \int_0^1 e_1(x) dx - \int_0^{1-F} e_2(x+F) dx \\ &\quad - \int_{1-F}^1 e_2(x+F-1) dx \\ &= m_1 - m_2 \end{aligned} \quad (6)$$

where m_1 and m_2 are the mean values of the start and stop interpolator errors. Thus, the gain error or the INL of interpolators reduces to a constant bias error independent of the time to be measured. This is an extremely important result as it indicates that the error due to the interpolator nonlinearities is effectively averaged out in a repeated measurement due to the randomization process present in the asynchronous measurement. This is the source for the excellent linearity of the method.

The nonlinearities of the interpolators do have an effect on the precision of the system, however. The variance (σ^2) of the TDC measurement result is (34)

$$\begin{aligned} \sigma^2(x) &= \int_0^1 [e(x) - m]^2 dx \\ &= e_{1\text{rms}}^2 + e_{2\text{rms}}^2 - (m_1 - m_2)^2 - 2 \int_0^{1-F} e_1(x) e_2(x+F) dx \\ &\quad - 2 \int_{1-F}^1 e_1(x) e_2(x+F-1) dx \end{aligned} \quad (7)$$

Therefore, the standard deviation of the measurement result is a function of the fractional part (F) of the input time interval ($Q + F$). Since $0 \leq F < T_{\text{clk}}$, the measurement precision due to interpolator nonlinearity or gain error has now a period of T_{clk} instead of LSB.

To clarify the effect of interpolator gain or linearity error on precision, it is relatively easy to evaluate Eq. (7) if only gain error is considered. Assuming an ideal gain of K and an actual gain of k , the gain error of the interpolator can be calculated as

$$e(x) = x \left(\frac{k}{K} - 1 \right) \quad (8)$$

By making use of Eqs. (6) and (7) the mean and standard deviation of the measurement results can now be calculated. In

Fig. 15 are shown three examples of the results due to the combined effect of quantization error and $\pm 1\%$ gain error in 8-bit interpolators. For ideal interpolators the mean value of the TDC measurement error is zero ($m_k = 0$) and the maximum value of σ is $0.5 \times \text{LSB} \approx 0.002 T_{\text{clk}}$. The effect of gain error on precision can be clearly seen, since, assuming $T_{\text{clk}} = 10$ ns, for example, the worst-case σ value increases from the theoretical value of 20 ps to 60 ps [Fig. 15(c)].

Gain error, unlike nonlinearity, is relatively easy to cancel by calibrating the interpolators. It is also possible to measure the gain of both interpolators and use these values for calculation of the measurement results provided that the worst-case measurement resolution is adequate and that no overflow occurs. Nonlinearity of the interpolators can only be compensated by measuring the linearity error and using this data for correction of the measurement result. However, since this is technically more complicated than in the case of gain error, minimization of interpolator nonlinearity is important.

Also, jitter in the input timing signals, clock, and timing logic deteriorates precision with respect to the theoretical value. However, their effect is usually small compared to the nonlinearity of the interpolators. Timing jitter of the logic due to thermal, shot, or flicker noise is fairly small if a resolution of tens of picoseconds is adequate. According to simulations (35) and measurements (11), rms jitter seems to be 0.1% to 0.2% of the gate delay for both CMOS and bipolar elements. For 20 to 30 gates in series in the timing logic, the total rms jitter is only 1 ps to 3 ps for 200 ps to 300 ps gate delay. However, power-supply noise or other types of noise coupling can significantly increase jitter.

Linearity

In asynchronous averaging the linearity of a TDC based on the Nutt method is basically as good as the linearity of the counting method. Gain error or nonlinearity of the interpolators increases the single-shot error from the theoretical quantization error, but for averaged results their effect is a constant bias error offset independent of the time to be measured (as previously shown). Thus, interpolator gain error and nonlinearity have no effect on the linearity of the TDC, provided that enough samples are being averaged. If the interpolators were exactly identical, their errors would cancel completely (zero offset). In practice, the magnitude of the offset depends on the matching of the interpolators. If the nonlinearity is due to systematic errors, the interpolators usually have very similar nonlinearities and only a small offset error can be expected to remain.

Figure 15. Simulated error of average (m_k) and standard deviation (σ_k) of the TDC result due to 8-bit quantization and $\pm 1\%$ interpolator gain error in asynchronous measurement.

However, if the nonlinearity is due to random mismatch (as in well-designed delay lines, for example), a similar cancellation cannot be assumed.

A prerequisite for the randomization of the systematic errors in averaging measurement is that the system clock and the time intervals are asynchronous, that is, the length of the time fractions T_1 and T_2 vary randomly in the operating range of the interpolator in a repeated measurement (although their difference has only two values). This is indicated by the simulation results of Fig. 16, which show the linearity error and standard deviation when Gaussian jitter with rms amplitudes $0.1 T_{\text{clk}}$ to $1 T_{\text{clk}}$ is added to the start input. It is clearly seen that jitter with a standard deviation of $1 T_{\text{clk}}$ effectively randomizes the measurement.

Stability

The stability error of a TDC based on the interpolation method can be divided into two components. The first is an offset-type

error that is independent of the input time interval and arises in the control logic (differences in delays) and interpolators (mismatch). If the start and stop signal paths in the control block and in the interpolators were identical, including the loading and layout, then, according to Eqs. (4) and (6), the measurement results would have zero offset. However, random mismatch cannot be avoided, and when this offset changes with temperature, for example, stability error is created. Methods for calibrating the TDC to compensate interpolator offset (and the stability error) are presented in Ref. 36. The effect of the mismatch in the interpolators can be minimized by using interpolators alternately in the start and stop channels, see Ref. 37.

The second error component arises from the temperature or time dependency of the reference oscillator. This gain error is dependent on the input interval. For example, a stability specification of ± 25 ppm inclusive of temperature dependency (0° to $+50^\circ\text{C}$) and aging corresponds to an error of $< \pm 25$ ps in a measurement range of $1 \mu\text{s}$.

Figure 16. Simulated error of average (m_k) and standard deviation (σ_k) of the TDC result in synchronous measurement as a function of Gaussian jitter amplitude ($0.1 T_{\text{clk}}$ to $1 T_{\text{clk}}$).

Table 1. Some Commercially Available Frequency- and Time-Interval Counters

Manufacturer	Model No.	Time Base	Resolution	Range	Method
Hewlett Packard	HP 5314A	10 MHz	100 ns	250 ns–1 s	Counting
Hewlett Packard	HP 53131A		500 ps	1 ns–105 s	Counting

Hewlett Packard	HP 5370B		20 ps	–10 s–10 s	Digital Vernier
Hewlett Packard	HP 53310A		200 ps		
Hewlett Packard	HP E1725B		100 ps		
Hewlett Packard	HP E1740A		100 ps		
Tektronix	CMC251		10 ns	40 ns–1 s	Counting
Tektronix	73A541	10 MHz	100 ns	0–25 s	Counting
Standford Research	SR620	10 MHz	25 ps	±1000 s	Counting
Fluke	PM 6665		100 ns	100 ns– 2×10^8 s	Counting
Fluke	PM 6666	10 MHz	100 ns	100 ns– 2×10^8 s	Counting
Fluke	PM 6685	10 MHz	250 ps	6 ns–100 ms	Counting
Fluke	PM 6680B		250 ps	0 s– 10^{10} s	
Fluke	PM 6681		50 ps	0 s– 10^{10} s	
EG&G Ortec	457		<100 ppm $\times$ FS	50 ns–80 μ s	Analog TAC
EG&G Ortec	566		<100 ppm $\times$ FS + 5 ps	10 ns–2 ms	Analog TAC
EG&G Ortec	567		<100 ppm $\times$ FS + 5 ps	10 ns–2 ms	Analog TAC
EG&G Ortec	9308		<25 ps + 10μ l/l $\times$ FS	0 μ s–325 μ s	
Lecroy	2228A/2229	20 MHz	250 ps	0 ns–500 ns	Counting
Lecroy	4208	125 MHz	1 ns	±8.3 ms	Digital interpolation
Berkeley Nucleonics	B980	20 MHz	48.8 ps	±6871 s	Interpolation
Leti Dept. Syst.	Asic-circuit	12.5 MHz	1.3 ns	0.7 ns–8.7 μ s	Analog interpolation
AMSC	TMC1004	31.25 MHz	530 ps	~4 μ s	Del line
Racal Instruments	2251A	10 MHz	±1 ns	–2 ns– 8×10^5 s	Interpolation
Racal Instruments	2351	10 MHz	8 ps	2 ns–8 s	

In summary, it can be concluded that the nonidealities of the interpolators to large extent cancel out in averaged results. The difference between the nonidealities of the interpolators remains, but in many cases (systematic error source) it can be expected to be smaller than the nonideality itself. Furthermore, this error is constant for all input intervals so it can be corrected simply by subtracting it from the measurement results provided that it does not change with temperature, supply voltage, and the like. Single-shot accuracy, on the other hand, is affected by all nonidealities.

Commercial Time-Interval Counters. Table 1 lists certain universal frequency- or time-interval counters that are currently commercially available. This is not an exhaustive list of all useful types nor of all manufacturers. The column headed Time Base tells the used base frequency of the oscillator in the digital counting principle, if it is given. The precision gives the least significant digit in display or single-shot precision, whichever is presented in the manufacturers data sheet. In analog TACs the time range is usually selectable, in which case the minimum and maximum time ranges are given. The precision of the TAC is given as a function of the full-scale (FS) range.

CLOCKS IN TELECOMMUNICATIONS

The concept of time flow is related to the possibility of arranging events in an ordered sequence, that is, saying which of two events comes earlier (1). Then, a timescale is a system of labeling events with real numbers according to their sequence. The labeling law is quite arbitrary, given that the order of events is left unchanged, but for practical purposes it must use equal intervals (two time intervals are defined equal if equal processes take place during these two intervals) for its successive scale intervals (*uniform time scale*).

Clocks are devices able to measure the time, that is, to produce time markers together with identification of these markers (1). Under different forms, they are widespread in everyday life and penetrate a surprisingly wide range of applications. Beyond ruling human (and automated) activities worldwide, for example, clocks provide the timing of digital electronics in almost all of the commonly used electronic equipment and synchronize the nodes of telecommunications systems and networks. The performance of such systems heavily relies on the quality of the synchronization signals.

The oldest historical examples of clocks date back to 1400 B.C. and are a sun dial and a clepsydra (water clock) made by Egyptians. With several technical improvements, sun dials (based on measuring the rotation of a shadow with the sun) and clepsydrae (based on measuring the level of water in a vessel with a regulated flow of water as input or output) had been in use until the Middle Ages. On the other hand, early mechanical clocks date back to the thirteenth century, and the first pocket watches, based on a spring mechanism, were constructed in the fifteenth century. However, the true milestone was the invention of pendulum clocks due to Galileo and Huygens and the introduction of the swing wheel as an oscillating element. After that, until the introduction of electrical clocks and then of clocks based on quartz and atomic oscillators, mechanical clocks did not change substantially, at least in their operating principle, until today.

From a theoretical viewpoint, the operating principle of clocks of any kind consists of a generator of oscillations and an automatic counter of such oscillations. Although differing in capability, the oscillator can be based on *any* (pseudo-)periodic physical phenomenon. The swinging of a pendulum or a wheel in mechanical clocks, the vibration of atoms in a crystal around their minimum-energy position in quartz clocks, the radiation of specific quantic atomic transitions in atomic clocks are the best known examples because of their wide application, but are not the only ones. Recently, even the rotation period of pulsars, after some (although not trivial) data processing, has been used to design clocks of the highest precision, comparable to that of the best atomic clocks.

CLOCK SIGNALS AND THEIR TIMING RELATIONSHIPS

A clock is a device supplying a *timing signal*, or *chronosignal*, defined as a pseudoperiodic (ideally periodic) signal for controlling the timing of actions. Examples of applications are the timing of digital hardware systems (gates, chips, or boards), where the operation of different modules must be synchronized to ensure proper transfer of binary symbols, and the timing of telecommunications systems, where digital signals are multiplexed; transmitted, and switched.

Typical chronosignal waveforms are sine and square waves. A general expression describing a pseudoperiodic waveform which models the timing signal $s(t)$ at the output of clocks is given by (2,3)

$$s(t) = A(t) \sin \Phi(t) \quad (1)$$

where $A(t)$ is the instantaneous amplitude (in the following, without loss of generality, we assume $A(t) \cong A_0$), $\Phi(t)$ is the total phase, and the instantaneous frequency $\nu(t)$ is given by

$$\nu(t) = \frac{1}{2\pi} \frac{d\Phi(t)}{dt} \quad (2)$$

Obviously, in the ideal case, when the pseudoperiodic timing signal is periodic, the total phase increases linearly with time, that is,

$$\Phi(t) = 2\pi \nu_n t \quad (3)$$

where ν_n is the nominal frequency. In the actual case, other components may affect the total phase increase, including frequency offset, drifts, and purely random fluctuations. This topic is thoroughly discussed in the section Characterization and Modeling of Clocks.

A chronosignal fulfils its duty by triggering events, that is, timing the controlled process. From this point of view, a timing signal can be also modeled by a series of pulses spaced T apart, at special instants called *significant instants*. The timing signal triggers the controlled process at those instants. Suitable significant instants can be identified, for example, at the signal zero-crossing instants for ease of implementation.

Synchronous and Asynchronous Clock Signals

Two *synchronous* (from the Greek etymon $\sigma\upsilon\gamma\chi\rho\nu\nu\omicron\varsigma$, built by $\sigma\upsilon\nu = with$ and $\chi\rho\nu\nu\omicron\varsigma = time$) clock signals have the same frequency, at least on average, and a precisely controlled phase relationship (i.e., with phase offset $\Delta\Phi = \text{constant}$, at least on average). The expression “at least on average” points out that some zero-mean small fluctuations may be accepted as unavoidable in real systems.

Conversely, two clock signals are *asynchronous* if they are not synchronous.

Mesochronous Clock Signals

Two *mesochronous* (from the Greek etyma $\mu\acute{\epsilon}\sigma\omicron\varsigma = medium$ and $\chi\rho\nu\nu\omicron\varsigma = time$) clock signals are asynchronous timing signals which have the same frequency, at least on average, but no control on the phase relationship. It is worth noting that because the phase fluctuation function is proportional to the integral of the frequency fluctuation function, the phase error

$\Delta\Phi$ is not theoretically limited over an infinite time interval, even for small zero-mean frequency fluctuations (thus, $\Delta\Phi = \text{any value}$).

Plesiochronous Clock Signals

Two *plesiochronous* (from the Greek etyma $\pi\lambda\eta\sigma\acute{\iota}\omicron\varsigma = close$ and $\chi\rho\nu\nu\omicron\varsigma = time$) clock signals are asynchronous timing signals that have the same frequency values only nominally, but actually are different within a given tolerance range.

Heterochronous Clock Signals

Two *heterochronous* (from the Greek etyma $\acute{\epsilon}\tau\epsilon\rho\omicron\varsigma = different$ and $\chi\rho\nu\nu\omicron\varsigma = time$) clock signals are asynchronous timing signals that have different nominal frequencies.

Practical Examples

To give sound examples of the above abstract concepts, a phase-locked loop (PLL), locked to its reference, outputs a timing signal that is synchronous with the input signal because of the feedback control on the phase error between the signals. A frequency-locked loop (FLL), which is a feedback system operating like a PLL, but which instead controls the frequency error between the input and the output signals, outputs a signal that is mesochronous with the input. Two oscillators, even designed and built as equal by the same supplier, output plesiochronous timing signals because of unavoidable manufacturing tolerances. In telecommunications networks also, two digital signals that have the same nominal bit rate (e.g., two 2.048 Mb/s digital signals) are always plesiochronous unless generated by the same piece of equipment (driven, in this case, by a single clock). On the other hand, two digital signals with different rates (e.g., 2.048 Mb/s and 8.448 Mb/s signals) are heterochronous.

NETWORK SYNCHRONIZATION STRATEGIES

Network synchronization deals with the distribution of time and frequency over a network of clocks spread over a wide geographical area (4). The goal is to align the time and frequency scales of all of the clocks by using the communications capacity of the links interconnecting them (e.g., copper cables, fiber optics, radio links). In particular, network synchronization plays a central role in modern digital telecommunications (5,6) and has a determining influence on the quality of most services offered by the network operator to its customers.

Many intriguing examples of synchronizing a large number of oscillators are found in nature. Lindsey et al. (4) pointed out as one of the most spectacular ones the synchronous fireflies described by Buck and Buck (7). These fireflies flash their light organs at regular but individual and independent intervals if they are not close together. Though, if many of these insects are placed in a relatively close proximity, they synchronize their light organs until they flash in unison. Other biological examples are the synchronization of individual fibers in heart muscles to produce the familiar heartbeat or the resting and active periods of mammals, which exhibit rhythms.

During the last few decades, many different network synchronization strategies have been conceived, mainly for synchronizing the nodes of telecommunications networks, nowadays the most demanding application of network

Figure 1. Network synchronization strategies. (a) Full plesiochrony; (b) Master-slave synchronization (despotism); (c) Mutual synchronization (democracy); (d) Mixed mutual/master-slave synchronization (oligarchy); (e) Hierarchical mutual synchronization (hierarchical democracy); (f) Hierarchical master-slave synchronization (hierarchical despotism).

synchronization. The main features of such strategies are now summarized briefly, pointing out for each one its sociopolitical analogy. Such an analogy may be helpful in understanding immediately the pros and cons of each strategy, because it may be more direct to assess a form for governing human beings rather than clocks.

Full Plesiochrony (Anarchy)

The full plesiochronous strategy is actually a *no-synchronization strategy*, that is, does not involve any synchronization distribution to the network of clocks. Each clock is independent of the others (*autonomous clocks*), as shown in Fig. 1(a), hence the expression synchronization *anarchy*.

Anarchy is the easiest form of government, but it relies on the good behavior of the single elements. Because of the lack of any timing distribution, the synchronization of the processes in different nodes is entrusted to the accuracy of the network's autonomous clocks, which therefore must feature excellent performance.

In the late 60s, this strategy was generally considered the most promising for synchronizing telecommunications networks because of the decreasing cost of atomic oscillators and the limited synchronization requirements envisaged then. Nevertheless, as the cost of such oscillators became stable and the new digital transmission and switching techniques demanded increasing timing performance, this strategy was eventually abandoned.

Master-Slave Synchronization (Despotism)

The principle of master-slave (MS) strategies is based on the distribution of the timing reference from a clock (*master clock*) to all of the other clocks of the network (*slave clocks*), directly or indirectly as shown in Fig. 1(b). Although the master clock must be an expensive high-precision oscillator (usually based on an atomic frequency standard), slave clocks can be much

less expensive. A slave clock is usually implemented as a PLL, mostly based on a quartz crystal oscillator and locked to the reference timing signal coming from the master. In PLLs, the output timing signal is kept synchronous with the input reference by a feedback control on the phase error between them.

The loop time constant of the PLL controls its filtering properties from the phase fluctuations of the input reference and of the internal oscillator. Further details can be found in the section "Characterization and Modeling of Clocks" and in Refs. 8–11. Therefore, an important step in designing a MS synchronization network is to design the loop time constants of the slave clocks in different nodes, according to specific requirements.

Despotism may look unethical, but it is certainly effective in ensuring very tight control on the slaves. A MS network is synchronous with the master clock and stable by definition. Therefore, MS-based strategies are currently the most widely adopted in many applications. Questions may arise, nevertheless, on what happens if the unique master fails. The hierarchical MS strategy has been conceived for this purpose.

Mutual Synchronization (Democracy)

Mutual synchronization is based on direct, *mutual control* among the clocks, so that the output frequency of each one is the result of the "suggestions" of the others, as shown in Fig. 1(c). Such pure democracy looks appealing. There are no masters and no slaves, but mutual cooperation exists, though the "discipline" of the mutually controlled elements is hard to guarantee.

Modeling the behavior of such networks or even ensuring the stability of the control algorithms (the control algorithm must damp the transient impairments, preventing them from propagating indefinitely) can be a very complex task (4,12,13). Thus networks so designed are quite expensive, but they are extremely reliable. Hence, till now, the field of application of

mutual synchronization has been limited mostly to special cases, for example, military networks.

Mixed Mutual/Master-Slave Synchronization (Oligarchy)

In this mixed solution, the mutual synchronization strategy is adopted for the main clocks of the network, and the MS strategy is adopted for the peripheral clocks, as shown in Fig. 1(d).

Oligarchy is a compromise that aims at mitigating the absolutism of despotism. Greater reliability is achieved, and the peripheral MS synchronization substantially simplifies the system control architecture compared with pure mutual synchronization.

Hierarchical Mutual Synchronization (Hierarchical Democracy)

Hierarchical mutual synchronization is a generalization of the democratic strategy. In hierarchical democracy, some count more than others.

All of the network nodes are given a relative weight p_i ($0 \leq p_i \leq 1$, $\sum_i p_i = 1$), as shown in Fig. 1(e). When all of the weights are equal, this strategy becomes pure mutual synchronization. When the weight of one clock is equal to one and all of the others are equal to zero, this strategy becomes a MS synchronization.

Hierarchical Master-Slave Synchronization (Hierarchical Despotism)

The Hierarchical Master-Slave (HMS) synchronization strategy is a variant of the pure MS strategy. A master clock synchronizes the slave clocks, directly or indirectly, and these are organized in two or more hierarchical levels [see Fig. 1(f)]. Protective mechanisms against link and clock failures are allowed through alternative transversal synchronization routes. If the master fails, another clock takes its place according to a hierarchical plan.

The HMS strategy is currently the most widely adopted for synchronizing modern digital telecommunications networks because of the excellent timing performance and reliability which is achieved at limited cost.

Mixed Plesiochronous/Synchronous Networks (Independent Despotic States)

Although most national administrations adopted the HMS strategy for synchronizing their national networks, locking all of them to a supranational timing reference is not feasible (it is worth noting that the GPS can take this role from a *technical* point of view, but for *political* reasons it is hardly accepted as first-choice reference by most national administrations). Therefore, the current arrangement is to have several synchronous HMS networks, each plesiochronous relative to the others. The political analogy is a set of independent despotic states.

CHARACTERIZATION AND MODELING OF CLOCKS

Designing such complex systems as networks of clocks or specifying the quality requirements of clocks suitable for a given application is not an obvious task. To face these issues effectively, first it is necessary to identify a proper mathematical model of the clock and of the timing signals generated and distributed. This section supplies this background knowledge. Simplified models of autonomous and slave clocks are described and the

basics of time and frequency stability characterization are provided.

Timing Signal Model

A general expression describing a pseudoperiodic waveform that models the timing signal $s(t)$ at the output of clocks is given by Eq. (1). A common and comprehensive model used to characterize $v(t)$, defined by Eq. (2), is given by [see the ideal case of Eq. (3)]

$$\begin{aligned} v(t) &= v_0 + v_d(t) + v_a(t) \\ &= v_n + \Delta v + \sum_{k=1}^{K-1} \frac{q_k t^k}{k!} + \frac{1}{2\pi} \frac{d\varphi(t)}{dt} \end{aligned} \quad (4)$$

The *nominal frequency* v_n (design goal) and the *starting frequency offset* Δv (also called *synchronization error*) make up the starting frequency v_0 of the oscillator:

$$v_0 = v_n + \Delta v \quad (5)$$

The term $v_d(t)$ is the deterministic (for a given oscillator) time-dependent component, modeling the *frequency drift* mainly caused by oscillator aging as a power series:

$$v_d(t) = \sum_{k=1}^{K-1} \frac{q_k t^k}{k!} \quad (6)$$

The coefficients q_i ($k = 1, 2, \dots, K-1$) are time-independent, random variables that are fixed for a given oscillator. The frequency drift in real clocks is caused by complex phenomena (14,15), but in practice, for simplicity, the previous summation is often truncated to the first term, so that

$$v_d(t) \cong q_1 t = D v_n t \quad (7)$$

where D is the *linear, fractional-frequency drift rate*.

Finally, the term $v_a(t)$ is the random time-dependent component

$$v_a(t) = \frac{1}{2\pi} \frac{d\varphi(t)}{dt} \quad (8)$$

where $\dot{\varphi}(t)/(2\pi)$ and $\varphi(t)$ are stochastic processes, respectively, the *random frequency deviation* and the *random phase deviation* that model oscillator intrinsic phase-noise sources.

Basic Quantities

Two functions strictly related to $\dot{\varphi}(t)$ and $\varphi(t)$ are used in treating random frequency and time fluctuations: the *random fractional-frequency deviation* $y(t)$ and the *random time deviation* $x(t)$, defined as

$$\begin{aligned} y(t) &= \frac{1}{2\pi v_n} \frac{d\varphi(t)}{dt} \\ x(t) &= \frac{\varphi(t)}{2\pi v_n} \end{aligned} \quad (9)$$

These functions, together with the model and definitions provided in the previous section, have been widely adopted by

specialists since the 60s (2,16). More recently, needs in particular in the telecommunications field for designing synchronization equipment and networks led to the introduction of the following other basic functions, more oriented to the timing aspects of clocks.

The generated *time* function $T(t)$ of a clock is defined in terms of its total instantaneous phase as

$$T(t) = \frac{\Phi(t)}{2\pi\nu_n} \quad (10)$$

It is worth noting that for an ideal clock $T_i(t) = t$ holds, as expected. For a given clock, the *time error* function $TE(t)$ between its time $T(t)$ and a reference time $T_r(t)$ is defined as

$$TE(t) = T(t) - T_r(t) \quad (11)$$

Whereas the time error variation over an interval of duration τ starting at time t (i.e., the error committed by the clock in measuring an interval τ with respect to the reference clock) is called *time interval error* $TIE_t(\tau)$ and is defined as

$$\begin{aligned} TIE_t(\tau) &= [T(t + \tau) - T(t)] - [T_r(t + \tau) - T_r(t)] \\ &= TE(t + \tau) - TE(t) \end{aligned} \quad (12)$$

Now, it must be pointed out that $x(t)$ and $TE(t)$ have very similar definitions, but they differ in that the $TE(t)$ function takes into account both deterministic [the $\Delta\nu$ and $\nu_d(t)$ terms in Eq. (4)] and random phase-noise components, whereas $x(t)$ depends only on random components. Finding the deterministic components in the TE measured data may not be straightforward, and the result can depend greatly on the parameter estimation technique adopted (14,17,18).

Basic Concepts of the Quality of Clocks

Characterizing the *quality* of a clock (or equivalently of its timing signal) is one of the most complex and debated tasks in coping with the issues involved in practical applications of clocks. In the most common sense, one simple term is used to refer to clock quality: the *precision*, somehow denoting how close the timing signal of the clock under test is to a reference timing signal. From a more technical viewpoint, the quality of a clock is usually defined by two other basic terms: stability and accuracy. Although it must be recognized that researchers and engineers working in different fields may understand these two terms with subtly different meanings, the definitions provided in the following can be considered quite general.

The *stability* of a clock deals with measuring the random and deterministic variations of the instantaneous frequency (or of the time) of the output timing signal, compared to the nominal value (i.e., in practice, to a reference clock), over a given observation interval. With reference to the mathematical model of Eq. (4), the clock stability depends on the random phase noise $\varphi(t)$, the frequency offset $\Delta\nu$, and the frequency drift D (and all the coefficients q_i). The relative weights of such parameters in affecting stability depend on the observation interval. If it is short, the frequency drift is negligible.

When the observation interval is small, the expression *short-term* stability is commonly used. Otherwise the expression *long-term* stability applies. What should be the meaning of the word “small”, that is, where the boundary between short and

long term is, depends on the specific application. For example, in the time metrology field, it is common to consider observation intervals longer than one day as long-term, whereas in telecommunication applications observation intervals over 100 s are also definitely considered long term.

Since the 1960s, several quantities have been defined that aim at characterizing clock stability. Although they differ in applicability, they highlight distinct phenomena in the phase noise or they are more oriented to some application. A few details are given in the following subsections.

Accuracy, on the other hand, denotes the maximum frequency error $\Delta\nu_{\text{MAX}}$ compared to the nominal value, which may be measured in general over the entire clock life (e.g., twenty years), unless specified differently. It must be pointed out that accuracy also depends in principle on the previously mentioned parameters $\varphi(t)$, $\Delta\nu$, and the coefficients q_i , but in this case the observation interval is so long that in practice the only relevant quantities are the frequency offset and drift. Accuracy is usually expressed by the dimensionless ratio $\Delta\nu_{\text{MAX}}/\nu_n$ and is often measured in 10^{-6} units ($\mu\text{Hz}/\text{Hz}$), in engineering practice also called parts per million and abbreviated as ppm (not a SI unit).

Autonomous Clocks

An *autonomous clock* is a device for generating a timing signal, suitable for measuring time intervals, starting from a periodic physical phenomenon.

Examples of state-of-the-art autonomous clocks are atomic frequency standards (such as the rubidium or cesium-beam or hydrogen-MASER oscillators) and crystal quartz oscillators. Some of them (the rubidium and the quartz oscillators) may also be locked to a reference timing signal and thus work as slave clocks.

A simplified model of an autonomous clock is shown in Fig. 2. Here, according to the timing signal model of Eq. (4), the total output phase $\Phi(t)$ consists of three deterministic terms that model the phase generated by an ideal oscillator, the frequency offset $\Delta\nu$, and the frequency drift D , together with the random phase noise $\varphi(t)$.

The parameter $\Delta\nu$ decreases with more accurate clock calibration procedures (this is part of the production process). Such calibration procedures aim at making the clock generate an output frequency as close as possible to the nominal frequency. As for the frequency drift coefficient D , it is worth noting that it is practically null in cesium-beam oscillators, but it cannot be neglected in rubidium and quartz oscillators, at least in the most demanding applications. Finally, some details above the characteristics of the random phase-noise process $\varphi(t)$ are provided in the section Common Types of Clock Noise.

Figure 2. Simplified model of autonomous clock.

Figure 3. Scheme of the principle of a phase-locked loop (PLL).

Slave Clocks

A *slave clock* is a device for generating a timing signal, suitable for measuring time intervals whose phase (or much less frequently frequency) is locked to a reference timing signal at its input. They are usually implemented as PLLs (or FLLs).

Slave clocks are very widely employed (see Network Synchronization Strategies) in synchronization networks and in digital telecommunication equipment. Such a widespread application of slave clocks calls for a somewhat detailed description of their models and properties. Therefore, the next subsections deal with the main characteristics of PLLs and the operating modes of slave clocks in synchronization networks.

Phase-Locked Loops. A device that implements phase locking to a reference timing signal commonly uses loop architecture, based on the negative feedback principle, where the output signal keeps tracking the phase fluctuations of the input reference. Such a device is called *phase-locked loop* (PLL).

A scheme of the principle of PLL operation is depicted in Fig. 3. In this scheme, the following functional blocks are used:

- *phase detector*, which supplies a signal proportional to the phase error between the PLL output signal $s_o(t)$ fed back and the input reference $s_r(t)$;
- *low-pass filter (loop filter)*, whose task is canceling the high-frequency phase fluctuations at the output of the phase detector;
- *voltage-controlled oscillator (VCO)*, which supplies a periodic signal that has a frequency dependent on its input signal; the VCO, with null input signal, oscillates with angular frequency ω_F (VCO free-run angular frequency).

To summarize, the phase detector supplies a signal proportional to the phase error between $s_o(t)$ and $s_r(t)$. This signal is low-pass filtered and feeds the VCO to control its oscillation frequency and keep the phase error between $s_o(t)$ and $s_r(t)$ around zero.

Analysis of the PLL operation is very complex because of the nonlinear phase-detector block. A detailed analysis of its properties can be found in Refs. 8–10. Moreover, Ref. 11 glances at practical implementation. In this section, only the main features of PLL are overviewed.

Assuming that the phase error between $s_o(t)$ and $s_r(t)$ remains small (PLL locked to the reference), the system can be described by a linear model. Therefore, its input-output transfer function $H(s)$ between the input and output phase-modulation signals in the Laplace-transform domain can be evaluated. The transfer function $H(s)$ is typically of the second-order low-pass type (because the loop filter is typically first-order), with cut-off frequency B (PLL bandwidth). It is characterized by the natural angular frequency ω_n and the damping factor ζ and

thus has the form

$$H(s) = \frac{\phi_o(s)}{\phi_r(s)} = \frac{Cs + D}{s^2 + 2\zeta\omega_n s + \omega_n^2} \quad (13)$$

where C and D are constants dependent on the particular PLL characteristics.

The PLL tracks the phase modulation of the reference signal $s_r(t)$ if the bandwidth of the phase-modulation signal is lower than B . Under static lock conditions (i.e., $s_r(t)$ is ideally periodic), the phase detector supplies a time-constant signal which makes the VCO oscillate at the same frequency of $s_r(t)$. The values ω_n and ζ are determined by the design of the PLL blocks, and they control the duration, amplitude, and shape of the transients in the PLL response $s_o(t)$ to disturbances in $s_r(t)$.

Noise in PLLs. Characterizing noise sources in a PLL is a very important topic that aims at evaluating slave clock performance. The linear model, depicted in Fig. 4, approximates PLL behavior by pointing out the main internal noise sources (a more thorough analysis is provided in Ref. 10). This model holds under the assumptions that the PLL is locked to the reference and that the noise amplitudes are small, compared to the signals.

In Fig. 4, ϕ_o and ϕ_r (rad) are the phase noises in $s_o(t)$ and $s_r(t)$, respectively, ϕ_{VCO} (rad) is the phase noise generated by the VCO, V_{DF} (V) is the tension noise produced by the phase detector and the loop filter, and $F(s)$ is the transfer function of the low-pass loop filter (all quantities in the Laplace domain).

By analyzing this model, considering one input at a time, the following transfer functions can be evaluated:

$$H(s) = \frac{\phi_o(s)}{\phi_r(s)} = \frac{K_0 K_d F(s)}{s + K_0 K_d F(s)} \quad (14)$$

$$H_A(s) = \frac{\phi_o(s)}{V_{DF}(s)} = \frac{K_0 F(s)}{s + K_0 K_d F(s)} \quad (15)$$

$$H_B(s) = \frac{\phi_o(s)}{\phi_{VCO}(s)} = \frac{s}{s + K_0 K_d F(s)} \quad (16)$$

The transfer functions $H(s)$ and $H_A(s)$ are low-pass, and $H_B(s)$ is high-pass (because the loop filter $F(s)$ is low-pass). Therefore,

- the phase noise in the reference signal $s_r(t)$ and the internal tension noise produced by the phase detector and the loop filter are low-pass filtered to the output signal $s_o(t)$;
- the internal phase noise produced by the VCO is high-pass filtered to the output signal $s_o(t)$.

Figure 4. Linear model in the Laplace-transform domain of a phase-locked loop (PLL) with the main internal noise sources.

Key Parameters of PLLs. Four key parameters describe the performance of a PLL (here, the angular frequencies ω are considered, but the equivalent frequencies f can also be considered because $\omega = 2\pi f$):

- the *hold-in range* $\Delta\omega_{\text{HI}}$, defined as the maximum deviation of the frequency of the input signal $s_r(t)$ from the VCO free-run angular frequency ω_F within which the PLL can track slow (quasi-stationary) variations of the input frequency;
- the *pull-out range* $\Delta\omega_{\text{PO}}$, defined as the maximum deviation of the input frequency from ω_F within which the PLL can track fast variations (e.g., like steps) of the input frequency;
- the *lock-in range* $\Delta\omega_{\text{LI}}$, defined as the maximum deviation of the input frequency from ω_F within which the PLL can lock fast (i.e., faster than $1/\omega_F$ seconds) to the new input frequency;
- the *pull-in range* $\Delta\omega_{\text{PI}}$, defined as the maximum deviation of the input frequency from ω_F within which the PLL can lock in any time to the new input frequency.

Typically, $\Delta\omega_{\text{LI}} < \Delta\omega_{\text{PO}} < \Delta\omega_{\text{PI}} < \Delta\omega_{\text{HI}}$.

Operating Modes of Slaves Clocks. A slave clock may operate in the following three modes in a synchronization network:

- *Locked Mode.* The PLL tracks the input frequency, which is always within the hold-in and pull-out ranges. The lock mode may be *ideal*, if the reference signal is always available and stable, or *real* (stressed), if the reference is affected by impairments of various kinds.
- *Free-Run Mode.* If the reference signals fails, the clock works autonomously, supplying the free-run frequency ω_F of the internal oscillator (VCO) that works with null control tension. Generally, the nominal ω_F is designed equal to the nominal reference frequency.
- *Hold-Over Mode.* As in the free-run mode, if the reference signals fails, the clock works autonomously, supplying the frequency generated by the VCO. In this case, nevertheless, the last control tension value at the input of the VCO before the reference failure is maintained, so as to hold over the last output frequency value. More sophisticated clocks even store several subsequent samples of the VCO control tension, so that after entering the hold-over mode the VCO is controlled with variable tension extrapolated from the last data. Excellent hold-over accuracy can be achieved in this way, even under a substantial VCO nonlinear frequency drift.

Clock Stability Characterization

The background work on clock stability characterization is immense and broad in range. By the late 1960s, the pressure from clock manufacturers, time and frequency metrologists, and application engineers, all demanding a common set of frequency stability characterization parameters, led the IEEE to convene a committee to recommend uniform measures of frequency stability (2,16). Before and after this breakthrough, since the 1960s, several quantities have been defined aimed at characterizing clock stability. Although differing in ability, they highlight distinct phenomena in the phase, time, or frequency noise, or they are more oriented to some applications. A thorough and

detailed treatise on time and frequency stability characterization and measurement is beyond the scope of this article. Refs. 2, 3, and 17–24 provide further information about this topic.

Frequency-Domain Versus Time-Domain Characterization.

The characterization of clock stability is usually carried out by characterizing, by suitable analytical tools, the random processes $\varphi(t)$, $x(t)$, $\text{TE}(t)$, $y(t)$, or $v(t)$ [see Eq. (4), Eq. (9), and Eq. (11)].

Historically, a dichotomy became established between the characterization of such processes in the *Fourier frequency domain* and in the *time domain*. The inadequacy of measurement equipment strengthened the barriers between these two characterizations of the same noise process. Though these barriers are mainly artificial, nevertheless, it is not always possible to translate unambiguously from any quantity in one domain to any in the other.

Examples of stability measures in the frequency domain are the one-sided power spectral densities (PSDs, or more simply spectra) of phase, time, and frequency fluctuations, as functions of the Fourier frequency. On the other hand, the variances of the fluctuations averaged over an observation interval (e.g., the Allan variance), apart from the fact that they are evaluated starting from samples of time error or of instantaneous frequency, are examples of stability measures in the time domain as functions of the observation interval (time).

Clock Stability Characterization in the Frequency Domain: Power Spectral Densities. The most straightforward and intuitive way to characterize the stability of a timing signal $s(t)$ is to evaluate directly its two-sided spectrum, often denoted as $S_s^{\text{RF}}(f)$ (spectrum in radio frequency), or more precisely its low-pass representation. The variable f is the Fourier frequency. Positive values of f denote frequencies above ν_n . Negative values denote frequencies below ν_n . The spectrum $S_s^{\text{RF}}(f)$ is a continuous-time function proportional to the timing signal power per unit of bandwidth centered around f . The spectrum $S_s^{\text{RF}}(f)$ is definitely *not* a good tool to characterize clock frequency stability. Unfortunately, given $S_s^{\text{RF}}(f)$, it is not possible to determine unambiguously if the power at the various Fourier frequencies results from amplitude rather than phase fluctuations in the timing signal $s(t)$.

Commonly used stability measures in the frequency domain are, instead, the one-sided PSDs of $\varphi(t)$, $x(t)$, and $y(t)$, denoted as $S_\varphi(f)$ (rad^2/Hz), $S_x(f)$ (ns^2/Hz) and $S_y(f)$ (Hz^{-1}), respectively, because they describe the time and frequency stability characteristics directly. The following relationships hold:

$$\begin{aligned} S_y(f) &= \frac{f^2}{\nu_n^2} S_\varphi(f) \\ S_x(f) &= \frac{S_\varphi(f)}{(2\pi\nu_n)^2} \\ S_y(f) &= (2\pi f)^2 S_x(f) \end{aligned} \quad (17)$$

For a long time, the analog measurement of these PSDs in the frequency domain has been the main technique for studying the behavior of oscillators. More recently, the introduction of high-resolution digital instrumentation for the measurement in the time domain (time counters) made time-domain measurement more appealing in most applications. As a matter of fact, the

recent telecommunication standards recommend time-domain quantities evaluated starting from measured samples of time error as standard stability measures.

Clock Stability Characterization in the Time Domain: Telecommunications Standard Quantities. Although the previous frequency-domain characterization has proven very meaningful and complete in studying the behavior of oscillators, it is important to point out that the main concern in many modern applications, for example, in digital telecommunications, lies in controlling *time* deviations over given observation intervals (the buffer fill level in digital telecommunications equipment is proportional to the time error cumulated between the write and read clocks). Therefore, the time-domain stability quantities, basically a sort of prediction of the expected time and frequency deviations over an observation interval τ , are more oriented to this purpose.

Because of the prominent role of timing and synchronization in modern digital telecommunications and therefore the increasing interest in clock stability time-domain characterization far beyond the narrow circle of oscillator designers and time and frequency metrologists, this section focuses in particular on the time-domain quantities adopted for telecommunication standards to specify clock stability.

Among the several quantities defined in the literature for characterizing time and frequency stability, the following five in the time domain have been considered by telecommunication international standard bodies (25,26) for specifying timing interface requirements: the *Allan Deviation* (ADEV) $\sigma_y(\tau)$ square root of the Allan Variance (AVAR); the *Modified Allan Deviation* (MADEV) $\text{mod}\sigma_y(\tau)$ square root of the Modified Allan Variance (MAVAR); the *Time Deviation* (TDEV) $\sigma_x(\tau)$ square root of the Time Variance (TVAR); the *root-mean-square of Time Interval Error* (TIErms); and the *Maximum Time Interval Error* (MTIE). For the formal definitions of the first three quantities and the relevant theoretical background, the reader is referred to the works cited (2,3,19–24). The last two quantities, on the other hand, have been widely used by telecommunication engineers and look somewhat “exotic” to the traditional world of time and frequency metrology. A rather detailed analysis of their properties is available in Refs. 27 and 28.

For the practical purposes of telecommunications clock stability measurement (29), processes $\text{TE}(t)$ and $x(t)$ are considered synonymous [see Eqs. (9) and (11)]. Therefore, based on a sequence of N TE samples, defined as

$$x_i = x[t_0 + (i - 1)\tau_0] \quad i = 1, 2, \dots, N \quad (18)$$

that is measured with sampling period τ_0 over a measurement interval $T = (N - 1)\tau_0$ starting at an initial observation time t_0 , the following five standard estimators have been defined by the ITU-T (25) and ETSI (26) bodies:

$$\text{ADEV}(\tau) = \sqrt{\frac{1}{2n^2\tau_0^2(N-2n)} \sum_{i=1}^{N-2n} (x_{i+2n} - 2x_{i+n} + x_i)^2} \quad (19)$$

$$n = 1, 2, \dots, \left\lfloor \frac{N-1}{2} \right\rfloor$$

$$\text{MADEV}(\tau)$$

$$= \sqrt{\frac{1}{2n^4\tau_0^2(N-3n+1)} \sum_{j=1}^{N-3n+1} \left[\sum_{i=j}^{n+j-1} (x_{i+2n} - 2x_{i+n} + x_i) \right]^2}$$

$$n = 1, 2, \dots, \left\lfloor \frac{N}{3} \right\rfloor \quad (20)$$

$$\text{TDEV}(\tau)$$

$$= \frac{\tau}{\sqrt{3}} \text{MADEV}(\tau)$$

$$= \sqrt{\frac{1}{6n^2(N-3n+1)} \sum_{j=1}^{N-3n+1} \left[\sum_{i=j}^{n+j-1} (x_{i+2n} - 2x_{i+n} + x_i) \right]^2}$$

$$n = 1, 2, \dots, \left\lfloor \frac{N}{3} \right\rfloor \quad (21)$$

$$\text{TIErms}(\tau) = \sqrt{\frac{1}{N-n} \sum_{i=1}^{N-n} (x_{i+n} - x_i)^2} \quad n = 1, 2, \dots, N-1 \quad (22)$$

$$\text{MTIE}(\tau) = \max_{1 \leq k \leq N-n} \left[\max_{k \leq i \leq k+n} x_i - \min_{k \leq i \leq k+n} x_i \right]$$

$$n = 1, 2, \dots, N-1 \quad (23)$$

where $\tau = n\tau_0$ is the *observation interval* and $\lfloor z \rfloor$ denotes “the greatest integer not exceeding z .”

Common Types of Clock Noise

Experimental measurements on clocks may exhibit a wide variety of types of noise, either generated by physical processes intrinsic to the oscillator hardware or caused by external phenomena, such as environmental perturbations, mechanical vibrations, residual ripples in the power supply, signal coupling via power supplies and ground paths, and electromagnetic interference.

Power-Law Noises

In the frequency domain, the model most frequently used to represent the output phase noise measured on clocks is the so-called *power-law model* (3). In terms of the one-sided PSD of $x(t)$, this model is expressed by

$$S_x(f) = \begin{cases} \frac{1}{(2\pi)^2} \sum_{\alpha=-4}^0 h_{\alpha+2} f^\alpha & 0 \leq f \leq f_h \\ 0 & f > f_h \end{cases} \quad (24)$$

where the coefficients h_{-2} , h_{-1} , h_0 , h_{+1} , and h_{+2} are device-dependent parameters [the reason for the subscript $\alpha + 2$, for $\alpha = -4, -3, -2, -1, 0$, is that, historically, the coefficients h_{-2} , h_{-1} , h_0 , h_{+1} , and h_{+2} have been used in defining the power-law model in terms of $S_y(f)$], and f_h is an upper cutoff frequency, dependent mainly on low-pass filtering in the oscillator and in its output buffer amplifier. This clock upper cutoff frequency is

usually in the range of 10 kHz to 100 kHz in precision frequency sources (30).

The five noise types of this model are White Phase Modulation (WPM) for $\alpha = 0$; Flicker Phase Modulation (FPM) for $\alpha = -1$; White Frequency Modulation (WFM) for $\alpha = -2$; Flicker Frequency Modulation (FFM) for $\alpha = -3$; and Random Walk Frequency Modulation (RWFM) for $\alpha = -4$. All of the stability quantities cited are sensitive, according to different laws, to the presence of these noises in the timing signal (3,27).

According to this model, the PSD $S_x(f)$, plotted on a log-log diagram, results approximately in a broken line composed of straight segments, one per each noise type and each having a slope equal to the corresponding power α . In the time domain, on the other hand, the random realizations of the noise process of each single type have characteristic trends which can be recognized at a glance by an experienced eye. To give an idea, Fig. 5(a) through (e) shows sample realizations of TE affected, respectively, by the five types of power-law noise, simulated according to the procedure outlined in Ref. 31. Each realization is made of 4096 random TE samples, normally distributed and having a spectrum that obeys the law of Eq. (24) according to the value of α specified.

These noise processes may be from different physical causes (17) and, on a particular oscillator, they may all be recognized

or some may not. The main features and the origin of each of the five types of power-law noise are now summarized as follows:

Random Walk Frequency Modulation (h_{-2}/f^4). Difficult to measure as close to the carrier (the ideal timing signal). It is mostly ascribed to environmental effects. If RWFM noise dominates, then it is likely that frequent perturbations like mechanical shocks or temperature variations cause random shifts in the oscillation frequency.

Flicker Frequency Modulation (h_{-1}/f^3). The causes of this type of noise are not fully understood, but they are ascribed mostly to the physical resonance mechanism of an active oscillator or to phenomena in the control electronic devices. FFM noise is commonly recognized in high-quality oscillators but can be hidden by WFM or FPM noise in lower quality oscillators.

White Frequency Modulation (h_0/f^2). This is a type of noise commonly recognized in passive-resonator frequency standards, based on a slave oscillator (mostly a quartz) locked to a resonance of another device. Cesium-beam and rubidium standards feature a dominant WFM noise.

Figure 5. Simulated realizations of TE affected by the five types of power-law noise. © 1995 IEEE (32).

Flicker Phase Modulation (h_1/f^1). Although it may be related to a physical resonance mechanism of the oscillator, this noise is added mostly by noisy electronics, especially in the output amplification stages and in the frequency multipliers.

White Phase Modulation (h_2). This noise has little to do with the clock resonance mechanism, but it is added mainly by noisy electronics. In the past, this type of noise was often negligible in high-quality clocks, featuring very low-noise output stages. Nowadays, conversely, the spreading of clocks based on digital control electronics (such as the Digital PPLs, DPLLs) made the WPM noise the most commonly found in several applications, for example on telecommunications clocks, which are maybe the most impressive case of wide application of high-precision frequency sources. The substantial WPM noise in DPLLs is caused by the quantization error in the phase-lock loop, which produces a broadband white noise in the output timing signal. Moreover, WPM is the test-bench background noise caused by the trigger and quantization errors of time counters in the digital measurement of the TE.

Periodic Noise. Though the power-law model has proved very general and suitable for describing most measurement results, yet other types of noise may result in experimental measurements. Periodic noises are quite common. They may be typically caused by 50/60 Hz ac power line interference, diurnal temperature variations, or sensitivity to acoustic or mechanical vibrations, but they may be also due to intrinsic phenomena, such as special frequency control algorithms in DPLLs.

An example of real periodic noise is provided in Fig. 6, which shows the PSD $S_x(f)$ estimated from the TE data ($N = 79000$ samples spaced $\tau_0 = 23$ ms over a total measurement period of $T = 1800$ s) measured on a telecommunications equipment [synchronous digital hierarchy (SDH) STM-16 Line Terminal] slave clock in the synchronized clock configuration (25) according to the procedure outlined in Ref. 29. This PSD exhibits several discrete terms (spikes) in the frequency domain at harmonic frequencies of about 1 Hz, superposed on a power-law noise.

Figure 6. Experimental results featuring periodic noise. This graph shows the PSD $S_x(f)$ measured on a telecommunications equipment slave clock (SDH STM-16 Line Terminal). Several spikes are evident at harmonic frequencies of about 1 Hz. © 1997 IEEE (30).

TECHNOLOGY OF CLOCKS

Clocks are implemented by exploiting a physical mechanism of resonance generating a (pseudo-)periodic signal. In early clocks the oscillation was mechanical (e.g., pendulum clocks). Nowadays in high-precision clocks, on the other hand, the oscillation of atoms around their minimum-energy position in a quartz crystal or the atomic transition between two quantum energy levels is exploited. This section simply summarizes the physical operating principles of high-precision clocks. For a closer look at the physics and technology of quartz and atomic oscillators and their performance, the reader is referred to Refs. 32–37 and to the wide bibliography cited by the articles of Ref. 32.

Quartz Crystal Oscillators

Quartz oscillators are based on the piezoelectric effect discovered by P. Curie in 1880 (Nobel prize, 1903): a mechanical strain in the crystal yields an electrical field and vice versa. Thus a crystal oscillator (XO) is based on exciting a quartz crystal with a periodic electric signal at the resonance frequency (10 kHz to 100 MHz). The resulting resonator has a quality factor quite high (10^3 to 10^6) and, used in a feed-back circuit, allows generating a timing signal featuring excellent short-term stability (in particular over observation intervals smaller than one second). Because it performs well and is inexpensive, it is widely employed in most electronic equipment, for example, as voltage-controlled crystal oscillator (VCXO) in PLLs.

Temperature-Compensated Crystal Oscillators. The main problem with a plain XO is that its natural frequency depends on aging (around 10^{-7} /day in plain models) and on the temperature (typical values are on the order of $10^{-7}/^\circ\text{C}$ or above). To overcome the latter problem, temperature-compensated crystal oscillators (TCXOs) implement feedback control on the oscillation frequency, based on measuring the crystal temperature. Such a device achieves frequency stability of 10^{-7} over a temperature interval from 0° to 50°C . Through digital control, more sophisticated models achieve frequency stability on the order of 10^{-8} in the temperature interval from 0° to 70°C .

Oven-Controlled Crystal Oscillators. Far better than compensating temperature variations with a feedback control is to insulate the oscillator thermally and to make it work in a constant-temperature oven. Such clocks are called oven-controlled crystal oscillators (OCXOs). Thus frequency stability values exceeding 10^{-9} /day are achieved. State-of-the-art OCXOs, based on a double-oven temperature control and on a special technology of crystal excitation, may even achieve frequency stability on the order of 10^{-10} /day.

Performance and Characteristics of Crystal Oscillators. Table 1 summarizes some typical performance data and characteristics of quartz oscillators (for further data see Refs. 35–37). Performance is expressed in terms of the short-term stability (Allan variance) over one second, of the linear drift D (in parts $\Delta\nu_{\text{MAX}}/\nu_n$ per year), of the accuracy expected over one year ($\Delta\nu_{\text{MAX}}/\nu_n$) and of the temperature sensitivity. Moreover, the warm-up time is expressed in terms of the time needed to achieve the accuracy specified between brackets.

Table 1. Typical Performance Data and Characteristics of Commonly Available Quartz Oscillators

	XO	TCXO	OCXO
Short-term stability $\sigma_y(\tau = 1 \text{ s})$		1×10^{-9}	1×10^{-13} to 2×10^{-11}
Linear drift D	$>1 \times 10^{-6}/\text{year}$	$5 \times 10^{-7}/\text{year}$	$5 \times 10^{-9}/\text{year}$
Accuracy, 1 year	2×10^{-6} to 1×10^{-5}	2×10^{-6}	1×10^{-8} to 1×10^{-7}
Temperature sensitivity	$>1 \times 10^{-7}/^\circ\text{C}$	$>5 \times 10^{-7}$ (-55° to 85°C)	1×10^{-9} (-55° to 85°C)
Warm-up time		10 s (to 1×10^{-6})	1 hour (to 1×10^{-8})
Lifetime (performance guaranteed)	10 years to 20 years	>5 years	10 years to 20 years

Atomic Frequency Standards

The operating principle of passive atomic frequency standards is based on achieving a resonance frequency maximizing the number of atomic transitions between two quantum energy levels A and B (characterized by different magnetic moments of one unpaired electron). The energy difference $E_B - E_A$ between the two states is proportional to Planck's constant h and to the frequency ν_0 of the electromagnetic radiation that excites the transition, according to Bohr's law

$$E_B - E_A = h\nu_0 \quad (25)$$

A feedback control, aiming at maximizing the number of atomic transitions from A to B, then allows the system to synchronize on the frequency ν_0 (in the microwave range) within the frequency width given by Heisenberg's uncertainty principle. Hence, the accuracy of the output timing signal is determined solely by the atomic physical properties of the element adopted, that is, on fundamental constants which do not depend on space and time (within known relativistic effects).

Cesium-Beam Frequency Standard. The scheme of the principle of a basic cesium-beam frequency standard is shown in Fig. 7. An oven with a few grams of the isotope ^{133}Cs effuses cesium atoms uniformly distributed among 16 quantum energy levels, and the resonator is based on the transition between the levels characterized by magnetic moments $F = 4$ (level A) and $F = 3$ (level B). The nonhomogeneous magnetic field in magnet 1 (polarizer) deflects only the level B

Figure 7. Scheme of the principle of a cesium-beam frequency standard.

atoms through the resonant cavity, where a microwave signal at frequency $\nu_0 = 9.192631770 \text{ GHz}$ stimulates their transition to level A. The nonhomogeneous magnetic field in magnet 2 (analyzer) deflects only the level A atoms to a detector. Thus the atom flux detected is proportional to the transition probability from level B to level A. Finally, the signal output by the detector is used to control a quartz VCXO, from which the microwave radiation and the output timing signal are synthesized, aiming at maximizing the number of transitions. Therefore the VCXO is locked to the atomic resonance frequency. The excellent short-term stability of the quartz oscillator is coupled with the excellent long-term stability of the atomic resonator.

Hydrogen MASER Frequency Standard. The operating principle of a hydrogen MASER (Microwave Amplification by Stimulated Emission of Radiation) frequency standard is based on the stimulated emission of electromagnetic radiation at the frequency ν_0 corresponding to the transition of hydrogen atoms between states that have magnetic moments $F = 1$ and $F = 0$. As shown in Fig. 8, the hydrogen atoms in the state $F = 1$ are deflected by a nonhomogeneous magnetic field of intensity 1 T into a storage bulb surrounded by a high- Q microwave resonant cavity, which is exposed to another internal magnetic field of intensity 10^{-7} T designed to resonate at the transition frequency $\nu_0 = 1.420450751 \text{ GHz}$. Then the hydrogen atoms decay to state $F = 0$ by bouncing inside the bulb, and microwave electromagnetic radiation at frequency ν_0 , stimulated by the magnetic field, is emitted and detected by an antenna. Finally, a quartz VCXO is kept locked to this signal to produce the output timing signal.

Figure 8. Scheme of the principle of a passive hydrogen MASER frequency standard.

Figure 9. Scheme of the principle of a rubidium gas-cell frequency standard.

Rubidium Gas-Cell Frequency Standard. This frequency standard is based on the transition of atoms of ^{87}Rb between the base levels characterized by magnetic moments $F = 1$ and $F = 2$. A scheme of the principle of a rubidium gas-cell frequency standard is shown in Fig. 9. Light from a lamp filled with ^{87}Rb is filtered through a cell (hyperfine filter) containing ^{85}Rb vapor before it excites ^{87}Rb gas atoms in a cell (absorption cell) inside a resonant microwave cavity. The filter cell allows only the light spectrum component that excites the level $F = 1$ to reach the absorption cell, where this level is thus depopulated as ^{87}Rb atoms absorb the light radiation and migrate to the upper level and then down to both the base levels $F = 1$ and $F = 2$ (optical pumping). If the level $F = 1$ is depopulated by light absorption, the cell becomes transparent, but microwave radiation at $\nu_0 \cong 6.834682613$ GHz is applied to the atoms and excites the transition again to level $F = 1$. In resonance, when the frequency of the applied microwave radiation is exactly ν_0 , the signal at the photodetector shows a minimum. Thus the VCXO is driven accordingly to keep light absorption at its maximum.

The center frequency generated may deviate considerably (10^{-9}) from the theoretical value because of several kinds of environmental causes. For this reason, Rb frequency standards are not suited as *primary* standards, but need to be calibrated against cesium-beam or hydrogen masers, though their short-term stability is usually much better than that of Cs standards.

Performance and Characteristics of Atomic Frequency Standards. Table 2 summarizes typical performance data and characteristics of atomic frequency standards (for further data, see Refs. 35–37). As in Table 1, performance is expressed in terms of the short-term stability (Allan variance) over one second, of the linear drift D (in parts $\Delta\nu_{\text{MAX}}/\nu_n$ per year), of the accuracy expected over one year ($\Delta\nu_{\text{MAX}}/\nu_n$) and of the temperature sensitivity. Moreover, the warm-up time is expressed in terms of the time needed to achieve the accuracy specified between brackets.

The Global Positioning System

The Global Positioning System (GPS) is not actually a *clock*, but rather a complex system of clocks and satellites. Because it supplies, beyond the positioning service, the most accurate

timing reference signal available worldwide, it is treated in this section as it can be considered, broadly speaking, a sort of *superclock*.

GPS is a satellite radio system providing continuous and real-time three-dimensional position, velocity, and time information to suitably equipped users anywhere on the surface of the earth. Born essentially as a navigation and positioning tool, it is used also as a pure time reference (e.g., in telecommunications).

The NAVSTAR system operated by the US Dept. of Defense is the first GPS system available to civilian users. It has been in design since 1973 to take the place of the older navigation system LORAN-C and was completed in 1994, when the last satellites were launched. The Russian GPS system, called GLONASS, is very similar to NAVSTAR. These systems consist of three segments, the space, the control, and the user segments.

This section provides a quite general overview of GPS. A starting point for further details on GPS and its applications are Refs. 38 and 39. Nice and thorough overviews, moreover, are available on the Internet web, in particular at the addresses (40,41). Official pages on the web are provided by the US Air Force on NAVSTAR (42) and by the Russian Space Forces on GLONASS (43), together with almost real-time information (e.g., satellite status reports).

Space Segment. The space segment consists of a set of satellites (constellation), equipped with Cs or Rb atomic clocks, controlled by earth, and transmitting radio signals which can be received by user equipment.

The NAVSTAR constellation is composed of 24 satellites on 6 orbital planes. The satellites operate in 20200 km circular orbits with an inclination angle of 55° and a period of 12 h. The spacing of satellites in orbit is arranged so that a minimum of four satellites are in view to users worldwide at any time. Using spread-spectrum techniques, each satellite broadcasts a pair of L-band RF signals, that is, L1 (1575.42 MHz) and L2 (1227.6 MHz). The L1 signal carries a Precise (P) code and a Coarse/Acquisition (C/A) code, whereas L2 carries only the P code. The P code is normally encrypted so that only the C/A code is available to civilian users.

On the other hand, the GLONASS constellation is composed of 24 satellites on three orbital planes. The satellites operate in 19100 km circular orbits with an inclination angle of 64.8° and a period of 11 h and 15 min. Each satellite transmits on two L frequency groups (the L1 group centered on 1609 MHz and the L2 group centered on 1251 MHz) on a unique pair of frequencies. Unlike NAVSTAR, the GLONASS signals carry both a P code and a C/A code. The P code is encrypted for military use and the C/A code is available for civilian use.

Control Segment. The control segment is composed of all of the GPS facilities on the ground that monitor and control the satellites. The NAVSTAR system consists of five monitor stations, a master control station (MCS), and unlink antennas. The monitor stations (located at Colorado Springs, Hawaii, Ascension Island, Diego Garcia, and Kwajalein) passively track all GPS satellites in view, collect ranging data from each satellite, and send these raw data in real time to the MCS for processing. The MCS (located at Falcon Air Force Base, Colorado) evaluates clock and ephemeris changes in the satellites and uploads such correction data with other maintenance commands to each satellite once or twice each day by the ground-based

Table 2. Typical Performance Data and Characteristics of Commonly Available Atomic Frequency Standards

	Rubidium Oscillator	Cesium-Beam Oscillator	Hydrogen MASER Oscillator
Short-term stability $\sigma_y(\tau = 1 \text{ s})$	2×10^{-11} to 5×10^{-12}	$\sim 10^{-11}$	1×10^{-13} to 1×10^{-12}
Linear drift D	5×10^{-11} /year to 5×10^{-10} /year	0	$< 10^{-13}$ /year to 5×10^{-13} /year
Accuracy, 1 year	5×10^{-10}	2×10^{-11} to 1×10^{-14}	$\sim 10^{-13}$
Temperature sensitivity	$1 \times 10^{-11}/^\circ\text{C}$	$1 \times 10^{-13}/^\circ\text{C}$	$1 \times 10^{-14}/^\circ\text{C}$
Resonance frequency ν_0	6.3846826128 GHz	9.192631770 GHz	1.42040575177 GHz
Warm-up time	2 min to 5 min (to 5×10^{-10})	30 min (to 3×10^{-12})	24 hours (to 1×10^{-12})
Lifetime (performance guaranteed)	5 years to 10 years	5 years	3 years
Basic wear-out mechanism	Rb lamp and cavity life (15 years)	Cs beam tube (5 years)	Ion pumps and H_2 source depletion, cavity resonance shift (7 years)
Portability and intended location	Space, air, ground	Ground and lab. oriented	Definitely ground and lab. oriented
Average size	8 cm $\times$ 8 cm $\times$ 12 cm	50 cm $\times$ 30 cm $\times$ 14 cm	50 cm $\times$ 30 cm $\times$ 50 cm
Weight	0.5 kg to 2 kg	10 kg to 30 kg	> 50 kg
Power consumption	10 W to 50 W	25 W to 50 W	70 W to 100 W

uplink antennas (located in Ascension Island, Diego Garcia, and Kwajalein).

User Segment. A GPS receiver calculates its four-dimensional position (space and time) on the basis of the radio signals received from at least four satellites in view. GPS receivers come in many different sizes, shapes and price ranges, according to their performance and the application for which they are intended. For positioning, for example, inexpensive palm-receivers determine their positions with 95% accuracy (i.e., the value of two standard deviations of radial error from the actual antenna position under specified test measurement conditions) on the order of 100 m, whereas highly sophisticated receivers for military applications may achieve even subcentimetric resolution.

Use of GPS as Timing Reference. Because of the MCS control, GPS provides a timing signal traceable to the Universal Time Coordinated (UTC). Its main problem is very poor short-term stability (95% time accuracy is guaranteed to be 340 ns for the NAVSTAR civilian standard positioning service) together with the possibility of transitory local signal unavailability. Therefore, GPS timing supplies are equipped with a slave quartz oscillator to couple the excellent short-term performance of the latter with the long-term accuracy of GPS. One of the most important applications of GPS receivers as timing supplies is in telecommunications networks to synchronize the nodes of networks spread over long distances.

Clocks in Digital Telecommunications Networks

As mentioned previously, clocks and network synchronization play a central role in modern digital telecommunications (5,6) because they have a determining influence on the quality of the services provided. Clocks used in telecommunications are mainly primary reference clocks and slave clocks in synchronization networks, equipment clocks, and real-time clocks. The next subsections give some detail on this topic.

Architecture of Synchronization Networks for Digital Telecommunications Networks

As mentioned previously in the section Network Synchronization Strategies, among the several network synchronization

strategies conceived, the HMS strategy is the most widely adopted worldwide for synchronizing modern digital telecommunications networks (and it is indicated as the standard choice by Ref. 44). The master-slave architecture is organized hierarchically in at least two levels:

- at level 0, one (or more, for reliability) master *Primary Reference Clock* (PRC) generates the reference signal by running in autonomous mode;
- at the lower levels, slave clocks are synchronized by the signals coming from the upper level (thus traceable to the PRC) and synchronize the clocks of the lower level.

Such slave clocks are called *Synchronization Supply Unit* (SSU) or *Stand-Alone Synchronization Equipment* (SASE) in Europe and in the ITU-T Recommendations. In North America they are commonly known as *Building Integrated Timing Supply* (BITS). These clocks are deployed in telecommunications offices to distribute their timing signal to all of the equipment in the building.

Each piece of equipment in a telecommunications network is provided with an *Equipment Clock* (EC) that distributes the timing to all of the cards and modules of the apparatus. The task of a synchronization network is to synchronize all the equipment clocks in the telecommunications network exactly.

The timing is carried from one clock to another of the synchronization network through *synchronization trails*, which may be direct digital links or even chains of SDH/SONET equipment clocks (44). Direct digital links are usually primary-level signals of the plesiochronous digital hierarchy (PDM) that is the European 2.048 Mb/s (E1) or the North-American/Japanese 1.544 Mb/s (T1), in some cases through a multiplexer-demultiplexer chain. Alternatively, they may be SDM/SONET signals (46) on optical fibers. Within an office, on the other hand, timing is usually distributed as analog 2.048 MHz signals.

Clocks in Synchronization Networks

According to their different roles in a synchronization network, PRCs and SASEs pose different requirements to designers. They are specified, respectively, by the new ITU-T Recommendation G.811 and G.812, which substitute for the previous ones, denoted by the same number, in the Blue Book series.

PRCs are autonomous clocks which are masters of the entire network (level 0). Therefore, they must have the highest long-term accuracy and stability. *Cesium-beam clocks* are well suited to this and therefore are adopted as a national reference.

SASEs are slave clocks designed to filter effectively the synchronization impairments in the incoming reference and have very good or even excellent stability in the hold-over mode, should all of the references fail. They pose different requirements according to their level in the synchronization network. At level 1, *rubidium clocks* are usually adopted, because of their excellent long-term stability coupled with lower cost compared to cesium clocks. At level 2 and below, *quartz OCXO clocks* are mostly adopted. The loop time constant of SASEs is usually on the order of 100 s to 10000 s.

GPS receivers are often used as additional reference at the input of SASEs (as noted previously, many national Administrations do not accept GPS as a first-choice primary reference for political reasons, because it is controlled by a foreign government), especially in very wide area networks to face the issue of timing transfer over long distances.

Equipment Clocks

ECs are designed to run mainly in the slave mode and take their reference either from a synchronization network or from another EC (e.g., the previous EC in a chain). Therefore, on the one hand, their long-term stability in hold-over is specified more loosely than for PRCs or SASEs. On the other hand, their noise filtering capabilities meet different requirements according to the specific type of equipment and network architecture.

As a first example, the ECs of user primary digital multiplexers, which are located at the lowest level of the synchronization hierarchy, are synchronized by an external reference or an incoming digital multiplex signal but do not distribute their timing to any other equipment. Their clocks are usually inexpensive quartz oscillators (XO) with poor accuracy in free run (just better than 50 $\mu\text{Hz}/\text{Hz}$).

The clocks of digital switching exchanges meet tighter requirements because they need to control the slips in the input digital signals by a suitable network synchronization strategy (usually HMS). Most commonly, such exchanges are equipped with high-precision OCXOs whose loop time constant is set to at least 100 s (1000 s is common) to filter out a substantial amount of phase noise on the input reference.

Finally, SDH Equipment Clocks (SECs) are the ECs which must comply with the tightest and best specified requirements. The ITU-T Recommendation G.813 (46) is devoted to their specification, especially as for their output noise and noise filtering capabilities. SECs are usually TCXOs, with a free-run accuracy better than 4.6 $\mu\text{Hz}/\text{Hz}$ and loop bandwidth on the order of 1 Hz to 10 Hz.

Real-Time Clocks

Real-time clocks are a very special kind of equipment clock, strictly related to network and equipment management. Modern telecommunications equipment performs quite sophisticated management functions (e.g., configuration and fault management, performance monitoring) through a local terminal or a remote control center which may even manage several networks of different kinds.

Management messages sent to the local terminal or to the remote control center must include the key information, the

date and time (with one second resolution) on which the fault, the data error, the configuration change, etc. occurred, to allow the network manager to correlate events reported from different nodes and after variable delays. This information is given in each node by the local real-time clock.

It is essential that the real-time clocks of the whole network be synchronized, otherwise it would become impossible to correlate meaningfully different messages (which may be *numerous* and come from different parts of the network) under a common label (i.e., the actual event that happened or the issue that the network manager is interested in knowing). Synchronizing the real-time clocks of a network is a very special issue of network synchronization.

The network synchronization addressed to SASEs and EC has the target of minimizing time error fluctuations among the clocks and mostly achieves deviations not greater than 10 ns or 100 ns, regardless of the starting phase offset. This implies that *synchronous timing signals* (e.g., sine waves) are distributed.

The network synchronization addressed to real-time clocks, on the other hand, is conceptually different: the *absolute time* information (e.g., 23 Dec 1998, 01.32.04 AM) is needed, but a time alignment error of a few ms can be allowed. Here, synchronization is often distributed through software messages carrying the date-and-time message to the network nodes, according to suitable algorithms, as reported, for example, in Refs. 47–49.

NOISE AND DISTORTION

ELECTRIC NOISE MEASUREMENT

The pursuit of extremely sensitive electronic measurements is a common goal among modern scientists and engineers. The limit to the signal energy that may be detected is a result of the noise energy that competes with the signal in a detection scheme. Thus, the measurement and accurate determination of the noise energy is of crucial importance when designing or assessing any signal detection system. Noise may be defined as an unwanted disturbance superimposed upon a useful signal, which tends to obscure the signal's information content. Electronic noise limits the signal detection sensitivity of a wide range of systems such as radar, ground based and satellite communication, cellular phones, and guidance and tracking systems, as well as ultrasensitive physical measurements such as radio astronomy and gravitational wave detection.

Many different types of electronic noise have been studied and characterized. Some types are fundamental in nature and can be derived from basic physical principles. Other types of noise may be classified as technical and are the result of the electronic configuration of the read-out system of the detection or measurement process. To reduce the interference from fundamental noise sources, the physical principle should be understood so that the particular detection scheme may be optimized to minimize the noise. To reduce the interference from technical noise calls for good electronic design that maintains the linearity and stability of the electronic read-out across the dynamic range of operation and the required frequency band.

A common figure of merit that is used when detecting a signal is known as the signal-to-noise ratio. It is defined as the ratio of the signal power to the noise power over the frequency band of the detection system. Filtering techniques exist to maximize the signal-to-noise ratio and are known as optimum filtering. This technique relies on knowing the form of the signal and biases the detection data at the frequencies in which the signal is strongest. However, this article focuses on the common types of electronic noise and the measurement and characterization techniques. Thus, the ways of maximizing the signal-to-noise ratio via filtering techniques will not be discussed, for further information on these methods see Refs. 1–4.

To measure the noise characteristics in an electronic system accurately, we usually use a device that can be referred to as a *null instrument*. Classic devices include a bridge circuit based on a mixer, the Dicke microwave radiometer, and the Michelson optical interferometer. These devices nominally have zero output and are highly sensitive to changes in the power level or phase delay; thus, they are able to make very sensitive measurements of either the power or phase fluctuations in the system. Modern applications of these instruments to state-of-the-art physical experiments include the study of the cosmic microwave background radiation (COBE project) (5), as well as the use of advanced microwave bridge techniques and large-scale optical interferometers for the search for gravitational waves from astrophysical sources (NIOBE, LIGO, and VIRGO projects) (6,7).

Electric noise measurements may be done in the presence or absence of a carrier signal. Modern communication systems make use of carrier signals to transmit information. For

example, mobile telephone systems typically operate at a frequency around 1 GHz. The voice frequencies modulate the carrier frequency as shown in Fig. 1, then the signal is transmitted through the atmosphere by the carrier at 1 GHz. At the receiving end, the signal is demodulated back to audio frequencies. The audio signal competes with the noise in the system, and as long as the signal power is much larger than the noise power, the signal can be heard at the receiver end. There is more than one way to characterize the noise in such a system. When there is a carrier signal present, it is common to measure the noise with respect to the carrier power as a ratio. This means just a relative measurement with respect to the carrier is made, which is comparatively easy to calibrate. If no carrier is present, then it is necessary to measure the absolute noise energy present. This requires a bit more effort in calibration. It is usual to equate the noise energy E_N to an effective noise temperature T_N via Boltzmann's constant, $E_N = k_B T_N$. For a system in equilibrium, this gives the fundamental relationship between the associated temperature and the energy. Basically, the more energy inside any system, the hotter it is. Likewise, when we characterize the electronic noise in a system, the higher the level of noise energy in the system, the higher the system effective noise temperature.

Many individual components make up a modern system. These include amplifiers, attenuators, mixers, and phase shifters. Each component can add to the overall system noise temperature. The common figure of merit that defines the performance of a component is the noise figure, which is equal to the ratio of the output noise density of an input source and that added by the component divided by the source alone (a full mathematical definition is given later). This type of noise characterization only characterizes the component in its small signal input regime (i.e., when no carrier signal is present). If a significant carrier signal is present, then the input power may be considered large, and the noise temperature and figure become functions of carrier power and offset frequency from the carrier. This is because many devices are nonlinear, and nonlinear up-conversions of the signal can cause a frequency dependence known as flicker noise, which can also be power-dependent. If a minimum noise temperature is essential, then

Figure 1. Spectral representation of a carrier signal with signal sidebands modulating the carrier in the presence of noise sidebands. f_C represents the carrier frequency and f_s represents the band of audio frequencies that modulate the carrier.

we must determine the restriction to the input power that is required to maintain small signal noise performance (8).

If a communication system is designed well and is not limited by technical noise, then it usually will be limited by the noise temperature of the components in the system. The noise power in this regime is independent of the carrier power. Thus, if the carrier power can be increased without creating any noise, the signal-to-noise ratio will increase as a result of the associated increase of signal power. Recently new interferometric techniques have allowed the detection of noise in the presence of a microwave carrier to be measured at high carrier powers close to a watt, with a noise performance still governed by the system noise temperature (8,9). This technique has allowed for a factor of 10,000 improvement in sensitivity of noise energy measurements in the presence of a carrier and is expected to have a significant impact on radar and metrology design for the future.

A carrier signal is a sinusoidal tone of single frequency f_c with phase and amplitude. Thus the signal frequencies f_s may be encoded with respect to the phase or amplitude of the carrier signal, and are known as phase modulation (PM) or amplitude modulation (AM). These two “quadratures” of modulation are ideally orthogonal and, thus, are independent and may exhibit vastly different levels of noise. When noise is present in the phase quadrature, it is known as *phase noise*; when noise is present in the amplitude quadrature, it is known as *amplitude noise*. Technical noise sources usually modulate the carrier with a constant fraction of phase or amplitude independent of the carrier power. Thus, if the carrier power is increased, both the signal sidebands and the noise sidebands increase, with the signal-to-noise ratio remaining constant. This is why it is useful to characterize the phase or amplitude noise in the presence of a carrier signal by a power ratio. However, it is not the purpose of this article to dwell on AM and PM signal encoding and noise measurement techniques. More on these topics can be found in the article on Measurement of Frequency, Phase Noise and Amplitude Noise. In this article, the focus is on the measurement and characterization of the small signal component noise, such as the more physically fundamental electric noise sources—thermal noise and shot noise—in the absence of a carrier signal.

Manufacturers of microwave components usually classify the noise performance in terms of the noise figure or temperature in the absence of a carrier (it is much harder to characterize the nonlinear flicker component in the presence of a carrier). Measurements of this kind are thus commonplace, and commercial noise figure test sets are available. High accuracy is available when characterizing modular components based on coaxial or waveguide input and outputs. However, the electronics industry has moved toward miniaturizing components, and many microwave circuits are produced not in modular form but rather are manufactured as part of one integrated circuit collectively called a *wafer*. Accurate characterization techniques of components “on-wafer” remains a principal concern of the metrology community and industry.

It is apparent that the accurate determination of the level of noise in a system is very important. Measurements of the noise temperature have become an art as many standards laboratories around the world strive to make their measurements of the absolute noise more accurate. The advent of the Dicke radiometer has made this possible (10). This article will focus only on the principles of noise types and measurements. To understand

the principles of the radiometer the reader is referred to the article on Radiometers. Recently, in the quest for more accurate measurements, an international comparison of noise temperature measurements has been undertaken between 2 GHz and 12 GHz. The institutes that took part in this comparison were: the National Institute of Standards and Technology, Boulder, Colorado, United States; the Laboratoire Central des Industries Electriques, Fontenay-aux Roses, France; the National Physical Laboratory, Teddington, United Kingdom; the Physikalisch-Technische Bundesanstalt, Braunschweig, Germany (11). The reader is also referred to the home page of these institutes for more details of state-of-the-art measurement techniques (12–15).

MATHEMATICAL REPRESENTATIONS OF NOISE

Noise is a fluctuating quantity that is described statistically by a random variable representing a fluctuating current, voltage, or power with time. When defining a random variable $X(t)$, it is important to have a measure of the extent of the fluctuations. A quantity that achieves this is known as the variance of X . To define the variance, the mean of the fluctuating quantity is first defined as $\langle X \rangle$ (it is common to use angle brackets to represent the mean of a quantity). Then a new variable representing the fluctuation about the mean can be defined, $\Delta X = X - \langle X \rangle$. Taking the mean square of this quantity defines the variance $\langle \Delta X^2 \rangle$. To calculate this quantity, we must know the probability density function $h(X)$ that describes the process. If $h(X)$ and thus the mean and variance are independent of time, the process is known as stationary.

For our purposes, the time domain representation given previously has limited use, and it is informative to introduce the Fourier method and represent $X(t)$ as a spectral density in the frequency domain. The relation between the frequency and time domains is given by the well-known Wiener–Khinchine theorem (16,17). Many undergraduate textbooks deal with this important theorem; for more details see Refs. 1, 18, and 19. The main result for our purposes is a particular case of the Wiener–Khinchine theorem that gives

$$\langle X^2 \rangle = \langle \Delta X^2 \rangle = \int_0^\infty S_x(f) df \quad (1)$$

for an independent stationary random process. Here, $S_x(f)$ is defined as the single-sided spectral density of the random variable, and we refer to f as the Fourier frequency. Equation (1) assumes that $\langle X \rangle = 0$, which is true for a sinusoidal variable. This term represents a direct current (dc) term and is not measured with a modern spectrum analyzer. In effect, the spectrum analyzer will set $\langle X \rangle$ to zero even if it is not.

Equation (1) gives an important result because it means that the spectral density of electronic noise may be measured very easily in principle. This can be done with a quadratic detector and a narrow band amplifier centered at the particular frequency f_0 . Assuming that the bandwidth of the amplifier B_r is small in comparison to the variation in frequency of the spectral density, a constant value of $S_x(f_0)$ can be assumed. From Eq. (1), the quadratic detector will measure a voltage at the output of the amplifier equivalent to

$$\langle v^2 \rangle = G S_x(f_0) B_r \quad (2)$$

and the spectral density is easily determined. Here, G is the power gain of the amplifier, and B_r is defined as the resolution bandwidth of the spectrum analyzer.

DEFINITIONS

Flicker and White Noise

White noise is a random noise with a flat frequency spectral density over the Fourier frequency range of interest. This type of noise is usually produced in the laboratory for testing purposes. For example, white noise generators such as hot or cold resistors are used as calibrated noise sources to calibrate noise measurement systems. In general, noise in system circuits is not white and has a frequency dependence. An example of a nonwhite noise is flicker noise, which has a spectrum proportional to $1/f$ and is prevalent in many circuit systems. Generally, at large values of Fourier frequencies, system noise is white; at small values of Fourier frequencies, system noise is flicker. The frequency at which the transition occurs is known as the flicker corner, which is typically but not necessarily about 10^5 Hz.

Signal-to-Noise Ratio

In general, the signal-to-noise ratio (SNR) in a system is defined as the ratio of available signal power to available noise power present in the system over the bandwidth of detection and is given simply by

$$\text{SNR} = \frac{\text{Signal power}}{\text{Noise power}} \quad (3)$$

In general, this value is dependent on the detection bandwidth. For example, if we detect a sinusoidal frequency of root mean square (rms) power S in the presence of white noise with a power spectral density of S_N (W/Hz), then the signal-to-noise ratio is given by

$$\text{SNR} = \frac{S}{BS_N} \quad (4)$$

where B is the detection bandwidth. Thus, the larger the bandwidth, the larger the detected noise power, which degrades SNR. In general, the signal might consist of more than one frequency and be more complicated than a single sinusoid frequency. To optimize the SNR, a standard result in signal detection theory states that the signal-to-noise ratio is optimized by a filter that has a transfer function proportional to the complex conjugate of the signal Fourier transform divided by the total noise spectral density (1). This technique accepts frequencies where the signal is large and the noise is low and filters out frequencies where the signal is low and the noise is large. Thus, it is prudent to know the signal bandwidth when designing a detection system.

Noise Temperature

From the equi-partition theorem, a gas molecule possesses a mean energy of $k_B T/2$ J/DOF and applies also to electronics, where T is the equilibrium temperature and k_B is Boltzmann's constant. Assuming that an electronic circuit has two degrees of freedom (i.e., amplitude and phase or resistance and

Figure 2. Schematic of a two-port device under test with the associated input and output.

reactance), then the mean noise energy in a passive circuit is $k_B T$ J. Because thermal noise is white, we may express this noise energy as a power spectral density given by $S_N(f) = k_B T$ W/Hz over all Fourier frequencies. Thus, the noise temperature at a selected frequency and reference point in the circuit may be defined as

$$T_N = S_N(f)/k_B \quad (5)$$

where $S_N(f)$ is the noise power spectral density measured or calculated at the circuit reference point and frequency. For a resistor, the noise temperature is approximately the actual temperature, whereas that observed by a diode or a transistor may be significantly larger than the absolute temperature.

Standard Reference Temperature

The standard reference temperature T_S for noise measurements is 290 K. This is an arbitrary choice; however, historically this has been chosen because it is close to room temperature.

Noise Figure

The spot noise figure (or narrow band noise figure) is defined as the ratio of the total noise power spectral density delivered to the output of the system divided by that caused by the source alone, when the source is at the standard reference temperature of 290 K. Assuming that the gain of the system is G (which may be fractional if the system has an overall attenuation), then the noise figure at a particular frequency is defined as (see Fig. 2)

$$F(f) = \frac{S_N(f)_{\text{out}}}{Gk_B T_S} \quad (6)$$

To calculate the overall noise figure $\overline{CIF}$, the spot noise figure is averaged over the frequency response of the system and is given by (18)

$$\overline{F} = \frac{\int_0^\infty F(f)G(f)df}{\int_0^\infty G(f)df} \quad (7)$$

Here $G(f)$ is now the system transfer function.

If a device is noiseless, then $S_N(f)_{\text{out}} = Gk_B T_S$, and both $\overline{CIF}$ and $F(f)$ are unity. However, for an active or dissipative device, there is some associated noise, and the noise figure is usually greater than unity. It is usual to compare noise figures in decibels ($10 \log_{10} [F]$); this is especially useful if the noise figures are close to unity.

NYQUIST'S THEOREM

When a resistor is at a finite temperature, a fluctuating current will occur as a result of random thermal motion of electrons in the resistor, which will in turn will give rise to a fluctuating electromagnetic force (emf). This is the electrical analogue to dissipative Brownian Motion giving rise to a fluctuating force. A detailed description of these principles are given in Ref. 19. This fluctuating emf was predicted by Einstein (20) and first discovered by Johnson [it is known as Johnson noise (21)]. Later, the physics was explained by Nyquist and is known as Nyquist's theorem (22).

To illustrate Nyquist's theorem, first we consider a resistance R in series with an arbitrary reactance $X(f)$, as shown in Fig. 3. It is known that $V(t)$ is a white noise source, and thus its spectral density $S_v(f)$ will be constant. From the Wiener-Khitchine theorem and linear circuit theory, the relation between the voltage and current spectral densities is given by

$$S_i(f) = \frac{S_v}{R^2 + X(f)^2} \quad (8)$$

Assuming $X(f)$ is inductive (we can also assume that it is capacitive and achieve the same result) and equal to $2\pi fL$, where L is the inductance, it can be shown from Eqs. (8) and (1) that

$$\langle i^2 \rangle = \int_0^\infty S_i(f) df = S_v \int_0^\infty \frac{df}{R^2 + 4\pi^2 f^2 L^2} = \frac{S_v}{4RL} \quad (9)$$

Now the equipartition theorem is invoked. It states the mean energy stored in an inductor (a similar equation governing the energy stored in a capacitor exists) is given by (19)

$$\frac{1}{2} L \langle i^2 \rangle = \frac{1}{2} k_B T \quad (10)$$

By combining Eqs. (10) and (9), Nyquist's theorem is derived:

$$S_v = 4k_B T R \quad (11)$$

This derivation gives only the classical solution and is not general for low temperatures and high frequencies. When $\omega \geq k_B T$, there is a quantum correction and takes the form (18,19,22)

$$S_v = \frac{4\hbar\omega R}{e^{\hbar\omega/k_B T} - 1} \quad (12)$$

where $\hbar$ is Planck's constant. When T is large Eq. (12) collapses back to the form given by Eq. (11).

Figure 3. Model of a resistor connected in series with a reactance at temperature T . The voltage generator represents the internal Johnson noise supplied by the passive circuit.

EQUIVALENT CURRENT AND VOLTAGE NOISE GENERATORS

The noise at the output of a two-terminal (or one-port) network can be represented as either a noise current generator in parallel with its admittance or a noise emf in series with its impedance. The equivalent networks are shown in Fig. 4. From Nyquist's theorem, the thermal noise of a resistance R at temperature T , measured in a frequency bandwidth Δf , can be represented by the voltage generator $\sqrt{4k_B T R \Delta f}$ in series with a resistance R , as shown in Fig. 4(b). Likewise, the noise may be equally represented by the current generator $\sqrt{4k_B T g \Delta f}$ in parallel to the resistance $R = 1/g$, where g is the conductance. Thus, the *equivalent noise resistance* or *equivalent noise conductance* of a device at temperature T_0 may be written as

$$R_n = \frac{\langle v^2 \rangle}{\Delta f} \frac{1}{4k_B T_0} = \frac{S_v(f)}{4k_B T_0}, \quad g_n = \frac{\langle i^2 \rangle}{\Delta f} \frac{1}{4k_B T_0} = \frac{S_i(f)}{4k_B T_0} \quad (13)$$

Thus, from a measure of the open circuit voltage $S_v(f)$ [V^2/Hz] or short circuit current spectral density $S_i(f)$ [A^2/Hz], the equivalent noise resistance and conductance may be calculated. Figure 4 implies that the noise spectral densities are related by $S_v(f)/S_i(f) = |Z|^2$; thus the noise conductance and resistance are in general related by

$$R_n = g_n |Z|^2 \quad (14)$$

The noise resistance and conductance can be related to the noise temperature by equating the spectral densities as follows:

$$S_i(f) = 4k_B T_n g, \quad S_v(f) = 4k_B T_n R \quad (15)$$

Thus by equating Eqs. (15) and (13), the relation between the noise temperature, noise resistance, and noise conductance may be written as

$$T_n = \frac{g_n}{g} T_0 = \frac{R_n}{R} T_0 \quad (16)$$

The noise of the device has been expressed in terms of the temperature T_0 , which is not necessarily the device temperature. This is because the device temperature is not necessarily well defined because a temperature gradient might exist, especially for active devices. Thus, it is common to define the noise characteristics with respect to the standard temperature $T_0 = T_s$ (290 K). However, if a device is passive and gives the expected thermal noise, then $T_n = T_0$, $g_n = g$, and $R_n = R$, and the

Figure 4. (a) Two-terminal network represented by a noise current generator in parallel with an admittance. (b) Two-terminal network represented by a noise voltage generator in series with an impedance.

device can be defined with respect to its own temperature as a reference.

It is necessary to mention here that these generators are one-port or two-terminal devices that, for example, may represent a diode or resistive noise source. If a device has more ports or terminals associated with its structure, then more than one noise generator must be considered when calculating the noise parameters. One such example is a transistor that is a three-terminal device. For example, a bipolar transistor has an emitter, base, and collector. In general, three noise generators between each terminal must be considered along with any correlated components. This article does not discuss this problem, and the reader is referred to Ref. 18 for more details. For our considerations, the noise added by a two-port system will be described by the noise figure and noise temperature concept and is discussed in more detail later.

TYPES OF NOISE

Thermal Noise

The basics of thermal noise was given previously by the Nyquist description and holds for a passive resistor as long as its temperature is in equilibrium. This description allows for the general quantification of any measurable noise power in terms of equivalent noise temperature, equivalent noise figure, equivalent noise conductance, and equivalent noise resistance. Thermal noise in a resistor is caused by the random motion of the current carriers, which produce a fluctuating voltage across its terminals. The problem can also be treated as a diffusion problem or velocity fluctuation problem of the current carriers (18). These descriptions are particularly useful when analyzing the thermal noise in a semiconductor. A semiconductor device has a nonlinear voltage current characteristic, and Nyquist's theorem holds for a $p-n$ junction at zero bias where the resistance is considered as dV/dI at the temperature of equilibrium.

Generation and Recombination Noise

Generation and recombination noise ($g-r$ noise) occurs in semiconductors that involve donors, traps, and recombination centers of the charge carriers. In general, the resistance of the material is dependent on the number of charge carriers; thus if the number of carriers fluctuates, the resistance will fluctuate also, causing a fluctuating voltage across the terminals. The appearance and disappearance of carriers by this process is described by

$$\frac{d}{dt}(\Delta n) = -\frac{\Delta n}{\tau} + H(t) \quad (17)$$

Here $H(t)$ is a random noise term, Δn is the fluctuation in number of carriers, and τ is the carrier life time. If we take the Fourier transform of Eq. (17) and apply the Wiener-Khinchine theorem, then the frequency domain representation can be written as

$$S_n(f) = \frac{S_H(f)\tau^2}{1 + 4\pi^2\tau^2 f^2} \quad (18)$$

Assuming that the spectral density of $H(t)$, S_H , is white,

the value of $\langle \Delta n^2 \rangle$ may be calculated from Wiener-Khinchine theorem as

$$\langle \Delta n^2 \rangle = \int_0^\infty S_n(f) df = S_H \tau \int_0^\infty \frac{\tau df}{1 + 4\pi^2\tau^2 f^2} = \frac{S_H \tau}{4} \quad (19)$$

Thus, by combining Eqs. (18) and (19), the spectral density of the number of fluctuating carriers can be shown to be

$$S_n(f) = \frac{4\langle \Delta n^2 \rangle \tau}{1 + 4\pi^2\tau^2 f^2} \quad (20)$$

The spectrum $S_n(f)$ can be calculated as soon as τ and $\langle \Delta n^2 \rangle$ are known.

Shot Noise

Shot noise occurs when there is current flow across a potential barrier. The current fluctuates around an average value as a result of a random emission of current carries across the potential barrier. This effect occurs in $p-n$ junctions in diodes and transistors, at the cathode surface of a vacuum tube, and so on. Shot noise can be driven by thermal fluctuations or other mechanisms such as noise due to recombination centers in the space charge region. To describe shot noise, we will consider a n^+-p junction as shown in Fig. 5.

The characteristic of the current crossing the depletion (or space charge) region can be written as

$$I(V) = I_0(V) \left(\exp \left[\frac{qV}{kT} \right] - 1 \right) \quad (21)$$

where q is the charge of the electron. Here, the first term in Eq. (21) is caused by electrons injected from the n^+ -region to the p -region, and the second term is the reverse current caused by electrons injected from the p -region into the n^+ -region. To proceed further, Schottky's theorem is invoked (23). It states that the spectral density of current fluctuations in an emission process is related to the current by

$$S_i = 2qI \quad (22)$$

for frequencies less than the inverse of the transit time. Because noise spectral densities are additive and do not depend on the direction of current flow, the spectral density of

Figure 5. Current flow across the space charge region (or depletion region) in a n^+-p junction when a voltage is applied from the p to n^+ terminal. The separation of charge in the space charge region causes an internal electric field that has the potential to create shot noise. The arrows show the direction of the electron flow, which is in the opposite direction of the current flow.

shot noise current in a $p - n$ junction is given by

$$S_i(f) = 2qI_0(V) \left[\exp\left(\frac{qV}{kT}\right) + 1 \right] = 2q[I(V) + 2I_0(V)] \quad (23)$$

Applying some algebra, it is also common to write Eq. (23) as

$$S_i(f) = 2qI \frac{\left[\exp\left(\frac{qV}{kT}\right) + 1 \right]}{\left[\exp\left(\frac{qV}{kT}\right) - 1 \right]} = 2qI \coth\left(\frac{qV}{kT}\right) \quad (24)$$

or

$$S_i(f) = 2kTg_0 \left(\frac{I + 2I_0}{I + I_0} \right), \text{ where, } g_0 = \frac{dI}{dV} = \frac{q(I + I_0)}{kT} \quad (25)$$

At zero bias, the conductance g_0 supplies the equivalent of full thermal noise as Eq. (25) reduces to $S_i(f) = 4kTg_0$, and half this value when $I \gg I_0$. A similar equation can be written for the open circuit voltage noise spectrum. At high frequencies, the transit time across the depletion region must be considered. This is cumbersome and will not be discussed here; the reader is referred to some standard texts (18,24) to understand this effect. Also, at low temperatures and high frequencies quantum shot noise must be considered just as quantum Nyquist noise was considered previously. Consideration of this effect can be found in Ref. 25.

It should be pointed out here that not all currents exhibit shot noise. If the arrival time of charge carriers are correlated and not random, then suppression occurs. Common examples are space charge limited emissions from a tube and a chemical battery (26). Also, if we design a feedback control system to detect and cancel the noise below, shot noise may be attained. This type of system will then be limited by the noise in the detection system.

Flicker Noise

At large Fourier frequencies most devices can be explained in terms of thermal or shot noise processes. However at small Fourier frequencies excess noise exists. Usually, low-frequency noise has an $f^{-\alpha}$ dependence where $\alpha \sim 1$, and is known as *flicker noise*. The frequency at which the flicker noise is equal to the normal white noise is known as the flicker corner f_c and can vary considerably from device to device. Also, it is not always constant because it can depend on the operating conditions such as input power and bias voltage. Also, it does not in general decrease with temperature as thermal and shot noise do. Similar components made from the same manufacturer can have very different levels of flicker noise, which suggests that it is associated with the fine details and is not under the manufacturer's control.

Flicker noise can be enhanced in nonlinear and chaotic systems, thus it is always prudent to try to maintain the linear operation of a device to keep the flicker noise to a minimum. Recently, a interferometric method, which significantly reduces the effects of flicker noise, was developed at microwave frequencies and is discussed later.

Flicker noise in general cannot be precisely calculated; instead it is common to introduce the noise model in terms of the

white power spectrum S_w

$$S_i(f) = S_w \left(1 + \frac{f_c}{f} \right) \quad (26)$$

In general, no single model can describe the physical principles of flicker noise, unlike shot and thermal noise. However, specific descriptions of flicker noise have been made based on surface and generation and recombination effects (27), quantum effects (28–30), and number and mobility fluctuations (31–33). No attempt will be made to explain these specifics, and the reader is referred to the cited references.

A model worth mentioning is a result of a continuous distribution of time constants (34). A process with a single relaxation time τ_j will have a power spectral density of

$$S_j(f) = \frac{4A_j\tau_j}{1 + (2\pi f\tau_j)^2} \quad (27)$$

At low frequencies, Eq. (27) varies as $1/f^2$ so flicker noise cannot be explained in terms of a single relaxation time process. However, assuming a distribution of relaxation times in the frequency range $1/\tau_2 \ll 2\pi f \ll 1/\tau_1$, the power spectral density can be shown to be

$$S_j(f) = \left[\frac{A}{2\pi \ln\left(\frac{\tau_2}{\tau_1}\right)} \right] \left[\frac{\tan^{-1}(2\pi f\tau_2) - \tan^{-1}(2\pi f\tau_1)}{f} \right] \quad (28)$$

This spectrum is constant at very low frequencies— $1/f$ for an intermediate range and $1/f^2$ for high frequencies. The model given by Eq. (26) cannot be true for very low frequencies because if the spectrum is integrated between 0 and ∞ , it diverges at both limits. Therefore, there must be a lower frequency, in which Eq. (26) is no longer valid and the spectrum varies slower than $1/f$, and an upper frequency, in which Eq. (26) varies faster than $1/f$; Eq. (28) fits this requirement. However, flicker noise in some systems can still be measured in the submicrohertz regime, and thus many processes must have long relaxation times indeed. However, we know that this should at least be limited by the age of the universe!

Burst Noise

Burst noise (also known as popcorn noise) occurs in semiconductor devices and is the result of a defect in manufacturing. The waveform typically consists of random pulses of variable length and constant height (35) and can be described by a random switch model (36). The mechanism of the burst is the result of edge dislocations in the emitter space charge region (37) resulting from lattice distortions caused by large emitter doping densities and metallic impurity. The way to reduce this effect is to keep doping densities below the critical density and to improve manufacturing process. The spectral density of the noise is typically $1/f^\gamma$, where γ is typically 2.

NOISE FIGURE AND TEMPERATURE OF A DEVICE UNDER TEST

To measure the noise in a system, a standard noise source is introduced at the input, as shown in Fig. 6. Referring the device

Figure 6. A standard noise source ($4k_B T_s g_s$) at the input of a noisy device under test may be represented as an enhanced noise generator at the input of an ideal noiseless device under test. The enhancement factor $F(f)$ is in general frequency dependent and known as the “spot noise figure.”

noise to the input of the device under test means that the equivalent enhanced current generator gives a noise output power of $F(f)$ times more than the reference temperature generator. This quantity is the spot noise figure defined in Eq. (6).

The spectral density of the equivalent enhanced current generator may be written as

$$S_i(f) = F(f)4k_B T_s g_s = 4k_B T_s g_s + [F(f) - 1]4k_B T_s g_s \quad (29)$$

The first term of the left-hand side in Eq. (29) is the thermal noise of the reference source and the second term is the noise of the device under test. The device is noiseless if the noise figure is unity; in this case, the only noise present in the system is the noise of the source. If the device under test adds the same level of noise as the reference, the noise figure is two.

To relate the noise figure to the noise temperature, T_{nDUT} , of the stage represented by the device under test, the second term on the left-hand side in Eq. (29) may be written as

$$[F(f) - 1]4k_B T_s g_s = 4k_B T_{nDUT} g_s \quad (30)$$

This means that the noise figure and temperature are related by

$$T_{nDUT} = [F(f) - 1]T_s \quad (31)$$

The advantage of the noise temperature notation is that if noise sources are uncorrelated, then noise temperatures are additive. The equivalent noise temperature of the system of Fig. 6 is thus given by $T_{eq} = T_s + T_{nDUT}$, and the spectral density of the equivalent current generator from Eq. (29) may also be represented by

$$S_i(f) = 4k_B T_{eq} g_s \quad (32)$$

When dealing with microwaves, it is more common to consider the noise as a power spectral density rather than a voltage or current spectral density. Microwave circuits are usually matched with the standard impedance of 50Ω . The available power at the output of the noise source is defined as the power fed into a matched load, and the equivalent circuit of a source connected to a load is shown in Fig. 7. If $g_1 = g_s$, then the current will be split into both resistances equally and the available noise power at the load will be

$$N_{av} = \frac{\langle i^2 \rangle}{4g_s} \quad (33)$$

Given that $S_i(f) = \langle i^2 \rangle / \Delta f = 4k_B T_s g_s$, then the power spectral

density of the available noise power will be

$$S_N = N_{av} / \Delta f = k_B T_s \quad (34)$$

This formula is similar to the initial definition of noise temperature in Eq. (5) (i.e., if we measure the noise power spectral density referred to the input of a device, then to calculate the noise temperature, we simply divide the spectral density by Boltzmann's constant).

In reality, devices are never perfectly matched; the effect of a mismatch in the context of a scattering matrix and reflection coefficient description will be discussed later. Also, the noise temperature and generator concept can be generalized to multiport devices, and in general correlations between noise sources must be considered. This will not be presented in this article, and the reader is referred to the literature (38).

NOISE FIGURE AND TEMPERATURE OF CASCADED STAGES

If two networks of noise temperature T_{N1} and T_{N2} and power gains G_1 and G_2 are cascaded and fed by a noise source of temperature T_s at the input of the first, then the output noise density is given by

$$S_N(f)_{out} = G_1(f)G_2(f)k_B T_s + G_1(f)G_2(f)k_B T_{N1} + G_2(f)k_B T_{N2} \quad (35)$$

To refer the noise to the input of the first stage, the noise power must be divided by the total gain $G_1(f)G_2(f)$, and the equivalent noise power density at the input is

$$S_N(f)_{in} = k_B \left(T_s + T_{N1} + \frac{T_{N2}}{G_1(f)} \right) \quad (36)$$

Thus, the equivalent noise temperature of the system is

Figure 7. Equivalent current generator of a resistor of conductance g_s with a resistive load g_l at the output.

given by

$$T_{\text{eq}} = T_s + T_{N1} + \frac{T_{N2}}{G_1(f)} \quad (37)$$

For the single stage introduced in the last section, it was noted that the noise temperature is additive. In general for cascaded networks, the noise temperature must be normalized by the preceding gain before it is summed. In general for a cascade of m networks,

$$T_{\text{eq}} = T_s + T_{N1} + \sum_{j=2}^m \left(\frac{T_{Nj}}{\prod_{i=1}^{j-1} G_i(f)} \right) \quad (38)$$

The noise figure for the cascaded network when $m = 2$ is given by

$$F_{\text{eq}}(f) = \frac{S_N(f)_{\text{in}}}{k_B T_s} = 1 + \frac{T_{N1}}{T_s} + \frac{T_{N2}}{G_1(f) T_s} \quad (39)$$

where $T_s = 290$ K. Combining the relationship between noise figure and noise temperature for a single network derived previously in Eq. (31), the following is obtained:

$$F_{\text{eq}}(f) = F_1(f) + \frac{F_2 - 1}{G_1(f)} \quad (40)$$

This may be generalized to a system consisting of m cascaded networks and is given by

$$F_{\text{eq}}(f) = F_1(f) + \sum_{j=2}^m \left(\frac{F_j(f) - 1}{\prod_{i=1}^{j-1} G_i(f)} \right) \quad (41)$$

This equation is known as Friis's formula (39).

NOISE FIGURE AND TEMPERATURE OF LOSSY TRANSMISSION LINE

When a system has a significant length of transmission line, which may be at different temperatures, then the losses may significantly contribute to the equivalent noise temperature of the system. Examples of this type can occur when undertaking cryogenic measurements of a device under test. If the noise source is at room temperature, then the transmission line must connect to the input via a long cable with a temperature gradient. Another example is a link connecting a satellite ground station antenna and a low noise amplifier. In this section, the physical temperature will be denoted by T and the noise temperature by T_N .

First, a piece of transmission line at temperature T and loss L , where $L = 1/G$, is considered. There are two ways in which the transmission line can degrade the noise performance of a system: (1) The loss attenuates the signal and thus effectively enhances the noise temperature of the following stages [see Eq. (38)]; (2) The lossy system is itself a noise generator in a similar way to a resistor (i.e., it generates Nyquist noise). This noise is dependent only on the dissipated power.

The noise generated by the transmission line is dependent on the power lost in transmission (i.e., the power dissipated).

The fraction of power that is transmitted is equal to $1/L$ (or G) and thus by conservation of energy, the fraction of dissipated power must be equal to $(1 - 1/L)$ or $(1 - G)$. Thus the available noise power density at the output of a lossy transmission line with a standard noise source of T_s at its input will be

$$S_N(f)_{\text{out}} = G_1 k_B T_s + (1 - G_1) k_B T_1 \quad (42)$$

The second term in Eq. (42) is the contribution of the first piece of transmission line after the source input (denoted by subscript 1). To calculate the effective noise temperature refer to the input of the transmission line, T_{N1} ; this term must be equated with $G_1 k_B T_{N1}$ and can be calculated to be

$$T_{N1} = \frac{(1 - G_1)}{G_1} T_1 = L_1 \left(1 - \frac{1}{L_1} \right) T_1 \quad (43)$$

From Eqs. (43) and (31), the noise figure of the transmission line may be calculated to be

$$F_1(f) = 1 + (L_1 - 1) \frac{T_1}{T_s} \quad (44)$$

If a transmission line is without loss, it will not add any extra noise to the system. However, if it is not, then the second term in Eq. (44) represents the extra noise resulting from the power dissipation. Also, if there are any other networks cascaded after the lossy line, the noise added when referred to the input of the transmission line will be degraded by its loss L (or $1/G$).

If a lossy transmission line exists in a system under measurement, it may be considered as a separate network among a cascaded system and treated as in the previous section. This gives a method for correcting for any significant transmission line losses if they are known.

TWO-NOISE SOURCE METHOD

The two-noise source technique makes use of connecting two different known noise sources to the input of a device under test and measuring the change in output (40). It is assumed that two known noise sources of temperatures T_h and T_c are connected in turn to the input of the device under test. In this case, the ratio of output power from the two sources will be equal to

$$Y = \frac{T_e + T_h}{T_e + T_c} \quad (45)$$

where T_e is the effective noise temperature of the device under test. (This is the same as T_N introduced previously, however, to be consistent with the literature for this technique we will use T_e .) Thus

$$T_e = \frac{T_h - Y T_c}{Y - 1} \quad (46)$$

This is referred to as the operational definition of T_e (40).

This method assumes perfect matching between components. In reality, the measurement technique is made more

complicated if mismatches occur between the source and device under test. To characterize the mismatch requires the use of more sources and a more complicated measurement procedure and is discussed in the next section.

EFFECTS OF MISMATCH

When considering the effect of mismatch on noise measurements of a device under test, it has been useful to use a scattering matrix or reflection coefficient method to describe the measurement (41,42). Mismatch effects are pronounced when measuring amplifiers because the optimum input impedance is not the same as the matching condition for maximum power flow. For this reason, it is common for a low-noise commercial amplifier to come with an isolator at the input. Complications in the measurement procedure occur because not only does the mismatch change the level of available power, but it also means that reflections will occur at two planes, as shown in Fig. 8. Consequently, reverse flow of power through the device under test must be considered. In the previous analysis, it was always assumed that the flow of power was one way (i.e., from the source to the output of the device under test). In general, the value of noise temperature is dependent on the mismatch, and to characterize the system completely, four independent parameters must be measured (43–46). There are two common approaches with different parameter sets that warrant further discussion.

Noise Parameter Set $T_{e(\min)}$, R_n , and Γ_{opt} (Complex)

The dependence on the reflection coefficient at the input port between the source and the device under test must be corrected for, and it has been traditional to use the four standard IEEE parameters given to characterize this correction. To solve for the four parameters, at least four different noise sources are needed, but it is advantageous to have more to allow averaging and to help ensure a unique solution. The classical way of measuring these parameters relies on using tuners on each end of the device under test to simulate the input and output matching networks when calibrating the system (47–50). This method relies on scalar information only and is sometimes unreliable. To determine the noise parameters more accurately, a vector network analyzer is needed to calculate the device under test scattering parameters and the reflection coefficient of the receiver (50).

Figure 8. Schematic of the noise temperature measurement of a device under test such as an amplifier. In general, the model uses either the reflection coefficient Γ concept or the scattering parameter S_{ij} concept. Many modern undergraduate textbooks discuss these concepts so they are not explained here.

T_e may be written in terms of $T_{e(\min)}$, R_n , and Γ_{opt} (contains two parameters because it is complex) as

$$T_e = T_{e(\min)} + \frac{4T_s R_n G_{\text{opt}} |\Gamma_1 - \Gamma_{\text{opt}}|^2}{(1 - |\Gamma_{\text{opt}}|^2)(1 - |\Gamma_1|^2)} \quad (47)$$

where

$$G_{\text{opt}} = \frac{(1 - |\Gamma_{\text{opt}}|^2)}{Z_0 |1 + \Gamma_{\text{opt}}|^2}$$

Here, T_s is a reference temperature (typically 290 K), Z_0 is the characteristic line impedance (normally 50 Ω for a microwave coaxial system). $T_{e(\min)}$ is the minimum effective input noise temperature, which is realized when $\Gamma_1 = \Gamma_{\text{opt}}$, and R_n characterizes how quickly T_e increases above $T_{e(\min)}$.

Noise Parameter Set T_a , T_{rev} , and β (Complex)

This set of parameters, developed at NIST (43), is useful because they are terminal invariant (i.e., their values do not change if a lossless two port is added or subtracted from the input). The method was developed to enable a direct measurement of one of the parameters, namely T_{rev} , the noise temperature of the radiation emerging from the input. Recently this method was shown to give an accuracy of ± 0.04 dB when measuring commercial low-noise microwave amplifiers (51). However, a disadvantage is that it requires skill in low-temperature measurements because T_{rev} is typically at cryogenic temperatures for a low-noise amplifier.

T_e can be expressed in relation to this model as

$$T_e = \frac{T_a + T_{\text{rev}} |\Gamma'_i - \beta|^2}{1 - |\Gamma'_i|^2} \quad (48)$$

where

$$\Gamma'_i = \frac{\Gamma_1 - S_{11}^*}{1 - S_{11} \Gamma_1}$$

Here, S_{11} is the input scattering parameter to the device under test (see Fig. 8), T_{rev} is the available noise power from the internal noise sources when the output of the amplifier is terminated in a noiseless matched load, β is a measure of the correlation of the available noise power emanating from the two amplifier ports, and T_a is the amplifier noise temperature if no mismatch exists at the amplifiers input.

As before, this method still requires accurate determination of scattering parameters and reflection coefficients using a vector network analyzer, as well as at least four different sources to determine the four parameters. However, it is also common to use more than four noise sources to add some redundancy to improve the accuracy of the experiments (46,51,52).

For a properly made measurement when mismatch is corrected, the major source of inaccuracy is the accuracy to which the noise source is calibrated. Other noise parameters are obtained from relative measurements and are not affected by noise source calibration errors. This fact has led some of the world's national metrological institutes to do a comparison of noise source calibration and is discussed later.

NOISE SOURCES

Calibrated noise sources are essential if accurate noise measurements as discussed previously are to be made. Noise sources may be categorized as either primary or nonprimary.

Primary Noise Standards

Primary noise standards are thermal noise sources that include a resistive device held at a known temperature. Examples include cooled coaxial resistive terminations immersed in liquid nitrogen at its boiling temperature (cold standard), high-temperature oven standards that operate at typically 500 K to 800 K (hot standards), and room temperature standards that operate at about 290 K. More information on these types of standards can be found in Refs. 53–59. The measurement and characterization relies on knowing the calculable output noise power of a black body radiator such as SiC at cryogenic temperatures or the known temperature and resistance of a passive termination.

Other noise sources can be classified as nonprimary and are usually calibrated against a primary standard if accurate measurements are to be made. They include gas discharge tubes, solid-state diode sources, and commercial “cold load” thermal noise sources operating at liquid nitrogen temperature as well as “hot load” noise sources operating at elevated temperatures. Because we have already discussed in detail thermal noise, only the former two will be discussed further.

Diode Noise Sources

In forward bias, a diode produces shot noise and may be used as a noise source. However, at high frequencies such as microwave, the noise is reduced as a result of transit time effects. Also, flicker noise is present. This means that a white noise spectrum is not generated so the effective noise temperature is a function of Fourier frequency.

Another way a diode may be used to produce noise is to reverse bias the diode near the breakdown (or avalanche) region. Such noise sources give white noise up to the gigahertz region and can be used as wide-band noise sources. They are relatively small devices that require only small voltages and operate with noise temperatures of order 10^4 K. The diode itself has a $T_N = 10^5$ to 10^6 K, which is reduced by a sizeable attenuator used to provide matching. These types of noise sources need calibration, remain calibrated for long times, and are available commercially.

Gas-Discharge Noise Sources

Gas discharges become electrical conductors at high temperatures. Typically a gas discharge tube consists of an ionized noble gas at low pressure. High voltages across the tube are necessary to create the discharge. Typically, these devices produce a discharge with excellent long-term stability that is practically independent of operating conditions, which varies little from tube to tube. The available noise power exhibits a flat power spectrum and an effective noise temperature of order 10^4 K. To make use of the noise generation at microwave frequencies, the tube can be mounted in a microwave waveguide.

INTERNATIONAL COMPARISON OF THERMAL NOISE TEMPERATURE MEASUREMENTS

The world's major state-of-the-art metrological institutes are the places where the most accurate measurements of absolute noise temperature can be made. Recently, an international comparison was undertaken to measure the noise temperature of two commercial microwave noise sources to try to obtain a measure of the absolute error (11). The institutes that took part were the National Institute of Standards and Technology in Boulder, Colorado, United States (13); the Laboratoire Central des Industries Electriques in Fontenay-aux Roses, France (14); the National Physical Laboratory in Teddington, Worcestershire, United Kingdom (12); and the Physikalisch-Technische Bundesanstalt in Braunschweig, Germany (15).

The measurements required each institute to provide its own noise standard and radiometer to perform measurements at three different frequencies. Two entirely different primary standards (cryogenic and oven) were implemented, along with two different types of radiometer (switching and total power). Uncertainties (2σ) between the institutes ranged from 0.5% to 2.9%. Expense and effort was required to fix the primary standards and sources under measurement at a fixed operating temperature. This achievement represents the best determination of absolute measurement uncertainties.

ON-WAFER NOISE MEASUREMENTS

The advent of integrated circuits designs on a single chip has enabled the industry to miniaturize circuits and reduce the expense of microwave and millimeter wave technologies. Collectively, a circuit of this type is often referred to as a *wafer*. The characterization of such devices is more challenging than the waveguide or coaxial counterpart because it is harder to isolate a single device in a wafer. Moreover, impedance matching the device under test to the measurement apparatus is difficult, and these characterizations are always implemented in a large mismatch environment. For accurate measurement, it is important to have a vector network analyzer, which is calibrated for *S*-parameter measurements. The measurement process is quite intensive because it requires the measurement of the *S*-parameters of the noise source, noise receiver, adaptors, probes, and the like.

Much work has been done to develop on-wafer techniques (50,60–63). Commercial systems exist; however, work still is being pursued to assess the accuracy and reliability of such measurements, and ways of improving on-wafer measurements are still under investigation. The chief problem arises as a result of the mismatch and loss of the adaptor to coaxial and waveguide noise standards. To reduce these errors, on-wafer calibrated noise standards are needed. Measurements have been achieved with off-wafer noise standards, and some initial steps using on-wafer uncalibrated noise sources have been achieved (64,65). Other problems include radiation entering the open stripline format of a wafer.

INTERFEROMETRIC NOISE MEASUREMENTS

Previous discussions have mainly been about noise temperature and figure measurements of a device under test (DUT)

Figure 9. Schematic of the microwave interferometer measurement system of a DUT in the presence of a carrier frequency.

when it is operating in the small signal regime (i.e., with no carrier signal present). A large carrier signal can cause non-linear effects such as up-conversions, which enhance noise at small values of Fourier frequency (offset from the carrier). Recently, interferometric measurement and signal generation schemes at microwave frequency have been developed (8,9) and allow component characterization and operation at the intrinsic small signal noise temperature independent of the carrier power. The basic noise measurement setup is shown in Fig. 9. It includes the microwave interferometer consisting of the DUT and a compensating branch that enables the cancellation of the carrier at the dark fringe of the interferometer. The signal without the carrier is then amplified by the low-noise microwave amplifier operating in the small signal regime. The low-noise microwave amplifier and a mixer form the microwave readout system, which can be either phase- or amplitude-sensitive depending on the setting of the reference phase shifter ϕ_{ref} .

One of the features of the interferometric measurement system is a greatly enhanced sensitivity to phase and amplitude fluctuations of the DUT. The sensitivity enhancement results from the ability of interferometric system to satisfy, on the first glance, two contradictory requirements: (1) having a high power at the input of the interferometer, and (2) enabling low-noise operation of the readout system. These requirements are met by interfering the two signals destructively from the output of the DUT and compensating branch (suppressing the carrier) before the noise is detected by the readout system. This enables the microwave amplifier in the readout system to operate in the small signal regime devoid of flicker noise and reduces the effect of the mixer flicker noise by the amplifier gain.

The effective noise temperature of the readout system T_{RS} limits the sensitivity of the interferometric noise measurement system, and the noise temperature is given by

$$T_{\text{RS}} = T_0 + T_a + \frac{T_m}{G_a} \quad (49)$$

where $T_0 \approx 290$ K is the ambient temperature; T_a and T_m are the effective noise temperature of the microwave amplifier and mixer, respectively; and G_a is the gain of the microwave amplifier. In general, T_{RS} is a function of Fourier frequency f and the power at the input of the low-noise microwave amplifier. This dependence is caused by the amplifier flicker noise, which generally scales proportionally with input power (66,67).

Suppressing the carrier at the interferometer output minimizes the degradation of T_{RS} as a result of the amplifier flicker noise, and choosing an amplifier with a low level of Johnson noise allows the measurement to be close to ambient temperature. There is some conflicting data published (68) that suggests flicker noise in amplifiers can be reduced as input power is increased. However, when the input to the amplifier is totally nulled, the resulting noise spectrum is white and devoid of flicker noise, and this represents the optimum operating condition.

These types of measurements are relatively new; consequently, the accuracy has not been determined, and mismatch correction techniques have not yet been applied.

ELECTRIC DISTORTION MEASUREMENT

In the context of the electrical domain, the term *distortion* may be broadly defined as any deviation of a signal in any parameter (time, amplitude, or wave shape) from that of an ideal signal. The term is usually associated with lack of fidelity. When referring to analog signals, distortion means shape alteration. For binary data transmission the term has a particular meaning commonly defined as a displacement in time of a signal from the time that the receiver expects to be correct. When applied to a system, distortion is a manifestation of its nonideal behavior in which the manipulation of at least some type of signal is involved.

DISTORTIONLESS SYSTEM

A periodic signal $s(t)$ may be represented by the following Fourier series:

$$s(t) = S_0 + \sum_{n=1}^{\infty} S_n \cos(n\omega_1 t + \varphi_n) \quad (1)$$

where S_0 represents the dc component of the signal, S_n is the amplitude and φ_n the phase of the n th harmonic, and ω_1 is the angular frequency of its fundamental component. If the signal is not periodic and it satisfies some conditions, the representation does not involve a series but an integral, the Fourier integral given by

$$s(t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \overline{S}(\omega) e^{j\omega t} d\omega \quad (2)$$

where

$$\overline{S}(\omega) = \int_{-\infty}^{+\infty} s(t) e^{-j\omega t} dt \quad (3)$$

is the Fourier transform of $s(t)$.

According to the Fourier representation, each signal $s(t)$ may be viewed as the sum of an infinite number of sinusoidal signals having a well-defined amplitude, frequency, and phase. The representation is unique. No two signals have the same Fourier representation and vice versa.

An electric analog signal $s(t)$ is said to suffer from distortion when, for some reason, it is transformed into a signal $s'(t)$ that does not satisfy the condition

$$s'(t) = ks(t - t_0) \quad (4)$$

where k is a constant that accounts for a change in amplitude and t_0 is a time delay. Any signal that does not satisfy Eq. (4) is not an exact replica of $s(t)$.

There are several causes for signal distortion: conducted or radiated interference (harmonics in the power network voltage and current, crosstalk between conductors, for instance); signal manipulation (modulation, mixing, etc.); and nonideal behavior of the media or of the systems used to transmit and manipulate the signal.

Even though the first two causes are important, the last deserves further consideration because real transmission media

and systems are always nonideal and thus may contribute significantly to signal distortion. To understand the mechanism of distortion produced in a signal by a medium or system, let us first consider that the media or systems are linear and time-invariant so that they are characterized by a transfer function in the frequency domain:

$$\overline{T}(\omega) = T(\omega) e^{j\theta(\omega)} \quad (5)$$

In such cases, both media and systems may be analyzed in terms of systems theory, and thus we will refer to both as a "system." Because the transfer function relates the output of a system to its input, it accurately describes the system's frequency response and thus the effect of such a system on its signals.

Considering that the input of the system is a periodic signal $x(t)$ represented by its Fourier series

$$x(t) = X_0 + \sum_{n=1}^{\infty} X_n \cos(n\omega_1 t + \varphi_n) \quad (6)$$

then the steady state output signal $y(t)$ is given by

$$y(t) = Y_0 + \sum_{n=1}^{\infty} Y_n \cos(n\omega_1 t + \Psi_n) \quad (7)$$

where

$$\begin{cases} Y_n = T(n\omega_1) X_n \\ \Psi_n = \varphi_n + \theta(n\omega_1) \end{cases} \quad n = 0, 1, 2, \dots \quad (8)$$

If $\overline{CTT}(\omega)$ is such that

$$T(\omega) = k \quad (9a)$$

and

$$\theta(\omega) = -t_0\omega \quad (9b)$$

then replacing Eqs. (9a) and (9b) in Eq. (7) yields

$$y(t) = k \left\{ X_0 + \sum_{n=1}^{\infty} X_n \cos[n\omega_1(t - t_0) + \varphi_n] \right\} = kx(t - t_0) \quad (10)$$

The same result is obtained for a nonperiodic signal provided that it may be represented by a Fourier transform $\overline{CTX}(\omega)$ and that the transfer function of the system satisfies Eqs. (9a) and (9b). In fact, extending the concept of the transfer function to the domain of negative frequencies and taking into consideration that because $x(t)$ and $y(t)$ are real, $T(\omega)$ must be an even function of ω , and $\theta(\omega)$ an odd function of ω , one may write:

$$\overline{Y}(\omega) = \overline{T}(\omega) \overline{X}(\omega) = k e^{-j\omega t_0} \overline{X}(\omega) \quad (11)$$

$y(t)$ is obtained by replacing Eq. (11) in Eq. (2):

$$y(t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} k \overline{X}(\omega) e^{j\omega(t-t_0)} d\omega = kx(t - t_0) \quad (12)$$

The analysis just presented leads to the important conclusion that a distortionless system must be linear and time-invariant

Figure 1. Transfer function of an ideal system. (a) Amplitude response; (b) phase response. A distortionless system is a linear and time-invariant system that has a constant amplitude frequency response k and a phase response that changes in frequency according to a straight line passing through the origin and whose slope is a time delay t_0 .

and have an amplitude response constant for all frequencies and a phase response linear with frequency. The transfer function of an ideal system is represented in Fig. 1.

In a nonlinear system, the output must be related to the input by means of a n -degree polynomial commonly called a transfer characteristic. In those systems distortion always occurs, because a sinusoidal input produces an output with an enriched spectral content.

DISTORTION TAXONOMY AND TERMINOLOGY

As already discussed, electric distortion produces a change in a signal parameter and, in the context of the Fourier representation of a signal, it corresponds to one or several of the following alterations: appearance of energy in new frequencies (nonlinear amplitude distortion); nonproportional change in the amplitudes of the fundamental and harmonic components of the signal (frequency distortion); or change in the phase of the frequencies of the signal (phase or delay distortion). These are the three principal types of distortion. The first is characteristic of nonlinear systems and thus is called nonlinear distortion. The other two are characteristic of dispersive systems and are called linear distortions.

The distortion produced in electrical signals becomes a problem when the information they convey is altered or even lost or when those distorted signals interfere with other signals. Because of the different origins of distortion and the need to characterize and evaluate the performance of systems, the terminology related to distortion includes several expressions that are worth examining because some of them define parameters used in specifying systems distortion performance.

Telecommunications is probably the electrical subdomain where distortion causes the most problems. Two main factors contribute to that: (a) the use of components and devices that are intrinsically nonlinear (mixers, loudspeakers, etc.) or potentially nonlinear (e.g., amplifiers) affect the spectra of the signals they process; (b) the congestion of the frequency spectrum. Thus it is only natural to expect the terminology of distortion to be directly related to sound and video signals.

The following terms are strongly supported by Ref. 1. The list is not exhaustive but aims to include those terms most relevant in electrical distortion measurements.

Amplitude nonlinearity (amplitude distortion) is the phenomenon through which frequency components appear at the

output of a system. They are dependent on the characteristics of the input signal but not present in it. Amplitude nonlinearity produces two types of amplitude distortion: harmonic distortion and intermodulation distortion. Crossover distortion caused by the nonlinear characteristics of a device that changes operating modes, such as a push-pull amplifier, is an example of amplitude distortion.

Harmonic distortion is the amplitude nonlinearity expressed in terms of the ratio of the harmonics in the output signal to the total output signal when a sinusoidal input signal is applied. It is caused by nonlinearity in the system's transfer characteristic. In harmonic distortion measurements, a single sinusoidal signal is applied to the system, and wave analysis at harmonic frequencies determines the percentage distortion.

Harmonic distortion of the n th order is the harmonic distortion expressed in terms of the ratio of the rms output signal due to the component of harmonic order n to the total rms output signal. Usually, the difference between the total rms and the rms of the fundamental is very small, and thus the latter is also used in the ratio. *Total harmonic distortion* is the harmonic distortion expressed in terms of the ratio of the rms output signal due to distortion to the total rms output signal. *Weighted total harmonic distortion*, used in sound system equipment, is the total harmonic distortion measured with a frequency weighting. *Noise harmonic distortion* (or noise distortion) is the harmonic distortion when one-third octave-band filtered noise is used as the input signal.

Intermodulation distortion is the amplitude nonlinearity expressed in terms of the ratio of the input signal of frequencies $pf_1 + qf_2 + \dots$ (where $p, q, \dots$, are positive or negative integers) to the total output signal, when (at least two) sinusoidal input signals having the fundamental frequencies $f_1, f_2, \dots$, are applied at the input. In radio frequency (RF) power amplifiers, for instance, the major causes of intermodulation distortion are crossover effects, gain reduction at high current, and device saturation.

In intermodulation distortion measurements, two sinusoidal signals of different frequencies f_1 and f_2 are applied to the system. *Modulation distortion* is the intermodulation distortion where the input signal is composed of a large-amplitude, low-frequency signal f_1 and a small-amplitude, high-frequency signal f_2 . In some systems two kinds of modulation distortion are present, both having the same spectral components and differing only in phase: (a) amplitude modulation distortion caused by the amplitude modulation due to nonlinearity; (b) frequency modulation caused by frequency modulation having no relationship to nonlinearity. In such cases, it is necessary to distinguish between these two types of distortion. The reference output at which the distortion occurs is taken as the arithmetic sum of the output signals at frequencies f_1 and f_2 .

Modulation distortion of the n th order is the modulation distortion in terms of the ratio of the arithmetic sum of the rms output signal components at frequencies $f_2 \pm (n-1)f_1$ to the rms output signal component at frequency f_2 . *Total modulation distortion* is the modulation distortion in terms of the ratio of the arithmetic sum of the rms output signal components to the rms output signal at frequency f_2 . *Difference-frequency distortion* is the intermodulation distortion where the input signal is composed of two sinusoidal signals f_1 and f_2 of similar or equal amplitude. The difference in the frequency of the two signals is less than the lower of the frequencies. The reference output at which the distortion occurs is taken as the arithmetic

Figure 2. Harmonic distortion. Total harmonic distortion, d_t , and n^{th} harmonic distortion, d_n , are two parameters for characterizing the harmonic distortion of a system. In the expressions, X_{out} represents the rms of the output signal (an electric voltage, in general), $X_{\text{out}}(f_1)$ represents the rms of the fundamental in the output signal, and $X_{\text{out}}(nf_1)$ represents the rms of the harmonic component of nf_1 in the output signal. The input of the system is a sine wave signal of frequency f_1 .

sum of the output signals at frequencies f_1 and f_2 . *Noise intermodulation distortion* is the intermodulation distortion where one-third octave-band filtered noise is used as the input signal. *Transient intermodulation distortion*, important in characterizing loudspeakers, results from nonlinear response to steep wavefronts. It is measured by adding square wave (3.18 kHz) and sine wave (15 kHz) inputs with a 4:1 amplitude ratio and observing the multiple sum and difference-frequency components added to the output spectrum.

In Figs. 2–5, excerpted from Ref. 1, some of the concepts previously discussed are presented in graphical and mathematical form.

Frequency distortion is the effect on a signal that results from variation in the amplitude response of a system as a function of frequency. Some authors also use attenuation distortion

Figure 3. Modulation distortion. Modulation distortion of the n^{th} order d_{m_n} is a parameter for characterizing the intermodulation distortion of a system. The input of the system is a signal with frequencies f_1 and f_2 . Refer to the legend of Fig. 2 for the meaning of the variables in the expressions.

$$X_{\text{out}}(f_1) = X_{\text{out}}(f_2)$$

$$X_{\text{out,ref}} = X_{\text{out}}(f_1) + X_{\text{out}}(f_2) = 2X_{\text{out}}(f_2)$$

$$f_2 - f_1 = 80 \text{ Hz, for instance}$$

$$f_m = \frac{f_2 + f_1}{2} \text{ is a preferred one-third octave band center frequency (for instance, 10 kHz)}$$

Second-order difference-frequency distortion

$$d_{d2} = \frac{X_{\text{out}}(f_2 - f_1)}{2X_{\text{out}}(f_2)} = \frac{X_{\text{out}}(f_2 - f_1)}{X_{\text{out,ref}}}$$

Third-order difference-frequency distortion

$$d_{d3} = \frac{X_{\text{out}}(2f_2 - f_1) + X_{\text{out}}(2f_1 - f_2)}{X_{\text{out,ref}}}$$

Figure 4. Difference-frequency distortion. Difference-frequency distortion of the n^{th} order d_{d_n} is a parameter for characterizing the intermodulation distortion of a system when a signal having two closely spaced frequency components of similar amplitudes is supplied to the input. In general, this parameter indicates the in-band distortion introduced by the system. Refer to the legend of Fig. 2 for the meaning of the variables in the expressions.

or amplitude distortion to designate this effect. If the amplitude response assumes values between k_{max} and k_{min} , the parameter $(k_{\text{max}} - k_{\text{min}})/[(k_{\text{max}} + k_{\text{min}})/2]$ may be used to express frequency distortion.

Phase or delay distortion results from the deviation from a constant slope of the output phase versus frequency response of a system. This produces echo responses in the output that precede and follow the main response and a distortion of the output signal when an input signal having a large number of frequency components is applied. When the phase characteristic of a linear system assumes the value θ at frequency f_1 , the system introduces at that frequency a time delay $t_{d1} = \theta_1/2\pi f_1$ between the input and the output. If the system is not ideal, the time delay $t_{d2} = \theta_2/2\pi f_2$ introduced at frequency f_2 differs from t_{d1} . In that case, the derivative of the phase with respect to frequency is not constant. In our opinion, the maximum value of that derivative over any frequency interval expressed in time units better characterizes phase distortion. Some authors (2) designate this parameter as envelope delay distortion. The experimental evaluation of this parameter may be cumbersome or even impossible, which leads to the implementation of alternative methods. Details are presented in a forthcoming section.

$$X_{\text{out}(f_1)} = X_{\text{out}(f_2)} \quad \text{with, for instance,}$$

$$f_1 = 8 \text{ kHz} \quad f_2 = 11.95 \text{ kHz}$$

$$X_{\text{out}_{\text{ref}}} = X_{\text{out}(f_1)} + X_{\text{out}(f_2)} = 2X_{\text{out}(f_2)}$$

$$f' = f_2 - f_1 = 3.95 \text{ kHz} \quad f'' = 2f_1 - f_2 = 4.05 \text{ kHz}$$

Total difference-frequency distortion:

$$d_{\text{d}_{\text{tot}}} = \frac{\sqrt{(X'_{\text{out}})^2 + (X''_{\text{out}})^2}}{X_{\text{out}}}$$

Figure 5. Total difference-frequency distortion. Total difference-frequency distortion $d_{\text{d}_{\text{tot}}}$ is a parameter particularly relevant in assessing the out-of-band distortion introduced by a system. Note that the frequencies of the two-tone signal supplied to the input are not closely spaced as in Fig. 4. Refer to the legend of Fig. 2 for the meaning of the variables in the expressions.

SIGNAL DISTORTION MEASUREMENT

Electric distortion measurements are usually carried out by examining signals (electric voltage, as a rule) in the frequency domain (harmonic analysis). However, both frequency-domain and time-domain instrumentation are used for that purpose. Frequency-domain instrumentation analyzes signals by using analog filtering techniques. Wave analyzers, such as the frequency selective voltmeter, the heterodyne tuned voltmeter, the heterodyne harmonic analyzer (wavemeter), and the heterodyne spectrum analyzer, are examples of this type of instrumentation designed to measure the relative amplitudes of single-frequency components in a complex signal. Time-domain instrumentation analyzes by time sampling the signals and subsequent numerical handling of the sampled data commonly using the fast Fourier transform (FFT) algorithm. The FFT spectrum analyzer is an example of time-domain instrumentation.

Special-purpose instruments, such as the one whose block diagram is presented in Fig. 6 (total harmonic distortion meter), directly display many distortion measurements. The spectrum analyzer is, however, the general-purpose instrument most often used to measure distortion. With it, the entire spectrum within its frequency band is analyzed even though second and third harmonic measurements are enough for many applications. The most common spectrum analyzers are the superheterodyne spectrum analyzer and the FFT spectrum analyzer.

Figure 6. Block diagram of a typical fundamental-suppression total harmonic distortion meter. Total harmonic distortion by the system under test (SUT) is evaluated by internally computing the ratio between the rms values of the output voltage and its value upon suppression of its fundamental frequency. The instrument includes the oscillator, and the rms values are measured by an rms responding voltmeter.

In the FFT spectrum analyzer the input signal is converted, the samples converted from analog to digital, and a FFT is performed. As a result, magnitude and phase spectra of the input signal are obtained. The main advantages of FFT spectrum analyzers compared to superheterodyne spectrum analyzers are their ability to measure phase and the possibility of characterizing single-shot phenomena. Their limitations are related to the frequency range (limited by the ADC maximum conversion rate) and sensitivity (related to quantization noise). FFT spectrum analyzers are very easily implemented by using PC-based automatic measuring systems with plug-in data acquisition boards or by using digitizers and digital oscilloscopes having computer interfaces like RS232 or IEEE488. Now manufacturers are including FFT spectrum analyses as an additional feature of digital oscilloscopes.

Figure 7 shows a simplified block diagram of a superheterodyne spectrum analyzer. After the input attenuator, the signal is applied to a low-pass filter, whose function is analyzed later. The output of the filter is applied to a mixer. Here the signal is mixed with the output of a voltage-controlled oscillator (VCO). The ramp generator sweeps the VCO linearly from f_{min} to f_{max} . Because the mixer is a nonlinear device, its output contains the two original signals and also their harmonics, the sums and differences of the original frequencies, and their harmonics. When any of the frequency components of the mixer output falls within the passband of the filter, a nonzero voltage is applied to the envelope detector and after amplification, to the vertical plates of a cathode-ray tube (CRT), producing a vertical deflection of the electron beam. As the ramp that commands the VCO is also applied to the horizontal plates of the CRT, the horizontal axis can be calibrated in frequency.

The central frequency f_{if} and the bandwidth of the intermediate-frequency filter are chosen so that at any time the only frequency component at the output of the mixer that is within the band of the filter is the difference between the frequency f_{vco} of the VCO and that of the input signal f_{signal} . This implies that f_{if} must be out of the input band. Otherwise, apart from the difference of frequencies we could have a component of the input signal within the passband of the filter. In this case, because the output of the mixer includes the original input signal, this would produce a constant vertical deflection of the CRT during all the frequency scanning of the VCO.

To display frequencies near 0 Hz, the lower frequency f_{min} of the VCO must be equal to f_{if} , because $f_{\text{if}} = f_{\text{vco}} - f_{\text{signal}}$. To display all the frequencies within the band of the spectrum analyzer, the maximum output frequency f_c of the VCO must be $f_{\text{max}} = f_{\text{if}} + f_c$.

Now let us suppose that we have a spectrum analyzer with an input range of frequencies from 0 to 3 GHz. In this case, f_{if}

Figure 7. Simplified block diagram of the superheterodyne spectrum analyzer. The superheterodyne spectrum analyzer allows measuring the amplitude or rms values of the frequency components of an electric voltage in a defined frequency band. Those values are obtained by measuring the output voltage of a narrow-passband, fixed-frequency filter when, upon being heterodyned, the spectrum of the input voltage passes the frequency window of the filter.

could be, for instance, 3.5 GHz, and then the output frequency of the VCO should vary from 3.5 GHz to 6.5 GHz. Suppose that we have an input signal with two frequency components, one at 1 GHz (f_{s1}) and the other at 2 GHz (f_{s2}). When the ramp begins, the beam is deflected to the left of the CRT screen, and the VCO oscillates at 3.5 GHz. As the ramp amplitude grows, the beam is moving to the right of the screen, and f_{vco} increases. Suppose that at a given moment $f_{vco} = 3.6$ GHz at the output of the mixer. Then we have the following components: 1 GHz (f_{s1}), 2 GHz (f_{s2}), 3.6 GHz (f_{vco}), 2.6 GHz ($f_{vco} - f_{s1}$), 4.6 GHz ($f_{vco} + f_{s1}$), 1.6 GHz ($f_{vco} - f_{s2}$), and 5.6 GHz ($f_{vco} + f_{s2}$). Because the bandwidth of the bandpass filter is much less than 0.1 GHz, none of the components appear after the filter, and so no vertical deflection occurs at the screen. This is the case until f_{vco} reaches 4.5 GHz. Then the components at the output of the mixer are 1 GHz (f_{s1}), 2 GHz (f_{s2}), 4.5 GHz (f_{vco}), 3.5 GHz ($f_{vco} - f_{s1}$), 5.5 GHz ($f_{vco} + f_{s1}$), 2.5 GHz ($f_{vco} - f_{s2}$) and 6.5 GHz ($f_{vco} + f_{s2}$). The output of the bandpass filter is no longer zero. There is a component at 3.5 GHz ($f_{vco} - f_{s1}$) whose amplitude is proportional to the amplitude of the input signal component of 1 GHz. This produces a vertical deflection when the horizontal deflection produced by the ramp corresponds to 1 GHz. During the rest of the sweeping the vertical deflection would be zero except when the frequency of the VCO reaches 5.5 GHz. At that time the difference between f_{vco} and f_{s2} is within the band of the filter, and a vertical deflection proportional to the amplitude of f_{s2} appears on the screen.

Now we are ready to understand the function of the low-pass filter at the input. Suppose that a component at 8.5 GHz (f_{s3}) is present in the input signal and that the spectrum analyzer does not have the low-pass filter. When $f_{vco} = 5$ GHz the difference between f_{s3} and f_{vco} is 3.5 GHz and falls within the passband of the filter. So it produces a vertical deflection on the screen proportional to the amplitude of f_{s3} . The problem is that this component would be displayed when the ramp reaches the voltage level corresponding to 2 GHz. This would give the user the erroneous indication that a 2 GHz component is present in the input signal, instead of the 8.5 GHz component really present. Then the function of the low-pass filter is to prevent these high frequencies from getting to the mixer. The bandwidth of this filter should be equal to the range of the spectrum analyzer.

Superheterodyne spectrum analyzers are not real-time instruments. They need the input signal to remain unchangeable during the sweep time, and storage CRTs are necessary to display the spectrum of the input signal.

To resolve signals with closely spaced frequency components, spectrum analyzers have bandpass filters with band-

widths as narrow as 10 Hz. Such narrow filters are difficult (or impossible) to achieve, especially at high center frequencies as in our example at 3.5 GHz. Adding mixing stages solves this problem. Figure 8 shows a simplified block diagram of a spectrum analyzer with two mixing steps. The output of the bandpass filter centered at 1 MHz differs from zero only when $f_{vco} - f_{\text{signal}}$ is equal to the central frequency of the first bandpass filter (3.5 GHz in the example), plus or minus the bandwidth of the last bandpass filter (the bandwidth of the 1 MHz filter in the example).

In some spectrum analyzers the signal is converted after the last bandpass filter from analog to digital (at a much lower rate than if it were converted at the instrument input), and then digital filtering is performed, allowing implementation of very narrow filters.

Sensitivity is the measure of the smallest amplitude that the spectrum analyzer can display. The ultimate limitation in measuring a low-level signal is the random noise generated by the instrument itself. The thermal noise generated in the circuit elements is amplified by the different gain stages, added to the noise they generate, and displayed on the screen as a noise signal below which one cannot make measurements. The instrument sensitivity is determined by measuring the noise level on the display without any applied input signal. Signals at lower levels cannot be measured because they are masked by the noise. Even though the input attenuator and mixers have little effect on the actual system noise before the first gain stage, they do have a marked effect on the ability of the instrument to measure low-level signals because they attenuate the input and so they reduce the signal-to-noise ratio. Choosing the minimum input attenuation maximizes the instrument's sensitivity.

To minimize the internal spectrum analyzer's harmonic distortion, signal levels should be kept as low as possible at the input of the spectrum analyzer mixer. This means that to increase accuracy, the input attenuator of the spectrum analyzer must be used to decrease the level of the signal applied to the mixer when high-level signals are applied. However, this reduces the signal-to-noise ratio and so the instrument's sensitivity.

The bandwidth of the bandpass filter (resolution bandwidth) affects sensitivity. The spectrum analyzer generates random noise of constant amplitude over a wide range of frequencies. Because part of the internally generated noise is present at the input of the bandpass filter, the noise present at the output also decreases and sensitivity increases when the filter bandwidth decreases.

Figure 8. Block diagram of the superheterodyne spectrum analyzer with two mixing steps. The inclusion of multiple mixing stages in a superheterodyne spectrum analyzer allows high-resolution spectral analysis of high frequency voltages and also analog-to-digital conversion of the voltage representing the components of the input voltages.

The dynamic range of a spectrum analyzer is defined as the difference between its maximum input voltage and its noise level.

Frequency resolution is the ability of the spectrum analyzer to separate closely spaced input signal frequency components. It depends on the bandwidth of the narrowest filter in the chain (see Fig. 8). As the VCO is swept in frequency, the input of the bandpass filter is also swept. Unless two distinct input signal frequency components are far enough apart when compared with the filter bandwidth, the traces they produce on the screen fall on top of each other and look like only one response.

Band-pass band filters, as with band-limited circuits, require finite time to respond to an input stimulus. Because the rise time of a filter is inversely proportional to its bandwidth, the narrower the resolution of the filter, the greater the time it needs to respond to the input. If the VCO is swept too quickly, there is a loss of displayed amplitude in the screen of the spectrum analyzer. This means that when a narrow filter is selected, sweep time must increase, otherwise the instrument's accuracy is affected. It can be shown (3) that the sweep time must decrease with the square of the bandwidth to assure that the time when the mixer output is within the passband is of the order of magnitude of the rise time of the filter. This means that each time the resolution bandwidth is reduced by a factor of 10, the sweep time goes up by a factor of 100. If we select a very narrow filter, the sweep time becomes prohibitive. For instance, a bandwidth of 30 Hz in a 10 division display with 50 MHz/div selected, leads to a sweep time of 34 days!!! Some spectrum analyzers automatically set sweep time to the span and bandwidth resolutions selected to maintain the instrument's calibration. Others allow the user to select sweep time also, but when this is too small it indicates that the display is uncalibrated.

The amplitude accuracy of the spectrum analyzer depends on several factors. The input attenuator and the first mixer must present a flat frequency response over the entire band of the instrument. In a low-frequency instrument, ± 0.5 dB of deviation from a flat response is a typical value, but for a spectrum

analyzer with a frequency range of tens of GHz, ± 4 dB is an acceptable value. The fidelity of the logarithmic characteristic of the log amplifiers and the linearity of the envelope detector characteristic also affect amplitude accuracy. Impedance mismatch is also a source of error at high frequencies. Spectrum analyzers do not have perfect input impedances. In most cases, however, uncertainty is relatively small. When this is not the case, the use of a well-matched attenuator at the instrument input solves the problem.

The measurement of signal distortion must consider the characteristics of the signal. The change with time of the harmonic components of a signal may create four types of signals: (a) signals with quasi-stationary components; (b) signals with fluctuating components; (c) signals with rapidly changing components; and (d) signals with interharmonics and other spurious components. Continuous real-time analysis is required for (b). For (c) continuous real-time measurement is absolutely necessary because the value of each component is meaningful only when obtained through statistical analysis of a set of values measured over time. Very precise requirements are necessary to get reproducible results.

The use of a superheterodyne spectrum analyzer is not incompatible with real-time analysis, but it requires (1) the possibility of external control of the analyzer's local oscillator; (2) that the analyzer have an analog-to-digital converter at the output of the bandpass filter, a digital memory, and a CPU so that successive values of each frequency component may be stored and processed. These features are common in many spectrum analyzers now commercially available.

SYSTEMS DISTORTION MEASUREMENT

The evaluation of distortion introduced into electrical signals by systems, such as electronic devices and equipment, consists of one or several of the following basic measurements involving electric voltages:

Figure 9. Setup for linear electric distortion measurement. The system under test (SUT) is subjected to a sine wave voltage. The voltmeter may be rms or peak responding. The function of the voltmeter and of the phase meter may be performed by a vector network analyzer.

1. Linear distortion (frequency and phase distortion): measurement of the amplitude and phase of a system's output voltage as a function of the frequency. The system is driven by a sine wave voltage whose amplitude is kept constant and whose frequency is swept in the range of interest. The output voltage amplitude and the phase shift between the input and output voltages are measured. Frequency distortion is evaluated by dividing the difference between the maximum and minimum indications of the voltmeter by half their sum. The result is expressed either as a percentage or in logarithmic units (dB). Delay distortion, expressed in time units, commonly μs or ms , is determined by dividing each phase shift (in rad) by the corresponding angular frequency (in rad/s) and selecting the maximum difference of the obtained ratios. The test setup for linear distortion measurements is shown in Fig. 9.
2. Harmonic distortion (nonlinear): measurement of the absolute values or values relative to the fundamental of the harmonics in the output voltage of the system when a sine wave voltage is applied to the system. In some cases, when the nonlinearity of the system depends heavily on frequency, the system is subjected to a band-limited noise signal. Harmonic distortion is usually expressed either as a percentage or in logarithmic units (dB or, sometimes, dBc, that is, dB relative to the fundamental, when the harmonics have small amplitudes compared to the fundamental). Figure 10 represents a possible test setup for harmonic distortion measurement.
3. Intermodulation distortion (nonlinear): the system is supplied with at least two sine waves of different frequencies, and the frequency components in the output voltage are measured. As in the case of harmonic distortion measurement, when the nonlinearity of the system depends heavily on frequency, the system is subjected to a band-limited noise signal. Intermodulation distortion is usually expressed either as a percentage or in logarithmic units (dB). The test equipment for intermodulation distortion measurement is shown in Fig. 11.

Figure 10. Setup for electric harmonic distortion measurement. The signal analyzer is generally a spectrum analyzer with an input voltage attenuator.

Figure 11. Setup for electric intermodulation distortion measurement. The two oscillators are connected to the system under test (SUT) through a directional coupler or a diplexer. The oscillators may be replaced by a multitone generator.

Testing to assess the performance of a system depends on the application. In sound systems, where harmonics and intermodulation products that fall in the audible spectrum produce distortion, harmonic and intermodulation distortion measurements are mandatory. Because the human ear is relatively insensitive to delay distortion, however, this type of electrical distortion needs no attention. In video and data signals, delay distortion constitutes one of the most limiting impairments, which means that it must be measured.

Following the ideas just presented, the measurement of electric distortion has been a subject of standardization. Thus the test of a loudspeaker, an audio amplifier, or a TV receiver involves many different distortion measurements according to specific methods and procedures. Standards IEC 268 Parts 3, 4, 5, and 6 for sound system equipment, IEC 244 Parts 4 and 4A for radio transmitters and IEC 244 Part 5 for television transmitters are texts where the reader may find useful information concerning the measurement of electric distortion in those systems.

The following are some considerations on equipment and measuring methods for distortion measurement:

1. The level of total harmonic distortion of the source of signals shall be at least 10 dB below the lowest level of distortion to be measured.
2. To correctly measure the distortion of a system, one must consider the distortion introduced by the test setup. For that purpose, it is good practice to calibrate the setup before testing the system under test (SUT). A measurement on the setup alone provides values that are used as correction factors.
3. The signal analyzer is often a spectrum analyzer. Network analyzers are also very much in use, particularly for testing RF and microwave devices (4). Available spectrum and network analyzers have three useful features: (a) an internal oscillator that may be used to excite the SUT; (b) digital interfaces for remote control that allow automated measurement procedures; (c) an internal CPU useful for reducing data and presenting distortion parameters.
4. Delay distortion is expressed by a parameter that is a function of the derivative of the phase with respect to frequency $d\theta/d\omega$. Several methods leading to different parameters are in use (4,5). One method very commonly implemented in network analyzers consists of measuring $d\theta/d\omega$ at two frequencies, one of which is a reference. Then delay distortion is expressed as the difference of the two derivatives.

Measuring the phase shift introduced by a system requires a reference signal. This may be a problem when testing tuners, for instance. The AM/FM-delay method for group delay measurement (4) is one solution to overcoming that difficulty.

Another delay distortion measurement problem arises when the input and output of the system are far apart as is the case with some communications systems. Solutions for this problem are discussed in (5).

Apart from the distortion due to the nonlinearity or the non-ideal frequency response of a system considered in this article, a signal may be distorted because of the interference of signals of the same system, for example, cross talk and cross-modulation. All of these types of distortions are included in what we designate an intrasystem distortion. A signal in a system, however, may be distorted by a signal from another system. This type of distortion that is designated as intersystem distortion is produced when a coupling between the two systems exists either by conduction or radiation. Intersystem distortion measurement and evaluation is an electromagnetic interference (EMI) or electromagnetic compatibility (EMC) problem and is thus beyond the scope of the present article. EMI/EMC is presently an extremely important domain of electrical engineering and it will be even more important in the future. The proper operation of electrical and electronic equipment requires increased attention to interference and susceptibility issues. Interested readers may refer to Refs. 6 and 7.

Legislation and standards for measurements on EMI/EMC have been produced all over the world. References 8–14, are examples of standards that may assist the reader in evaluating intersystem distortion. For a more detailed list, readers should consult Ref. 7.

INTERMODULATION MEASUREMENT

Virtually all electronic circuits and systems exhibit nonlinear input-output transfer characteristic. Mixers, frequency multipliers, modulators, and square-law detectors represent examples of intentional class members, while linear power amplifiers, active filters, and microwave transmitters, in which nonlinearity represents an undesirable deviation of the system from ideal, or linear, operation, are examples of unintentional members.

Whenever a number of signals of differing frequencies pass through a nonlinear device, energy is transferred to frequencies that are sums and differences of the original frequencies. These are the intermodulation products (IMPs). In such cases, the instantaneous level of one signal may effectively modulate the level of another signal, whence the name *intermodulation*. It is interesting to note that the ear's cochlea has a similar nonlinear response and produces sums and differences of the input frequencies in the same way, particularly with loud sounds (1).

It has also been found that passive components, normally considered to be linear, can also generate IMPs. A variety of situations can arise in which nonlinear-resistance junctions can be formed at metallic mating surfaces. Such junctions may result from salt or chemical depositions or from corrosion. The result is sometimes known as the "rusty bolt effect" because rusted bolts in structures have been known to exhibit such nonlinearities. This phenomenon is referred to as passive intermodulation (PIM). Sources of PIM include waveguides, directional couplers, duplexers, and antennas (2–6).

Intermodulation may also occur at the amplifier-loudspeaker interface (7), or in general due to the nonlinear interaction between the input signal of a two-port network and a signal injected to the output port and propagating into the

input via a feedback network (8). Externally induced transmitter intermodulation, also known as reverse intermodulation, back intermodulation, and antenna-induced intermodulation, is the mixing of a carrier frequency with one or more interfering signals in a transmitter's final stage (9). Moreover, lack of screening of open-wire transmission lines can result in significant coupling to adjacent lines, frequently giving rise to intermodulation products (10). Furthermore, intermodulation may arise when an array of receiving antennas is illuminated with a transient impulsive electromagnetic plane wave (11).

In discussing the sources of IMPs it is convenient to divide nonlinear mechanisms yielding IMPs into two principal forms. The first is due to a nonlinear amplitude input/output characteristic (AM/AM), which causes amplitude compression with increasing input amplitude. The second mechanism occurs because of the variation of phase shift through the device, or the system, as the input amplitude is changed (AM/PM).

Depending on the signal characteristics, sources of IMPs can be divided into two categories: (1) static nonlinearity, depending solely on the amplitude of the signal, and (2) dynamic nonlinearity, depending not only on the amplitude but also on the time properties or frequency composition of the signal.

Static nonlinearities usually encountered in electronic circuits and systems can be classified into clipping, crossover, and soft nonlinearities (12), as shown in Fig. 1. In contrast with the *hard* nonlinearities of clipping (which is significant near maximum input amplitudes) and crossover (mostly significant at small input amplitudes), soft nonlinearity is usually the most important in the transfer characteristic of an electronic circuit. If the frequency content or the time properties of the input signal affect the transfer characteristic of the circuit or the system, the resulting nonlinearities may be called *dynamic*. Intermodulation products resulting from dynamic nonlinearities are referred to as transient intermodulation (TIM), slew-induced distortion (SID), or dynamic intermodulation distortion (DIM) (13–16).

SIMPLE INTERMODULATION-PRODUCT THEORY

IMPs occur when two or more signals exist simultaneously in a nonlinear environment. In general, if N signals, with frequencies f_1 to f_N , are combined in a static nonlinearity, the output

will contain spectral components at frequencies given by

$$f = \sum_{n=1}^N k_n f_n$$

where k_n is a positive integer, a negative integer, or zero and $\sum_{n=1}^N |k_n|$ is the order of the IMP. Even with a small number of input signals, N , a very large number of IMPs are generated. Fortunately, not all products are equally troublesome. Depending on the system involved, some of these IMPs can be neglected, since they will be filtered out at some point. For example, most communication systems operate over a limited frequency band. Thus, IMPs falling out of the band will be attenuated. Moreover, the amplitudes of the IMPs generally decrease with increasing order of the products, and high-order products can often be neglected. Low-order intermodulation components such as the second-order components $f_m - f_n$ and $f_m + f_n$ and the third-order components occurring at frequencies $2f_m - f_n$ and $f_m + f_n - f_q$ are usually the most troublesome, having the largest magnitudes and/or lying close to the originating frequencies, which makes their removal by filtering practically difficult. However, a salient characteristic of PIM, as distinguished from the conventional IM counterpart discussed in the preceding, is that the PIMs causing trouble are of a high order, say the eleventh through the twenty-first.
