Analysis of nonlinear systems differs from that of linear systems in several respects: There is no single analytical approach which is generally applicable (such as Fourier or Laplace transforms in linear systems); closed-form analytical solutions of nonlinear equations are not ordinarily available; and there is rarely sufficient information available to enable a set of equations which accurately model the system to be derived. These factors preclude the exact analytical determination of nonlinear effects, such as IMPs, in the general case. In order to get anything done at all, it is usually necessary to make various simplifying assumptions and then to use an approximate model which will provide results of acceptable accuracy for the problem in hand.

A simple approach, therefore, is to use frequency-domain techniques, which provide a separate solution for each frequency present in the output. In general, such methods are (1) centered around a description of the nonlinear mechanism by a continuous-function characteristic (for example, a polynomial or a Fourier-series representation of the output in terms of the input) and (2) based on the simplifying assumption that this characteristic does not vary with frequency—that is, it is a memoryless characteristic.

Memoryless nonlinear circuits are often modeled with a power series of the form

$$V_{\text{out}} = \sum_{n=0}^N k_n V_i^n \quad (1)$$

The first coefficient, k_0 , represents the dc offset in the circuit. The second coefficient, k_1 , is the gain of the circuit associated with linear circuit theory. The remaining coefficients, k_2 and above, represent the nonlinear behavior of the circuit. If the circuit were completely linear, all of the coefficients except k_1 would be zero.

The model can be simplified by ignoring the terms that come after the k_3 term. For soft nonlinearities, the size of k_n decreases

rapidly as n gets larger. For many applications the reduced model of Eq. (2) is sufficient, since the second-order and third-order effects dominate. However, there are many devices, circuits, and systems presenting difficulties for the polynomial approximation.

We have, then,

$$V_{\text{out}} = k_0 + k_1 V_i + k_2 V_i^2 + k_3 V_i^3 \quad (2)$$

Assuming that the input is a two-tone signal of the form

$$V_i = V_1 \cos \omega_1 t + V_2 \cos \omega_2 t \quad (3)$$

then combining Eqs. (2) and (3) yields

$$\begin{aligned} V_{\text{out}} = & a_0 + b_1 \cos \omega_1 t + c_1 \cos \omega_2 t + b_2 \cos 2\omega_1 t + c_2 \cos 2\omega_2 t \\ & + b_3 \cos(\omega_1 + \omega_2)t + c_3 \cos(\omega_1 - \omega_2)t + b_4 \cos 3\omega_1 t \\ & + c_4 \cos 3\omega_2 t + b_5 \cos[(2\omega_1 + \omega_2)t + \cos(2\omega_1 - \omega_2)t] \\ & + c_5 [\cos(2\omega_2 + \omega_1)t + \cos(2\omega_2 - \omega_1)t] \end{aligned} \quad (4)$$

where

$$a_0 = k_0 + \frac{k_2}{2}(V_1^2 + V_2^2)$$

$$b_1 = k_1 V_1 + \frac{3}{4}k_3 V_1^3 + \frac{3}{2}k_3 V_1 V_2^2$$

$$c_1 = k_1 V_2 + \frac{3}{4}k_3 V_2^3 + \frac{3}{2}k_3 V_1^2 V_2$$

$$b_2 = \frac{1}{2}k_2 V_1^2$$

$$c_2 = \frac{1}{2}k_2 V_2^2$$

$$b_3 = c_3 = k_2 V_1 V_2$$

$$b_4 = \frac{1}{4}k_3 V_1^3$$

$$c_4 = \frac{1}{4}k_3 V_2^3$$

$$b_5 = \frac{3}{4}k_3 V_1^2 V_2$$

$$c_5 = \frac{3}{4}k_3 V_1 V_2^2$$

For equal-amplitude input tones, Eq. (4) shows that the second-order terms, of amplitudes b_2 , c_2 , b_3 , and c_3 , will be increased 2 dB in amplitude when input tones are increased by 1 dB. Third-order terms, of amplitudes b_4 , c_4 , b_5 , and c_5 , are increased 3 dB in amplitude when input tones are increased by 1 dB.

SIMPLE TRANSIENT-INTERMODULATION THEORY

To illustrate how TIM distortion arises, consider a differential amplifier with negative feedback applied between the output and the inverting input and with a voltage step applied to the noninverting input. If the open-loop gain of the amplifier were flat and the time delay through it were zero, the voltage step would instantaneously propagate undistorted through the

amplifier, back through the feedback loop, and into the inverting input. There it would be subtracted from the input signal, and the difference signal, which is a voltage step occurring at the same time that the input voltage does, would be amplified by the amplifier. However, this is not the case when the open-loop gain of the amplifier is not flat and the time delay through it is not zero. When the voltage step occurs, the limited high-frequency response of the amplifier prevents the appearance of a signal at the amplifier output terminal until the internal capacitors of the amplifier can charge or discharge. This causes the momentary absence of a feedback signal at the inverting input to the amplifier, possibly causing the amplifier to severely overload until the feedback signal arrives.

If the input signal to the differential amplifier is formed from a sine wave superimposed on a square wave, the amplifier will exhibit the same response to the abrupt level changes in the square wave as it did to the voltage step discussed in the preceding. During the momentary absence of the feedback when the square wave changes level, the amplifier can either saturate or cut off. If this occurs, the sine wave momentarily disappears from the signal at the output terminal of the amplifier, or it momentarily decreases in amplitude. This happens because the saturated or cut-off amplifier appears as a short circuit or open circuit, respectively, to the sine wave, and this component of the input signal is interrupted from the output signal, thereby resulting in TIM (16).

A point to be noted is that if the term TIM were understood literally, it would imply transients of both high and low frequencies and/or high or low operating levels—in other words, all transients. In actual practice, however, TIM occurs only for signals with simultaneous high level and high frequencies, not lower levels or lower frequencies. The key characteristic of such signals is high signal slopes, not just high frequencies or high levels. Neither high frequencies nor high levels in themselves necessarily result in distortion, unless their combination is such that a high effective signal slope is produced. TIM is actually generated when the signal slope approaches or exceeds the amplifier slew rate. This can happen for either transient or steady-state signals. Thus, a more easily understood term to describe what actually happens would be one which relates slew rate and signal slope, such as *slew-induced distortion* (SID). Other descriptive variations of the terminology are “slew-rate distortion” and “slewing distortion” (17).

Due to the complexity of the mechanism resulting in TIM, especially the frequency dependence of the amplifier and the incorporation of the feedback, the use of Volterra series to characterize the output as a function of the input (18) is needed to provide closed-form expressions for all the distortion products. However, techniques using Volterra series suffer from the disadvantage that a complex mathematical procedure is required to obtain a closed-form expression for the output amplitude associated with a single component of the output spectrum. Moreover, the problem of obtaining output products of orders higher than the third becomes prohibitively difficult unless it may be assumed that higher-order contributions vanish rapidly (19). The Volterra series approach is therefore most applicable to mild nonlinearities where low-order Volterra kernels can adequately model the circuit behavior.

With appropriate assumptions and simplifications, many useful features of the Volterra series technique can be used to find approximate expressions for TIM (SID). These are quite accurate for small distortion conditions (20,21).

INTERMODULATION CHARACTERIZATION

Although it is important to understand the origin of intermodulation and the engineering techniques for avoiding it, it is equally important to be able to characterize it objectively, preferably in a way that correlates well with the subjective perception of the intermodulation. Being able to characterize an imperfection in this way is an important step toward eliminating it as a system performance degradation.

Several techniques for characterizing intermodulation distortion have been proposed. While some of these techniques measure the total intermodulation distortion, others distinguish between the various intermodulation products. The latter are much to be preferred, because subjective perception of intermodulation shows that equal amounts of total intermodulation distortion differ widely in their effect according to how the total is made up.

Depending on the signal characteristics, techniques for characterization of intermodulation distortion can be classified into two categories: (1) steady-state techniques, where characterization is performed on the assumption that the input to the system under consideration is a multisinusoidal signal, and (2) dynamic techniques, where characterization is performed on the assumption that the input to the system under consideration is formed of a sinusoidal signal superimposed on another signal characterized by rapid changes of state—for example, a square wave.

Steady-State Techniques

The Intercept Point. Increasing the signal level at the input to a weakly nonlinear device will cause the IMPs to increase at the output (22). In fact, the increase in the amplitudes of the IMPs is faster than the increase in the output version of the input signal. For increasing fundamental input power, the fundamental output power increases in a linear manner, according to the gain or loss of the device. At some point, gain compression occurs and the fundamental output power no longer increases with input power. The output power of the second-order intermodulation products also increases with fundamental input power, but at a faster rate. Recall that the second-order intermodulation changes 2 dB per 1 dB of change in the fundamental. Similarly, the third-order intermodulation changes 3 dB per 1 dB of change in the fundamental. Thus, on a logarithmic scale, as shown in Fig. 2, the lines representing the second- and third-order intermodulation products have twice and three times, respectively, the slope of the fundamental line.

If there were no gain compression, the fundamental input power could be increased until the second-order intermodulation eventually caught up with it and the two output power levels were equal. This point is referred to as the second-order intercept point. The third-order intermodulation product also increases faster than the fundamental, and those two lines will intersect at the third-order intercept point. Rarely can either of these two points be measured directly, due to the gain compression of the fundamental. Instead, the intercept points are extrapolated from measurements of the fundamental and intermodulation products at power levels below where gain compression occurs. The intercept points are usually specified in dBm and may refer either to the output or to the input; the two points will differ by the gain of the system under consideration. The second-order and third-order intercept points are figures of

Figure 2. Third-order and second-order intercept points are determined by extending the fundamental, the second-order, and the third-order intermodulation transfer function lines. (a) Fundamental transfer function, slope = 1; (b) second-order intermodulation, slope = 2; (c) third-order intermodulation, slope = 3. IP3, third-order intercept point; IP2, second-order intercept point.

merit which are independent of the signal level. Therefore, the intermodulation performance of two different systems can be compared quite easily if their intercept points are known (22).

Using the intercept point, it is easy to calculate the relative intermodulation level corresponding to a given input signal level. In fact, the difference between the level of the second-order intermodulation and the fundamental signal level is the same as the difference between the fundamental signal level and the intercept point. Thus, if the second-order intercept point is +15 dBm and the fundamental signal level is -10 dBm (both referred to the output of the device), the difference between these two values is 25 dB. Therefore, the second-order intermodulation products will be 25 dB below the fundamental, or -35 dBm. So the intercept point allows easy conversion between fundamental signal level and the intermodulation level.

The difference between the level of the third-order intermodulation products and the fundamental signal level is twice the difference between the fundamental signal level and the third-order intercept point. (Note that the second-order intercept point is not the same as the third-order intercept point.) Suppose that the third-order intercept point is +5 dBm and the fundamental signal is -25 dBm, both referred to the output of the device. The difference between the intercept point and the fundamental is 30 dB, so the third-order intermodulation products will be two times 30 dB down from the fundamental. The relative distortion level is -60 dB, and the absolute power of the intermodulation products is -85 dBm.

It is important, however, to note that the preceding analyses assume that the second-order and third-order intermodulation curves have slopes of 2 dB/dB and 3 dB/dB respectively.

Thus, theoretically, the intercept points are not functions of the input power level. If a power sweep is performed, it is expected that the intercept points will remain constant. The intercept points can therefore be calculated from measurements at only one power level. However, if the input signal exceeds a certain limit, the amplitudes of the output fundamentals and the resulting intermodulation products will start to saturate, and the intercept points will usually drop off, indicating an invalid measurement. It is essential to know this limit. Expanding the model of Eq. (2) to include fourth- and fifth-order terms (23) can do this.

Moreover, at low power levels, the intercept points will start to change as the noise floor of the measuring instrument (usually a spectrum analyzer) is approached, thus indicating an invalid measurement. It is important, therefore, to look at the variation of the intercept points as functions of power, as this provides a good way of checking the valid measurement range. This is particularly useful for large-dynamic-range circuits and systems with low output power where the intermodulation is low, but only for signals that are low enough.

Two-Tone Test. The two-tone test is extensively used in characterizing a wide range of devices. A few examples are (a) magnetic tapes (24), (b) microwave- and millimeter-wave diode detectors (25), (c) analog-to-digital converters (26, 27), (d) gamma correctors (28), and (e) electrical components such as resistors, capacitors, and inductors, as well as contacts of switches, connectors, and relays (29). The two-tone test is also used to characterize the performance of the basilar membrane of the cochlea (30).

The two-tone test can also be used to determine the transfer characteristic of a nonlinear device modeled by the polynomial approximation of Eq. (2). With the input formed of two properly selected frequencies ω_1 and ω_2 , if the second-order and third-order intermodulation products are measured separately, then it is possible to find, from the measured data, the coefficients of the quadratic and cubic terms, k_2 and k_3 respectively, in the polynomial approximation of Eq. (2). If, in addition, the IMPs are measured at two sets of values of ω_1 and ω_2 , then it is possible to identify the dominant physical nonlinear process from the variation of IMPs with test frequencies (13).

The two-tone test can also be used to determine the complex transfer characteristic of a nonlinear device exhibiting AM/AM nonlinearity only, with fixed phase shift between the output and the input. In this case a complete set of measurements, for all the two-tone intermodulation products produced by the nonlinearity, at two different power levels is necessary (31). If the device under consideration exhibits both AM/AM and AM/PM nonlinearities, then determination of a unique set of polynomial coefficients requires a complete set of intermodulation measurements at three different power levels (31). The set obtained at the highest power level will decide the amplitude range within which the characterization will be valid.

Due to the basic assumption that the nonlinearities are represented by polynomials, high-accuracy representation of the device characteristics will require difficult accurate measurements of higher-order intermodulation products, in addition to the increased complications and considerable efforts involved in the analysis (31). Another difficulty from which this method suffers arises from the necessity of measuring complete sets of two-tone intermodulation products which are spread over a wide frequency range and consequently may put stringent

specifications on the measuring instruments and techniques if accurate measurements are to be achieved.

In the two-tone test, use is made of one of the in-band IMPs to describe a device, a circuit, or a system nonlinearity. Measurements are made in or near the frequency range of interest. In this test, the input signal consists of two frequencies, ω_1 and ω_2 , of equal amplitude and a fixed amount of frequency spacing. At the output of the circuit or the system under test, the amplitudes of the third-order intermodulation products, $2\omega_1 - \omega_2$ and $2\omega_2 - \omega_1$, are measured. The intermodulation distortion is defined as the ratio between the root sum square of the intermodulation products and the root sum square of the twin-tone amplitudes.

Unless a wave analyzer or a spectrum analyzer is available, the implementation of the two-tone test invariably requires amplification of the whole output spectrum to get the components ω_1 and ω_2 at a normalized value (100%). Then, ω_1 and ω_2 are suppressed, and the remaining components $2\omega_1 - \omega_2$ and $2\omega_2 - \omega_1$ are measured with an ac voltmeter or oscilloscope. Especially at audio frequencies, this approach requires steep filters, one set of filters for each set of ω_1 and ω_2 . For the same reason, $\omega_2 - \omega_1$ cannot be too low. So it will never be a real narrow-band system. This narrowband aspect is particularly important for higher frequencies, where equalizers, in the reproduction audio channel, may give unequal amplification of the components in the spectrum (32).

In the audio-frequency range, a new version of the two-tone test overcomes the above-mentioned disadvantages (32). This is based upon the multiplication of the spectrum by itself. Thus, if the two-tone input signal is given by Eq. (3), with $V_1 = V_2 = V$, then multiplying the input spectrum by itself—that is, squaring—yields

$$\begin{aligned} V_i^2 &= V^2(\cos \omega_1 t + \cos \omega_2 t)^2 \\ &= V^2 \left(1 + \frac{1}{2} \cos 2\omega_1 + \frac{1}{2} \cos 2\omega_2 \right. \\ &\quad \left. + \cos(\omega_1 + \omega_2) + \cos(\omega_1 - \omega_2) \right) \end{aligned} \quad (5)$$

Assuming that the system under test is narrowband, Eq. (4) reduces to

$$\begin{aligned} V_{\text{out}} &= b_1 \cos \omega_1 t + c_1 \cos \omega_2 t + b_5 \cos(2\omega_1 - \omega_2)t \\ &\quad + c_5 \cos(2\omega_2 - \omega_1)t \end{aligned} \quad (6)$$

Multiplying the output spectrum by itself—that is, squaring—yields

$$\begin{aligned} V_{\text{out}}^2 &= [b_1 \cos \omega_1 t + c_1 \cos \omega_2 t + b_5 \cos(2\omega_1 - \omega_2)t \\ &\quad + c_5 \cos(2\omega_2 - \omega_1)t]^2 \end{aligned} \quad (7)$$

$$\begin{aligned} &= \frac{1}{2}(b_1^2 + c_1^2 + b_5^2 + c_5^2) + \left(\frac{1}{2}b_1^2 + c_1b_5 \right) \cos 2\omega_1 t \\ &\quad + \left(\frac{1}{2}c_1^2 + b_1c_5 \right) \cos 2\omega_2 t + \frac{1}{2}b_5^2 \cos(4\omega_1 - 2\omega_2)t \\ &\quad + \frac{1}{2}c_5^2 \cos(4\omega_2 - 2\omega_1)t + (b_1c_1 + b_5c_5) \cos(\omega_1 + \omega_2)t \\ &\quad + (b_1c_1 + b_1b_5 + c_1c_5) \cos(\omega_1 - \omega_2)t + b_1b_5 \cos(3\omega_1 - \omega_2)t \\ &\quad + c_1c_5 \cos(3\omega_2 - \omega_1)t + (b_1c_5 - c_1b_5) \cos(2\omega_1 - 2\omega_2)t \\ &\quad + b_5c_5 \cos(3\omega_1 - 3\omega_2)t \end{aligned} \quad (8)$$

where

$$b_1 = c_1 = k_1 V + \frac{9}{4} k_3 V^3$$

and

$$b_5 = c_5 = \frac{3}{4} k_3 V^3$$

Inspection of the spectra of Eqs. (5) and (8) shows that:

1. Both spectra are split into two parts, a lower region and a higher region. All components in the lower region are unaffected by the choice of ω_1 and ω_2 . They are affected only by the difference in frequencies $\omega_2 - \omega_1$. This means that as long as $\omega_2 - \omega_1$ is kept constant, the lower region of the spectrum will not be affected if measurement is swept through the whole band.
2. If the distortion is not too high—that is, for $k_3 \ll k_1$ —then the dc component is essentially constant. Also, Eqs. (5) and (8) show that the amplitudes of the components at frequencies ω_1 and ω_2 are equal to the dc component. In fact this dc component represents the 100% level.
3. The amplitude of the components at frequencies $3\omega_2 - \omega_1$ and $3\omega_1 - \omega_2$ is given by $b_1 b_5 = c_1 c_5$. Thus if $b_1 = c_1$ are normalized to unity—that is, the dc component is unity—then the amplitude of these frequency components is directly proportional to the amplitude of the third-order IMPs at frequencies $2\omega_2 - \omega_1$ and $2\omega_1 - \omega_2$.

Thus the IMP measurement reduces to Ref. 32:

1. Squaring
2. Keeping the dc level to a normalized value
3. Filtering out the component at frequency $3\omega_2 - \omega_1$ or $3\omega_1 - \omega_2$
4. Measuring the result with an ac voltmeter

While this approach offers simpler and more flexible instrumentation, its application is limited to low-distortion circuits and systems.

Three standard two-tone test methods are in common use for testing audio-frequency circuits and systems. These are the SMPTE, the CCIF, and the IEC intermodulation tests.

SMPTE Intermodulation Test. In the SMPTE (Society of Motion Picture and Television Engineers) test of intermodulation distortion, the system input is a combination of a large-amplitude low-frequency sine wave with a small-amplitude high-frequency sine wave (33). Often the large-amplitude component is 80% of the rated maximum input amplitude, and its frequency ω_1 is either 50 Hz or 60 Hz. The small-amplitude component is often 20% of the rated maximum input amplitude and therefore falls within the small-signal regime of the system operation; its frequency ω_2 is often 7 kHz. The large sine wave excites nonlinearities in the system under test, and hence it modulates the small-signal transfer function. Because the two input components are independent, the response of the system under test (in the presence of the large component) is

effectively the response of a linear time-varying network. The SMPTE intermodulation test quantifies nonlinearity by reference to the amplitude modulation of the small-amplitude high-frequency component as it appears at the output of the system under test.

CCIF Intermodulation Test. In the CCIF (International Telephonic Consultative Committee) test of intermodulation distortion, the input to the system under consideration is a mixture of two sinusoids, each 50% of full rated amplitude, one at $\omega_1 = 14$ kHz and the other at $\omega_2 = 15$ kHz (34). Intermodulation distortion is quantified by reference to the amplitude of the resulting $\omega_2 - \omega_1 = 1$ kHz difference-frequency tone at the output.

The CCIF intermodulation test has been successfully used for measurement of high-frequency distortion in audio systems. But it is sensitive only to asymmetrical distortion mechanisms which produce even-order products. If a spectrum analyzer, or other sharp-cutoff filtering technique, is used to look at the odd-order products, $2\omega_2 - \omega_1$ and $2\omega_1 - \omega_2$, as well, which in this case lie at 16 kHz and 13 kHz, then the test is also sensitive to symmetrical distortion mechanisms.

IEC Total Difference-Frequency Test. In the IEC (International Electrotechnical Commission) total difference-frequency distortion test, the input is a mixture of two sinusoids, each 50% of full rated amplitude, and angular frequencies ω_1 and ω_2 chosen such that $\omega_1 = 2\omega_0$ and $\omega_2 = 3\omega_0$. Intermodulation distortion is quantified by reference to the amplitude of the difference-frequency tone at ω_0 . In the original proposal for the test, ω_0 was chosen to correspond to 5 kHz; this has been changed to 4 kHz (35).

The IEC intermodulation test is fully in-band and detects both even-order and odd-order nonlinearities. However, it does not distinguish between them. A modified version of this test using $\omega_1 = 7\omega_0$ and $\omega_2 = 5\omega_0$ results in second-order IMPs at $2\omega_0$ and $12\omega_0$, and it results in third-order IMPs at $3\omega_0$, $9\omega_0$, $17\omega_0$, and $19\omega_0$. Thus, all the IMPs are well separated in frequency from each other and from harmonics of the test signals. Proper selection of ω_0 results in ω_1 and ω_2 , and at least one second-order and one third-order product fall within the bandwidth of the system under consideration (13).

Three-Tone Test. In this test, again, specific in-band IMPs are selected to characterize the overall system nonlinearities (36). The more even spectral distribution and flexibility, while still allowing discrete frequency evaluation, make this an attractive test for multifrequency systems such as communication and cable television systems.

In this test, three equal-amplitude tones are applied to the input of the nonlinear system under consideration. Thus,

$$V_i = V(\cos \omega_1 t + \cos \omega_2 t + \cos \omega_3 t) \quad (9)$$

Combining Eqs. (2) and (9) and using simple trigonometric identities, it is easy to show that the third-order term, $k_3 V_i^3$, will contribute to the output spectrum the following:

1. Three components at frequencies ω_1 , ω_2 , and ω_3 , each with amplitude given by

$$A_1 = \frac{15}{4} k_3 V^3 \quad (10)$$

2. Three components at frequencies $3\omega_1$, $3\omega_2$, and $3\omega_3$, each with amplitude given by

$$A_3 = \frac{1}{4}k_3 V^3 \quad (11)$$

3. Twelve components at frequencies $2\omega_m \pm \omega_n$, $m, n = 1-3$, each with amplitude given by

$$A_{21} = \frac{3}{4}k_3 V^3 \quad (12)$$

4. Four components at frequencies $\omega_m + \omega_n \pm \omega_p$, $m, n, p = 1-3$, each with amplitude given by

$$A_{111} = \frac{3}{2}k_3 V^3 \quad (13)$$

Equations (12) and (13) show that an intermodulation product of frequency $\omega_m + \omega_n \pm \omega_p$ is 6 dB higher than an intermodulation product of frequency $2\omega_m \pm \omega_n$.

The intermodulation distortion is defined as the ratio of the amplitude of one of the intermodulation products of $\omega_m + \omega_n \pm \omega_p$ to the amplitude of one of the three output tones.

In this test the choice of frequencies ω_1 , ω_2 , and ω_3 used to make the measurement is important. This is because a system's intermodulation performance may not be constant over its operating frequency range.

The three-tone test is widely used in characterizing the performance of RF amplifiers used in television broadcast transposers, where the vision carrier, color subcarrier, and sound carrier frequency components interact in the presence of amplifier nonlinearities. If the three frequency components are represented as single frequencies— ω_v the vision carrier, ω_{sc} the color subcarrier, and ω_s the sound carrier with amplitudes V_v , V_{sc} , and V_s , respectively—then the input signal can be expressed as

$$V_i = V_v \cos \omega_v t + V_{sc} \cos \omega_{sc} t + V_s \cos \omega_s t \quad (14)$$

Combining Eqs. (2) and (14) and using simple trigonometric identities, it is easy to show that the third-order term of Eq. (2) produces, among others, two in-band intermodulation components given by

$$V_{ip} = \frac{3}{2}k_3 V_v V_{sc} V_s \cos(\omega_v + \omega_s - \omega_{sc})t + \frac{3}{4}k_3 V_s V_{sc}^2 \cos(2\omega_{sc} - \omega_s)t \quad (15)$$

The intermodulation performance of the transposer is measured by taking it out of service and using the three-tone simulation of a composite video and sound signal, given by Eq. (14), as its input. The three levels and frequencies vary from system to system. Typical levels, below the peak synchronous pulse level, are $V_v = -6$ dB, $V_{sc} = -17$ dB, and $V_s = -10$ dB. Under these conditions, the first term of Eq. (15) is the most visible, and the second term will be much lower in amplitude, typically 17 dB less. Using a spectrum analyzer, the relative amplitude of the major in-band intermodulation is measured and referenced to the level of peak synchronous pulse. Usually, the permissible level of the major in-band intermodulation component is -53 dB below the reference level.

This three-tone test method is slow and requires spectrum analyzers with large dynamic ranges. Moreover, it measures

the system performance at one luminance level and one chrominance level only. Thus, it does not test the system over its full operating range (37).

The inadequacy of the internationally accepted three-tone test method can be overcome by using a modified color-bar test signal (37). The color bars are applied to the transposer via a test transmitter. The color bars and sound carrier therefore apply the three tones to the transposer, changing levels in rapid succession. With suitable processing, based on sampling the demodulated color-bar signal for short intervals corresponding to a selected color, intermodulation can be measured simultaneously at seven different luminance levels (37).

Four-Tone Test. This test is commonly used in voice-frequency circuits. In it, the input consists of two pairs of tones, thus approximating an input with Gaussian amplitude distribution, which is a more realistic representation of real-life signals. The frequencies of the input tones are selected to generate second- and third-order intermodulation products within the bandwidth of the device under test. These intermodulation products must be easily separated from the input tones. A variety of frequencies can be selected for the input tones; a typical widely used set is described here. The first pair of tones is separated by $6 \text{ Hz} \pm 1 \text{ Hz}$ and centered at $860 \text{ Hz} \pm 1 \text{ Hz}$, and the second pair of tones is separated by $16 \text{ Hz} \pm 1 \text{ Hz}$ and centered at $1380 \text{ Hz} \pm 1 \text{ Hz}$. The four tones are of equal level within ± 0.25 dB. Using Eq. (2), it is easy to show that the output of the device under test will contain six third-order intermodulation products in the range 1877 Hz to 1923 Hz, four second-order intermodulation products in the range 503 Hz to 537 Hz, and four second-order intermodulation products in the range 2223 Hz to 2257 Hz. Thus, the second-order products measured are the combination of two band-pass filters, one having a passband from 503 Hz to 537 Hz, and the other having a passband from 2223 Hz to 2257 Hz. The third-order products measured are the output of a band-pass filter having a passband from 1877 Hz to 1923 Hz.

Noise-Power Ratio (NPR) Test. In the NPR test, the input to the device under test is obtained from a white-noise source which is band-limited to the instantaneous frequency range of interest. This emulates a situation with many simultaneous input signals. Provided that none of the signals dominate, according to the central-limit theorem, the resulting voltage obtained when many uncorrelated signals are added will approach a Gaussian distribution. True white noise covers a frequency range of interest continuously, unlike discrete signals.

The NPR test measures the amount of intermodulation product power between two frequency ranges of white Gaussian noise. A white-noise generator is used with its output frequency range limited by a band-pass filter according to the bandwidth of the device under test. A quiet channel, of bandwidth $\delta\omega$, is formed by a switchable bandreject filter, as shown in Fig. 3. Then, the resulting white-noise signal of Fig. 3 is applied to the input of the device under test. At the output of the system under test is a receiver which is switch-tuned to the frequency of the bandreject filter used to produce the quiet channel.

The NPR test is widely used for evaluating the intermodulation performance of systems whose input-signal spectrum can be approximated by that of white noise. However, the NPR may

Figure 3. The output spectrum of a noise-power ratio measurement. (a) Injected noise. (b) Noise and intermodulation generated in the measurement bandwidth, $\delta\omega$, by the DUT. $\text{NPR} = A - B$.

be degraded by the noise floor of the system under test, especially under very low loading. It may also be degraded by the distortion products which are produced under high loading (38).

Cross-Modulation. Cross-modulation occurs when modulation from a single unwanted modulated signal transfers itself across and modulates the wanted signal. Cross-modulation is troublesome primarily if the desired signal is weak and is adjacent to a strong unwanted signal. Even when the carrier of the strong unwanted signal is not passed through the system, the modulation on the undesired carrier will be transferred to the desired carrier. Cross-modulation is therefore a special case of intermodulation. Recall that when the input to a nonlinear system is a two-tone signal of the form of Eq. (3), then the amplitudes of the output components at frequencies ω_1 and ω_2 will be given by

$$b_1 = k_1 V_1 + \frac{3}{4} k_3 V_1^3 + \frac{3}{2} k_3 V_1 V_2^2 \quad (16)$$

and

$$c_1 = k_1 V_2 + \frac{3}{4} k_3 V_2^3 + \frac{3}{2} k_3 V_1^2 V_2 \quad (17)$$

respectively. Thus, the output obtained at each frequency, ω_1 and ω_2 , is dependent upon the amplitude of the signal component of the other frequency. If the amplitude of the wanted unmodulated carrier is V_1 and the instantaneous amplitude of the unwanted amplitude-modulated carrier is

$$V_2(t) = V_2(1 + m \cos \omega_m t) \quad (18)$$

then, using Eq. (16), the amplitude of the wanted carrier will be

$$b_1 = k_1 V_1 + \frac{3}{4} k_3 V_1^3 + \frac{3}{2} k_3 V_1 V_2^2 (1 + m \cos \omega_m t)^2 \quad (19)$$

For small values of m and with $k_3 \ll k_1$, Eq. (19) can be approximated by

$$b_1 \approx k_1 V_1 + 3k_3 V_1 V_2^2 m \cos \omega_m t \quad (20)$$

Thus the wanted carrier will be modulated by a modulation index

$$p = 3 \frac{k_3}{k_1} V_2^2 m \quad (21)$$

The cross-modulation factor is then defined as

$$K = \frac{p}{m} \quad (22)$$

Thus, one frequency will be modulated by the modulation of the other frequency. Similar results can be obtained if the unwanted carrier is FM-modulated.

Cross-modulation can be measured as the change in the amplitude of the wanted unmodulated carrier as a function of the amplitude of the unwanted unmodulated carrier. This is the procedure used by the NCTA (National Cable Television Association) standard cross-modulation measurement (39).

Alternatively, the cross-modulation can be measured using the definition of Eq. (22)—that is, the percentage modulation that appears on an unmodulated desired carrier due to the presence of an undesired modulated carrier, divided by the percentage modulation on the undesired carrier (40).

Cross-modulation can also be measured using two equal-amplitude carriers. The wanted carrier, ω_2 , is unmodulated while the unwanted carrier, ω_1 , is FM-modulated. The output spectrum clearly shows the frequency deviation of the wanted carrier. Moreover, it can be shown that the frequency deviation of the intermodulation components of the output spectrum is larger than that of the original FM-modulated unwanted carrier. For the intermodulation product of frequency $\alpha\omega_1 \pm \beta\omega_2$, the deviation will be multiplied by α . Thus, it may be easier to measure the cross-modulation by measuring the deviation of an intermodulation product rather than the deviation of the wanted unmodulated carrier (41).

Differential Gain. The differential gain (DG), a parameter of special interest in color-TV engineering, is conventionally defined as the difference in gain encountered by a low-level high-frequency sinusoid at two stated instantaneous amplitudes of a superimposed slowly varying sweep signal. In video signal transmission, the high-frequency sinusoid represents the chromatic signal and the low-frequency sinusoid represents the luminance signal. Corresponding to the theoretical conditions of the differential measurement, DG measurement is performed with a signal of the form of Eq. (3) with $\omega_2 \gg \omega_1$ and $V_2 \rightarrow 0$ at $V_1 = 0$, X (42). Therefore—recalling that if the input to a nonlinear system is a two-tone signal of the form of Eq. (3) then the amplitude of the output component at frequency ω_2 will be given by

$$c_1 = k_1 V_2 + \frac{3}{4} k_3 V_2^3 + \frac{3}{2} k_3 V_1^2 V_2 \quad (23)$$

Thus, the DG can be expressed as

$$\text{DG} = 1 - \frac{k_1 + \frac{3}{4} k_3 V_2^2}{k_1 + \frac{3}{4} k_3 V_2^2 + \frac{3}{2} k_3 X^2} \quad (24)$$

DG can therefore be considered, to some extent, as a measure of the intermodulation performance of a system under test.

Dynamic Range. The dynamic range can be defined as the amplitude range over which a circuit or a system can operate without performance degradation. The minimum amplitude is dictated by the input thermal noise and the noise contributed by the system. The maximum amplitude is dictated by the

Figure 4. The dynamic range is the difference between the fundamental response input level and the third-order response input as measured along the noise floor. (a) Fundamental response. (b) Third-order intermodulation response. (c) Noise floor.

distortion mechanisms of the system under consideration. In general, the amount of tolerable distortion will depend on the type of the signals and the system under test. However, for the purpose of an objective definition the maximum amplitude will be considered the input signal level at which the intermodulation distortion is equal to the minimum amplitude (43). The dynamic range can therefore be considered, to some extent, as a measure of the intermodulation performance of a system under test.

A useful working definition of the dynamic range is that it is two-thirds the difference in level between the noise floor and the intercept point in a 3 kHz bandwidth (44). Or it is the difference between the fundamental response input level and the third-order response input as measured along the noise floor (sometimes defined as the 3 dB bandwidth above the noise floor) in a 3 kHz bandwidth, as shown in Fig. 4. Reducing the bandwidth improves the dynamic range because of the effect on noise.

Alternatively, in receiver circuits the intermodulation-free dynamic range (IFDR) is widely used to quantify the ability of the receiver to listen to a weak station without disturbance from an intermodulation product generated by strong stations on other frequencies. The IFDR is in fact a measure of how strong two signals can be before the level of their intermodulation products reaches the noise floor of the receiver. The IFDR is defined as the difference between the signal strengths of the strong signals and the noise floor of the receiver. The larger the IFDR, the better.

Adjacent-Channel and Cochannel Power Ratio Tests. In modern telecommunication circuits signals comprising one or more modulated carriers are handled. The characterization of the intermodulation performance of such circuits cannot, therefore, be performed using two-tone and three-tone input signals. A combination of equally spaced tones—in practice ten or more

sinusoids (45), with constant power and correlated or uncorrelated phases—is more appropriate (46).

Because of the nonlinearity of the device under test, intermodulation products will be generated. These intermodulation products can be classified as adjacent-channel distortion when their frequencies are located to the right or to the left of the original spectrum, or cochannel distortion when their frequencies are located exactly over the original spectrum. The adjacent-channel power ratio (ACPR) is defined as the ratio of the total linear output power to the total output power collected in the upper and lower adjacent channels (47). The cochannel power ratio (CCPR) is defined as the ratio of the total linear output power to the total distortion power collected in the input bandwidth (47). The intermodulation distortion ratio (IMR) is the ratio of the linear output power per tone to the output power of adjacent-channel tones (47).

In fact the ACPR, CCPR, and IMR distortion measurements are simple extensions of the two-tone intermodulation measurement (48). However, it is important to first generate a very clean multitone signal. This can be easily achieved using the technique described in Ref. (49).

Dynamic Techniques

Sine-Square Test. This test employs a square wave as a type of signal characterized by rapid change of state (50). In fact, this is a two-tone test where the signal consists of a 3.18 kHz square wave, which has been filtered with a simple one-pole, low-pass RC filter, at either 30 kHz or 100 kHz, and combined with a 15 kHz sine wave. The peak-to-peak amplitude ratio of the sine wave to the square wave is 1 : 4. The resulting square-wave signal component has a very high slope, which is in theory limited only by the low-pass filter. This test has the capability of stressing the amplifier to a high degree of nonlinearities related to signal slope and/or slew rate.

The output spectrum of the system under test is analyzed for the intermodulation products generated by nonlinear mixing of the sine and square waves. The rms sum of the intermodulation products relative to the amplitude of the 15 kHz sine wave is defined as the percentage distortion.

Because the test signal's rate of change depends heavily on out-of-band (>20 kHz) harmonics of the square wave, this test can give somewhat optimistic results for audio systems incorporating front-end low-pass filters (51). Moreover, each component in the output spectrum has two contributory parts: (1) the dynamic intermodulation component caused by the rise-time portion of the square wave driving the amplifier to frequency-dependent nonlinearity—that is, TIM—and (2) the static intermodulation component caused by the amplitude-dependent nonlinearity of the amplifier.

In order to separate the static intermodulation component, the sine-triangle test was proposed (50). The sine-triangle test is similar to the sine-square test with the square wave replaced by a triangular wave of equal peak-to-peak amplitude. This reduces drastically the rise time, leaving only the intermodulation components caused by the static nonlinearities. However, neither the sine-square nor the sine-triangle test uniquely separates the static and dynamic nonlinearities.

The high-pass-square-wave/sine (HP-SQ/S) test is a distinct modification of the sine-square and sine-triangle tests (52). The HP-SQ/S test is based on the sine-square test with the test signal further shaped by a single-pole RC high-pass filter

Figure 5. The input signal of a sawtooth wave test is derived from inverting the phase of a 30 kHz sawtooth waveform with a 30 kHz/256 period. $T_1 = 1/30$ kHz, $T_2 = 256T_1$.

with a 3 dB rolloff frequency of 5 kHz. Thus sine-square test signal generators can be applied, requiring only an additional *RC* high-pass filter. The HP-SQ/S test signal better resembles real-life signals and acquires both static and dynamic nonlinear distortions simultaneously. As in the sine-square test, the distortion factor is defined as the ratio of the rms sum of the amplitudes of the intermodulation products to the amplitude of the sinusoid.

Sawtooth-Wave Test. In this method a sawtooth wave is used as the signal that changes its state rapidly (53). The signal is derived from inverting the phase of a 30 kHz sawtooth waveform with a 30 kHz/256 period as shown in Fig. 5. The signal therefore consists of two alternating series of signals: one series of instantaneously rising, the other of instantaneously falling signals.

Without reversal, application of the high-frequency asymmetrical sawtooth signal to a system under test causes the system's symmetrical and asymmetrical nonlinearities to generate a dc offset whose magnitude depends on the severity of the nonlinearity. The periodic polarity reversal merely "chops" this dc offset into an easily measured low-frequency ac signal. Thus, if the system under test is prone to TIM, then at the output of the low-pass filter a signal appears whose shape is rectangular. Each time the input signal reverses polarity, a rectangular output waveform appears that is due to the shift in average voltage or dc level. This output signal represents the amount of TIM in the system under test. TIM is calculated as

$$\text{TIM} = \left(\frac{\text{amplitude (peak-to-peak) of sawtooth}}{\text{amplitude (peak-to-peak) of square wave}} \right) 100\% \quad (25)$$

Because this test depends so heavily on extreme signal slope (and hence on out-of-band sawtooth harmonics), it may easily be misled in its assessment of TIM by systems incorporating input low-pass filters (51).

Multitone Intermodulation (MIM) Test. The MIM test is a variation of the CCIF intermodulation test in which two high-frequency tones spaced apart by a small frequency difference are applied to the system under test (51). In order to retain the advantages of the CCIF test while incorporating sensitivity to symmetrical distortion mechanisms, a third tone, at frequency ω_3 , is added. The three frequencies are chosen so that the resulting triple-beat product at $\omega_3 - \omega_2 - \omega_1$ is slightly below 1 kHz, while two of the tones produce a CCIF-like difference-frequency product $\omega_2 - \omega_1$ at slightly above 1 kHz. Specifically, the three equal-amplitude tones are at frequencies 20 kHz, 10.05 kHz, and 9 kHz, resulting in a triple-beat product at 950 Hz and a difference-frequency product at 1050 Hz.

The difference-frequency and triple-beat products are selected to lie so close to each other that both products can be passed through a narrow band-pass filter centered about 1 kHz. The distortion percentage is defined as the value of the 950 Hz and 1050 Hz distortion products, measured together on an rms-calibrated average-responding ac voltmeter, referred to the rms value of the sine wave of the same peak-to-peak amplitude as the three-tone MIM test signal.

The MIM test enjoys the following attractive features:

1. Inexpensive instrumentation; no spectrum analyzers are required.
2. Simple measurement procedure.
3. Fully in-band stimulus and response.

The MIM test is not as stringent as the sine-square and sawtooth wave tests in terms of peak rate of change, and as a result it yields smaller TIM distortion percentages. However, because it does not resort to unrealistically high rates of change to stress the audio system under test, good subjective correlation can be expected.

INTERMODULATION MEASUREMENT

Measurement Equipment

Multitone Tests. A block diagram of the system used for multitone intermodulation measurement is shown in Fig. 6. The multiple frequency source can be implemented from two or three synthesized sine/square/triangular wave generators. Amplifier/attenuator pairs can be added at the output of each generator. Bandpass filters can also be added to suppress the harmonic contents at the output of each generator. For RF

Figure 6. Block diagram of the two-tone test setup. Multitone tests require additional signal generators, combiners, amplifiers and bandpass filters. SG, signal generator; A, amplifier; BPF, bandpass filter; C, combiner; DUT, device under test; SA, spectrum analyzer.

Figure 7. Different types of resistive combiners used in audio-frequency tests. SG, signal generator; OA, operational amplifier.

measurements, harmonic suppression and isolation between different generators is achieved by using amplifier/circulator combinations and cavity resonators (49). The synthesized sources are combined using hybrids or combiners of adequate isolation. Spectral purity at this point is crucial to the accuracy of the measurement. The multitone output is fed to the device under test (DUT). The output of the DUT is fed to the spectrum analyzer. For audio-frequency measurements, the intermodulation components of interest can be filtered out, using band-pass filters, and fed to ac voltmeters. Alternatively, for RF measurements, the output of the DUT can be fed to directional couplers. The outputs of the directional couplers are fed to a television oscilloscope and/or a spectrum analyzer.

For audio-frequency measurements, resistive combiners are widely used for combining the outputs of two, or more, signal generators. Figure 7 shows a number of the widely used resistive combining networks.

Measurement Using a Microcomputer. Intermodulation can also be measured using a microcomputer (50). The block diagram of this technique is shown in Fig. 8. This technique is based on measuring the single tone input-output characteristic of the DUT using a vector voltmeter. The output of the vector voltmeter is fed to a microcomputer, which converts it into three digital data lines representing the input amplitude, the output amplitude, and the phase lag between the input and output signals. After storing the data, the microcomputer increments the amplitude of the input signal. After storing all the necessary data, the microcomputer, using a stochastic method, calculates the amplitudes of the intermodulation components of the DUT. Although the procedure reported in Ref. 55 uses a stochastic method for calculating the amplitudes of the intermodulation components resulting from a two-tone input signal, the same procedure can be applied to any number of input tones, using different analytical techniques for modeling the nonlinear characteristics of the DUT.

Alternatively, microcomputers can be added to the measurement setup of Fig. 6 to:

1. Control the frequencies of the signal sources, especially in the millimeter-wavelength range, where the difference in

frequencies between the signal sources may be less than 0.001 times the base signal frequency (56).

2. Scan the base signal frequency over the measurement range of interest in predefined steps (57).
3. Correct the power from each source so that power delivery to the DUT will be the same across the whole frequency range scanned.
4. Read and calculate the parameters of interest during the measurements (58,59).

Noise-Power Ratio Test. Figure 9 shows a block diagram of a noise-power ratio test setup (38). The setup consists of a white-noise generator which applies an accurate level of white Gaussian noise power with known bandwidth (equal to $\Delta\omega$ and centered around ω_0) to the DUT. The output of the DUT is measured with the bandreject filter out. When the bandreject filter, with bandwidth $\delta\omega$ and centered around ω_0 , is switched in, a narrow band of frequencies is attenuated by about 70 dB, and

Figure 8. Block diagram of a microcomputer-based intermodulation measurement setup. SG, signal generator; DC, directional coupler; DUT, device under test; VV, vector voltmeter; MC, microcomputer.

Figure 9. Block diagram of the noise-power ratio test setup. WNG, white-noise generator; BPF1, band-pass filter with bandwidth $\Delta\omega$ centered around ω_0 ; BRF, bandreject filter with bandwidth $\delta\omega$ centered around ω_0 ; DUT, device under test; BPF2, band-pass filter with bandwidth $\delta\omega$ centered around ω_0 ; PM, power meter.

a quiet channel, of width $\delta\omega$ and centered around ω_0 , is formed as shown in Fig. 3. At the output of the DUT, the noise power is measured in the quiet channel, using a band-pass filter with bandwidth $\delta\omega$ and centered around ω_0 . This noise power is due to the thermal noise and the intermodulation introduced by the device under test. The NPR is the ratio of the noise power measured without the bandreject filter inserted before the DUT to that measured with the bandreject filter inserted. The white-noise generator corrects the loading power level for the insertion loss of the bandreject filter.

Externally Induced Intermodulation Test. This is a two-tone test with one signal applied to the input and the other signal applied to the output (9). A test setup is shown in Fig. 10. Two directional couplers are used to gauge both the forward-carrier power and the intermodulation product levels. Two more directional couplers are added to inject the interfering signal and to measure the actual injected value using the spectrum analyzer.

Measurement Accuracy

Multitone Tests. For accurate measurements of the intermodulation products, using multitone tests, it is essential to reduce or remove the nonlinear distortion originating in the signal sources and/or the measurement equipment. Measurement accuracy may therefore be affected by the purity of the signal sources, the linearity of the combiners, and the performance of the spectrum analyzer.

Signal Sources. Measurement of the amplitudes of the intermodulation components requires the use of two or more signals. The frequencies of these signals must be noncommensurate. Otherwise, harmonics in one source might beat with the fundamental(s) of other signal(s) and interfere with the desired intermodulation components.

Ideally the signal generators would produce perfect sinusoids, but in reality all signals have imperfections. Of particular interest here is the spectral purity, which is a measure of the inherent frequency stability of the signal. Perhaps the most common method to quantify the spectral purity of a signal generator is its phase noise (60). In the time domain, the phase noise manifests itself as a jitter in the zero crossings of a sine wave. In the frequency domain, the phase noise appears as sidebands surrounding the original frequency. Thus, mixing with other frequencies due to the nonlinearities of the DUT would result in additional intermodulation products. It is therefore important to consider the intermodulation due to phase noise when calculating the intermodulation performance of the DUT (61).

Signal generators with automatic level control (ALC) may produce signals with unwanted modulation. The ALC is implemented by rectifying the output signal of the generator and feeding back the resulting dc voltage to drive an amplitude modulator. If a second signal is applied to the output of the signal generator, the detector will produce a signal at the difference in frequency between the two frequencies. This signal will modulate the generator's output. The frequency of the modulation

Figure 10. Measurement of externally induced intermodulation can be performed by using two tones: one injected at the input and one injected at the output of the DUT. SG, signal generator; DC, directional coupler; PM, power meter; SA, spectrum analyzer; BPF, band-pass filter; A, amplifier.

sidebands will share the same spectral lines as the intermodulation products of interest. Isolating the signal generators and the combiners can minimize this effect. This can be achieved by ensuring that there is as much attenuation as possible between them.

Combiners. Measurement of intermodulation products is performed by applying to the input of the circuit, or the system, under test a signal consisting of two or more different frequencies. The outputs of the signal generators are therefore combined by a combiner. The combiner must provide sufficient isolation between the signal sources to reduce the possibility of producing intermodulation products before the combined input signal is applied to the circuit or the system under test. While resistive combiners are adequate for input signal levels up to a few millivolts, for larger voltage levels the use of power combiners may be necessary (62). Insertion of an attenuator in each arm of the combiner helps in minimizing the distortion components resulting from the interaction between the two signal sources. Such components, if generated, should be at least 80 dB below the fundamental components.

A simple test to determine whether adequate isolation has been achieved can be effected by introducing a variable attenuator between the signal source combiner and the DUT in Fig. 6. This is set to a low value during measurements, but at setup, when IMPs have been located on the spectrum analyzer, increasing the attenuation by 3 dB will result in a reduction in the observed IMP level. If this reduction is only 3 dB, then it has to be assumed that the IMP observed has originated in the signal sources, not in the DUT. If, however, the reduction is 6 dB for a second-order IMP or 9 dB for a third-order [see Eq. (4)], then it is safe to assume that the IMP has originated in the DUT or the spectrum analyzer.

Alternatively, a technique which attenuates the parasitic intermodulation products arising from the interaction between the generators of the fundamental components, before the input of the spectrum analyzer, was described in Ref. 63.

A block diagram of the technique is shown in Fig. 11. The input to the system under test is formed by combining the outputs of two signal generators at frequencies ω_1 and ω_2 in the combiner. The hybrid splitter-combiner (HSC1) splits the combined signal into two branches with voltage-transfer ratio $a = \alpha$ and $b = \sqrt{1 - \alpha^2}$ at the first and second outputs. Using Eq. (1) and assuming that the system under test and the compensator have identical nonlinear characteristics, the inputs of the second hybrid splitter-combiner (HSC2) can be expressed as

$$V_a = \sum_{n=0}^N k_n (\alpha V_i)^n \quad (26)$$

and

$$V_b = \sum_{n=0}^N k_n (\sqrt{1 - \alpha^2} V_i^n) \quad (27)$$

Using Eqs. (26) and (27), the output of HSC2, with voltage transfer ratio opposite in sign and equal to the reciprocal of that of HSC1, can be expressed as

$$V_{out} = \sum_{n=0}^K -k_n [\sqrt{1 - \alpha^2} (\alpha V_i)^n - \alpha (\sqrt{1 - \alpha^2} V_i^n)] \quad (28)$$

According to Eq. (28), broadband compensation occurs for the linear components of the combined signal, with $n = 1$. Thus, all the linearly transformed spectral components are eliminated. This is also true for the intermodulation components which may result from the nonlinear interaction between the two signal generators. The output of HSC2 can therefore be applied directly to the spectrum analyzer.

This technique does not require complicated high-order selective filters and can attenuate the parasitic intermodulation components and the fundamental frequency components by about 50 dB over a wide range of frequencies differing by 7 to 10 octaves. However, it requires a compensator with a nonlinear characteristic similar to that of the system under test.

Spectrum Analyzers. Spectrum analyzers are widely used in measuring the intermodulation performance of electronic circuits and systems. Internal circuits of the spectrum analyzers are themselves imperfect and will also produce distortion products (22). The distortion performance of the analyzers is usually specified by the manufacturers, either directly or lumped into a dynamic-range specification. The performance of the analyzer can be stretched, however, if the nature of these distortion products is understood.

Amplitudes of the distortion products, resulting from the internal circuits of the analyzer, can be reduced by reducing the signal levels at the analyzer's input. Thus, using internal and/or external attenuators can reduce the input signal levels to the analyzer and hence reduce its distortion products and improve the intermodulation measurement range of the spectrum analyzer. However, reduced input levels to the analyzer mean reduced signal-to-noise ratio, and the distortion component to be measured may be buried in the noise. White noise can be reduced by reducing the resolution bandwidth of the analyzer, this may lead to a lower sweep rate. Thus, achieving an optimum dynamic range involves tradeoffs between input signal levels and analyzer distortion. Usually, data sheets of analyzers will contain information about the noise level in each

Figure 11. A technique for attenuating the intermodulation products arising due to the interaction between the signal generators of the fundamental components. SG, signal generator; C, combiner; HSC, hybrid splitter-combiner; DUT, device under test; CO, compensator; SA, spectrum analyzer.

resolution bandwidth and about distortion products generated by the analyzer for each input level. Using this information, the dynamic range of the analyzer for various input levels can be determined (64).

Whenever good selectivity, as well as sensitivity and dynamic range, is of prime importance, test receivers may be used in preference to spectrum analyzers (6).

Alternatively, if the frequencies of the intermodulation components of interest are sufficiently lower (or higher) than the fundamental frequencies, then low-pass (or high-pass) filters can be used to remove the fundamental components which would give rise to other nonlinear distortion components in the spectrum analyzer. Attenuation factors of 80 dB or more, at frequencies outside the band of interest, are recommended. The insertion loss of the low-pass (or the high-pass) filter should be as small as possible; 0.4 dB or less is recommended.

If the frequency of the intermodulation component of interest is not sufficiently higher (or lower) than the fundamental frequencies, then it will be necessary to have complicated multiple-section high-order filters with amplitude-frequency characteristics that are nearly rectangular. Such filters will change, to some extent, the amplitude of the intermodulation components, and this will complicate the calculation of the intermodulation performance of the system under test. A method for compensating for a large fundamental component, thus allowing the measurement of small intermodulation components in its presence, was described in Ref. 65.

A block diagram of the compensation method is shown in Fig. 12. The input to the system under test is formed from one large-amplitude signal at frequency ω_1 and one small-amplitude signal at frequency ω_2 with $\omega_1 \ll \omega_2$. The output of the system under test contains fundamental components at frequencies ω_1 and ω_2 , and intermodulation components at frequencies $\omega_2 \pm n\omega_1$, $n = 1, 2, \dots, N$. In order to measure the small-amplitude intermodulation components, it is necessary to avoid applying to the analyzer the fundamental component at frequency ω_2 . This can be achieved as follows. The output of the system under test is fed to the bandreject filter BRF2 to suppress the fundamental component at ω_1 . The output of the signal generator of frequency ω_2 is fed to the bandreject filter BRF1 to suppress the possible entry through the combiner of any component at frequency ω_1

before reaching the phase shifter. The phase shifter compensates, at the frequency ω_2 , the phase shift through the system under test.

Ideally, the voltages, of frequency ω_2 , at the inputs of the differential amplifier are in phase with the voltage at the non-inverting input, equal to half the voltage at the inverting input. Thus, the output of the differential amplifier at frequency ω_2 is ideally zero. Practically the output voltage at ω_2 will be attenuated by 50 dB to 60 dB (6). The output of the differential amplifier, with the suppressed fundamental component at frequency ω_2 , can be applied to the spectrum analyzer.

This compensation technique, which entails additional filters and matching units, can be used only for broadband measurements with $\omega_1 \ll \omega_2$.

While spectrum analyzers using digital IF sections may not suffer from the internally generated distortion discussed in the preceding, they may suffer from the relatively low-level distortion products resulting from the analog-to-digital conversion. The amplitudes of these products are usually less sensitive to the amplitude of the signal components.

Noise-Power Ratio Test. The accuracy of the noise-power ratio (NPR) test is affected mainly by two factors: (1) the noise floor of the amplifier, which will dominate under very low loading, and (2) the distortion products, produced under very high loading. It is therefore recommended to sweep the loading between two prespecified start and stop levels. The NPR is measured at different levels, and the largest measured value of NPR is considered as the worst case.

Microcomputer-Based Tests. Quantization errors associated with the analog-to-digital conversion of the data in microcomputer-based intermodulation tests must be taken into account. Measurement errors due to quantization are affected by the length of the binary digits and determine the dynamic range of operation (53).

MEASUREMENT OF FREQUENCY, PHASE NOISE AND AMPLITUDE NOISE

Frequency metrology has the highest resolution of all the measurement sciences. Simple systems readily achieve a fractional frequency resolution of 1 ppm (part per million) and some elaborate systems achieve 1 part in 10^{17} or less. Because of the readily achieved resolution, the growing trend is to convert the measurement of many different parameters to the measurement of frequency or frequency difference.

In the following we describe the basic ideas and definitions associated with various aspects of the specification and measurement of frequency, phase (or time), and the two components of spectral purity—phase modulation (PM) noise and amplitude modulation (AM) noise. The three topics are fundamentally linked, since as we will see below, frequency is proportional to the rate of change of phase with time, and the degree to which we can specify or measure signal phase, amplitude, or frequency is limited by the spectral purity of the signals.

BASIC CONCEPTS AND DEFINITIONS

Figure 1 shows the output voltage signal of an ideal sinusoid oscillator as a function of time. The maximum value V_0 is the nominal amplitude of the signal. The time required for the signal to repeat itself is the period T of the signal. The nominal frequency ν_0 of the signal is the reciprocal of the period, $1/T$. This voltage signal can be represented mathematically by a sine function,

$$v(t) = V_0 \sin \theta = V_0 \sin(2\pi \nu_0 t) \quad (1)$$

Figure 1. Output voltage of an ideal sinusoidal oscillator.

where the argument $\theta = 2\pi \nu_0 t$ of the sine function is the nominal phase of the signal. The time derivative of the phase θ is $2\pi \nu_0$ and is called the nominal angular frequency ω_0 . In the frequency domain, this ideal signal is represented by a δ function located at the frequency of oscillation.

In real situations, the output signal from an oscillator has noise. Such a noisy signal is illustrated in Fig. 2. In this example we have depicted a case in which the noise power is much less than the signal power. Fluctuations in the peak values of the voltage result in AM noise. Fluctuations in the zero crossings result in PM noise. Fractional frequency modulation (FM) noise refers to fluctuations in the period of the signal. Since the period (and thus the frequency) of the signal is related to the phase of the signal, FM noise and PM noise are directly related.

Figure 3 shows the power spectrum of a noisy signal (power as a function of frequency) as measured by a spectrum analyzer. Although the maximum power occurs at the frequency of oscillation, other peaks are observed at frequencies of $2\nu_0$, $3\nu_0$, $\dots$, $n\nu_0$. These frequencies are called *harmonics* of the fundamental frequency ν_0 ; $2\nu_0$ is the second harmonic, $3\nu_0$ is the third harmonic, and so on. The power at these harmonic frequencies will depend on the design of the source. The spectrum around the fundamental frequency displays power sidebands at frequencies above the carrier (upper sideband) and at frequencies below the carrier (lower sideband). These power sidebands are the result of PM and AM noise in the signal. While the power spectrum gives an idea of the total noise of a signal, it does not give information about the relative magnitude of the PM and AM noise. Furthermore, at frequencies close to ν_0 , it is difficult to separate noise power from the power of the fundamental frequency. Therefore, special measurement techniques are needed to measure PM and AM noise in oscillators.

Figure 2. Output voltage of a noisy sinusoidal oscillator.

Figure 3. Power spectrum of a noisy signal.

Characterization of Frequency Stability and Amplitude Stability of a Signal

A noisy signal can be mathematically represented by

$$v(t) = [V_0 + \epsilon(t)] \sin[2\pi\nu_0 t + \phi(t)] \quad (2)$$

where $\epsilon(t)$ represents amplitude fluctuations (amplitude deviation from the nominal amplitude V_0) and $\phi(t)$ represents phase fluctuations (phase deviation from the nominal phase $2\pi\nu_0 t$) (1). The instantaneous frequency of this signal is defined as

$$\nu(t) = \frac{1}{2\pi} \frac{d}{dt}(\text{phase}) = \nu_0 + \frac{1}{2\pi} \frac{d}{dt} \phi(t) \quad (3)$$

Frequency fluctuations refer to the deviation of the instantaneous frequency from the nominal frequency: $\nu(t) - \nu_0$. Fractional frequency fluctuations, denoted as $y(t)$, refer to frequency fluctuations normalized to ν_0 , that is,

$$y(t) = \frac{\nu(t) - \nu_0}{\nu_0} = \frac{1}{2\pi\nu_0} \frac{d}{dt} \phi(t) \quad (4)$$

Equation (4) indicates that there is a direct relation between phase fluctuations and fractional frequency fluctuations. Therefore if the PM noise of a signal is measured, the FM noise can be easily obtained and vice versa. The time deviation or fluctuation $x(t)$ of a signal is equal to the integral of $y(t)$ from 0 to t . This relation can be expressed as

$$y(t) = \frac{d}{dt} x(t) \quad (5)$$

Units of Measure for PM Noise, FM Noise, and AM Noise

Phase fluctuations in the frequency domain are characterized by the spectral density of the phase fluctuations $S_\phi(f)$, given by

$$S_\phi(f) = \text{PSD}[\phi(t)] = [\phi(f)]^2 \frac{1}{\text{BW}} \quad (6)$$

where PSD refers to power spectral density, $[\phi(f)]^2$ is the mean-squared phase deviation at an offset frequency f from the frequency ν_0 (called the carrier in this context), and BW is the bandwidth of the measurement system (1–4). The offset frequency f is also called Fourier frequency. The units for $S_\phi(f)$ are rad^2/Hz . Equation (6) is defined for $0 < f < \infty$; nevertheless it includes fluctuations from the upper and lower sidebands and thus is a double sideband unit of measure.

The PM noise unit of measure recommended by the IEEE (1,2,4) is $\ell(f)$, defined as

$$\mathcal{L}(f) = \frac{S_\phi(f)}{2} \quad (7)$$

At Fourier frequencies far from the carrier frequency, where the integrated PM noise from ∞ to f (the Fourier frequency) is less than 0.1 rad^2 , $\ell(f)$ can be viewed as the ratio of phase noise power in a single sideband to power in the carrier (single-sideband phase noise). When $\ell(f)$ is expressed in the form $10 \log[\ell(f)]$ its units are dB below the carrier in a 1 Hz bandwidth ($d\beta c/\text{Hz}$).

Frequency fluctuations in the frequency domain are characterized by the spectral density of the fractional frequency fluctuations $S_y(f)$, given by

$$S_y(f) = \text{PSD}[y(t)] = [y(f)]^2 \frac{1}{\text{BW}} \quad (8)$$

where $y(f)^2$ represents the mean-squared fractional frequency deviation at an offset (Fourier) frequency f from the carrier. $S_y(f)$ is defined for Fourier frequencies $0 < f < \infty$, and its units are $1/\text{Hz}$.

The conversion between $S_y(f)$ and $S_\phi(f)$ can be obtained from Eq. (4). Applying the Fourier transform to both sides of Eq. (4), squaring, and dividing by the measurement bandwidth result in

$$S_y(f) = \left(\frac{1}{2\pi\nu_0} \right)^2 (2\pi f)^2 S_\phi(f) = \left(\frac{f}{\nu_0} \right)^2 S_\phi(f) \quad (9)$$

Amplitude fluctuations in the frequency domain are characterized by the spectral density of the fractional amplitude fluctuations $S_a(f)$, given by

$$S_a(f) = \text{PSD} \left(\frac{\epsilon(t)}{V_0} \right) = \left(\frac{\epsilon(f)}{V_0} \right)^2 \frac{1}{\text{BW}} \quad (10)$$

where $\epsilon(f)^2$ represents the mean-squared amplitude deviation at an offset frequency f from the carrier (1). $S_a(f)$ is defined for Fourier frequencies $0 < f < \infty$, and its units are $1/\text{Hz}$.

Figure 4(a) and (b) shows the common noise types characteristic of the PM noise and the AM noise of an oscillator (1,2,4–6).

Effects of Frequency Multiplication and Heterodyning on PM, FM, and AM Noise

When the frequency of a signal is multiplied by N , the phase fluctuations are also multiplied by N , as shown in Fig. 5(a). The PM noise of the multiplied signal is given by

$$\begin{aligned} S_{\phi_2}(f) &= \frac{[\phi_2(f)]^2}{\text{BW}} + S_{\phi,M}(f) = \frac{N^2[\phi_1(f)]^2}{\text{BW}} + S_{\phi,M}(f) \\ &= N^2 S_{\phi_1}(f) + S_{\phi,M}(f) \end{aligned} \quad (11)$$

where $S_{\phi,M}(f)$ is the PM noise added by the frequency multiplier. Similarly, when the frequency of a signal is divided by N , the PM noise $S_\phi(f)$ of the divided signal is divided by N^2 . Frequency multiplication and frequency division do not alter the fractional FM noise $S_y(f)$ of a signal since both the frequency

(a)

(b)

(c)

Figure 4. Common types of noise (fluctuations) in oscillators: (a) PM noise; (b) AM noise; (c) $\tau_y(\tau)$ (1,2,4–6).

fluctuations and the nominal frequency are multiplied by N , and the ratio remains constant (7). Ideally, frequency multiplication or division should not have an effect on AM noise either. Nevertheless, the AM noise of the multiplied or divided signal can be affected and determined by the multiplication or division scheme.

Figure 5. (a) Block diagram of a frequency multiplication system. (b) Block diagram of a frequency heterodyne or translation system.

A system that translates or shifts the frequency of an input signal by a fixed frequency is shown in Fig. 5(b). In this system, a mixer is used to multiply the input and reference signals. The output signal after the high-pass filter has a frequency of $v_{in} + v_{ref}$. (Alternately the lower sideband $v_{in} - v_{ref}$ could just as well have been chosen.) The input frequency has been shifted by the frequency of the reference. The PM noise of the output signal of a frequency translation or frequency heterodyne system is given by

$$S_{\phi,o}(f) = S_{\phi,in}(f) + S_{\phi,ref}(f) + S_{\phi,T}(f) \quad (12)$$

where $S_{\phi,in}(f)$ is the PM noise of the input signal, $S_{\phi,ref}(f)$ is the PM noise of the reference, and $S_{\phi,T}(f)$ is the PM noise of the translator (in this case the mixer and the high-pass filter). The AM noise of the output signal will depend on the details of the translation scheme.

Time-Domain Fractional Frequency Stability of a Signal

In the time domain, the fractional frequency stability of a signal is usually characterized by the Allan variance, a type of two-sample frequency variance given by

$$\sigma_y^2(\tau) = \frac{1}{2(N-2)\tau^2} \sum_{i=1}^{N-2} (x_{i+2} - 2x_{i+1} + x_i)^2 \quad (13)$$

$$\sigma_y^2(\tau) = \frac{1}{2(M-1)} \sum_{i=1}^{M-1} (\bar{y}_{i+1} - \bar{y}_i)^2 \quad (14)$$

$$\sigma_y^2(\tau) = \frac{2}{(\pi v_0 \tau)^2} \int_0^\infty S_\phi(f) \sin^4(\pi f \tau) df \quad (15)$$

where N is the number of time deviation samples, x_i is the time deviation over the interval τ , $M = N - 1$ is the number of frequency samples, and $\bar{y}_i$ is the fractional frequency deviation for interval i (1–4). Equation (13) is used when time data are available, Eq. (14) is used when frequency data are available, and Eq. (15) is used to convert frequency domain data (PM noise) to the time domain. The squared root of the Allan variance, $\sigma_y(\tau)$, is generally used to specify the frequency stability of a source. Figure 4(c) shows the slopes of the common noise types characteristic of the $\sigma_y(\tau)$ of oscillators. If the dominant noise type in

short-term is flicker PM or white PM, the modified Allan variance given by Eq. (16), (17), or (18) can be used to improve the estimate of the underlying frequency stability of the sources (1,2,8):

$$\text{mod } \sigma_y^2(\tau) = \frac{1}{2\tau^2 m^2 (N - 3m + 1)} \sum_{j=1}^{N-3m+1} \left(\sum_{i=j}^{m+j-1} (x_{i+2m} - 2x_{i+m} + x_i) \right)^2 \quad (16)$$

$$\text{mod } \sigma_y^2(\tau) = \frac{1}{2(N - 3m + 1)} \sum_{j=1}^{N-3m+1} (\bar{y}'_{j+m} - \bar{y}'_j)^2 \quad (17)$$

$$\text{mod } \sigma_y^2(\tau) = \frac{2}{m^4 (\pi \nu_0 \tau_0)^2} \int_0^\infty S_\phi(f) \frac{\sin^6(\pi \tau f)}{\sin^2(\pi \tau_0 f)} df \quad (18)$$

where

$$\bar{y}'_j = \frac{\bar{x}_{j+m} - \bar{x}_j}{\tau} \quad (19)$$

and

$$\bar{x}_j = \frac{\sum_{k=0}^{m-1} x_{j+k}}{m} \quad (20)$$

Here $\bar{x}_j$ is the phase (time) averaged over n adjacent measurements of duration τ_0 . Thus $\text{mod } \sigma_y(\tau)$ is proportional to the second difference of the phase averaged over a time $m\tau_0$. Viewed from the frequency domain, $\text{mod } \sigma_y(\tau)$ is proportional to the first difference of the frequency averaged over m adjacent samples.

The confidence intervals for $\sigma_y(\tau)$ and $\text{mod } \sigma_y(\tau)$ as a function of noise type and the number of samples averaged are discussed in Refs. 1 and 4.

MEASUREMENT SYSTEMS

Direct Measurements

Direct Measurements of Frequency and Frequency Stability Using a Counter. Figure 6 shows the timing diagram for the direct measurement of signal frequency relative to a reference frequency using a counter. The normal convention is to start with the signal under test and stop with the reference. The user typically chooses the nominal measurement period, which is an integral number of cycles of the reference. For example $\tau = N_{\text{ref}}/\nu_{\text{ref}} \cong 1$ s. The instrument counts N_{sig} , the nominal number of cycles of the signal under test that occur before the reference signal stops the count. The frequency of the signal averaged over a measurement interval τ is given by

$$\nu_{\text{sig}}(\tau) = N_{\text{sig}}(\tau) \frac{\nu_{\text{ref}}}{N_{\text{ref}}} \quad (21)$$

where ν_{ref} is the frequency of the reference. Since the measured signal frequency is proportional to the time base or ref-

Figure 6. Timing diagram for a direct frequency measurement system.

erence frequency, an error in the time-base frequency leads to a proportional error in the determination of the signal frequency.

The intrinsic fractional frequency resolution of a simple counter is $\pm 1/N_{\text{sig}}$. Some sophisticated counters have interpolation algorithms that allow them to improve the intrinsic resolution by a factor of β , which can be 100 or more. If the frequency of the signal under test is less than the frequency of the reference, the resolution can often be improved by reversing the roles of the signal and reference. The counter reading can then be inverted to find the frequency of the signal.

The uncertainty in the frequency from a particular measurement taken over a measurement time τ is the intrinsic resolution plus the combined fractional instability of signal $\sigma_{y,\text{sig}}^2(\tau)$ and the reference $\sigma_{y,\text{ref}}^2(\tau)$. When these factors are independent, they are added in quadrature:

frequency uncertainty

$$= \frac{\Delta \nu(\tau)}{\nu} = \left[\left(\frac{1}{\beta N_{\text{sig}}} \right)^2 + \sigma_{y,\text{ref}}^2(\tau) + \sigma_{y,\text{sig}}^2(\tau) \right]^{1/2} \quad (22)$$

The time-domain fractional frequency stability of the signal $\sigma_{y,\text{sig}}^2(\tau)$ relative to the frequency stability of the reference can be estimated from a series of consecutive frequency measurements using Eq. (14) (1,2). There is often dead time between frequency measurements in the direct method, which leads to biases in the estimation of fractional frequency stability; these biases depend on noise type (9). More elaborate techniques that eliminate this bias and offer better intrinsic frequency resolution are described in later sections on heterodyne measurements.

Direct Measurements of Phase or Time Using a Counter. For sinusoidal signals, phase or time is usually referenced to the positive-going zero crossing of the signal. For digital signals, time is usually referenced to the mean of the 0 and the 1 states at the positive-going transition. Although the counter can be started with the signal or the reference, we usually start with the signal. Then advancing phase (time) corresponds to a

signal frequency that is higher than the reference. The instrument counts N_{ref} , the nominal number of cycles of the counter time base frequency ν_{ref} that occur before the reference signal stops the count. The phase of the signal relative to the reference is

$$\theta_{\text{sig}} = 2\pi N_{\text{ref}} \frac{\nu_{\text{sig}}}{\nu_{\text{ref}}} \quad (23)$$

where ν_{sig} is the frequency of the signal. The time of the signal relative to the reference is

$$t_{\text{sig}} = \frac{N_{\text{ref}}}{\nu_{\text{ref}}} \quad (24)$$

Since the measured phase (time) is proportional $1/(\nu_{\text{ref}})$, an error in the time base (reference) frequency leads to an error in the determination of the signal phase. There may also be phase errors or time errors in the measurement due to the voltage standing wave ratio (VSWR) on the transmission lines to the counter from the signal and the reference (10).

For a simple counter the intrinsic phase resolution is $2\pi \nu_{\text{sig}}/\nu_{\text{ref}}$, while the time resolution is $1/\nu_{\text{ref}}$. Some sophisticated counters have interpolation algorithms that allow them to improve the intrinsic resolution by a factor of β , which can be 100 or more.

The uncertainty in the measurement of phase $\Delta\phi$ or time ΔT using this approach is given by the intrinsic resolution plus the combined fractional instability of signal $\sigma_{y_{\text{sig}}}^2(\tau)$ and the reference $\sigma_{y_{\text{ref}}}^2(\tau)$. When these factors are independent, they are added in quadrature:

$$\Delta\phi = \theta_{\text{sig}} \left[\left(\frac{1}{N_{\text{ref}}\beta} \right)^2 + \sigma_{y_{\text{ref}}}^2(\tau) + \sigma_{y_{\text{sig}}}^2(\tau) \right]^{1/2} \quad (25)$$

$$\Delta T = t_{\text{sig}} \left[\left(\frac{1}{N_{\text{ref}}\beta} \right)^2 + \sigma_{y_{\text{ref}}}^2(\tau) + \sigma_{y_{\text{sig}}}^2(\tau) \right]^{1/2} \quad (26)$$

The time-domain fractional frequency stability of the signal $\sigma_{y_{\text{sig}}}^2(\tau)$ relative to the frequency stability of the reference can be estimated from a series of consecutive phase measurements separated by a time τ , using Eq. (13) (1,2). More elaborate techniques that offer better resolution are described in later sections on heterodyne measurements.

Heterodyne Measurements

Heterodyne techniques offer greatly improved short-term resolution over direct measurement techniques of frequency, phase, and time (see Fig. 7). In this technique the signal under test is heterodyned against the reference signal ν_{ref} and the difference frequency or beat frequency (lower curve) ν_b measured. The frequency resolution is improved by a factor ν_{ref}/ν_b over direct measurements.

Heterodyne Measurements of Frequency. Using the heterodyne method, the frequency of the signal source is

$$\nu_{\text{sig}} = \nu_{\text{ref}} \pm \nu_b \quad (27)$$

Additional measurements are required to determine the sign of the frequency difference. The usual method is to change the

Figure 7. Timing diagram of a heterodyne time measurement system.

frequency of the reference by a known amount and determine whether the beat becomes smaller or larger. The resolution for frequency measurements is given by

$$\frac{\Delta\nu}{\nu_{\text{ref}}} = \Delta t \frac{\nu_b^2}{\nu_{\text{ref}}} \quad (28)$$

where Δt is the timing resolution. The uncertainty is limited by the frequency stability of the reference and the phase variations of the phase detector. The minimum time between data samples is $1/\nu_b$ for clocks that are nearly at the same frequency (a limitation in many situations).

Fifty percent of the time this approach is insensitive to the phase fluctuation between the signal and the reference. This down time, called “dead time” (5,9), biases the calculation of $\sigma_y(\tau)$ and $\text{mod } \sigma_y(\tau)$ by an amount that depends on the noise type and the duration of the dead time. Bias tables as a function of noise type and percent dead time are given in Ref. 9. The dead-time limitation can be circumvented by using two counters triggered on alternate cycles of ν_b .

Heterodyne Measurements of Phase (Time). The resolution for heterodyne measurements of time or phase is increased to

$$\Delta\tau = \frac{\nu_b}{\nu_{\text{ref}}} \Delta t \quad (29)$$

where Δt is the timing resolution of the counter. To avoid ambiguity ν_b should be larger than the frequency fluctuations of both the reference and the source under test. Additional measurements are required to determine if the frequency of the source is higher or lower than the reference. The phase of the beat signal goes through zero when the phase difference between the two signals is $\pm(2n + 1) \times 90^\circ$ where $n = 0, 1, 2, 3, \dots$. The time of the zero crossing is biased or in error by $\Delta\phi$ due

Figure 8. Basic building block for AM and PM noise measurement systems.

to imperfections in the symmetry of the phase detector and/or the VSWR in the reference and signal paths (10). Timing errors due to VSWR effects and typical temperature coefficients for mixer biases are given in Ref. 10 for frequencies of 5 and 100 MHz. These errors generally scale as $1/\nu_{\text{sig}}$.

The time of the source under test is

$$t_{\text{sig}} = T_{\text{ref}} \pm \frac{n}{\nu_{\text{ref}}} \pm \Delta\phi \quad (30)$$

where n is the number of beat cycles that have occurred since the original synchronization. The minimum time between data samples is $1/\nu_b$. For clocks that are at nearly the same frequency, this limitation can be very restrictive.

The time-difference data can be used to characterize the fractional frequency stability of the sources using Eq. (13). The resolution for short-term time domain frequency stability (τ less than 0.1 s) is typically much worse than that obtained from integrating the phase noise using Eq. (15) (8,11)

Basic Configuration of PM and AM Noise Measurement Systems

Figure 8 shows the basic building block used in PM and AM noise measurement systems. It consists of a phase shifter, a mixer, and a low-pass filter. The two input signals to the mixer can be represented as

$$\begin{aligned} v_1(t) &= A_1(t) \cos[2\pi\nu_0 t + \Phi_1(t)] \\ &= [V_1 + \epsilon_1(t)] \cos[2\pi\nu_0 t + \phi_1 + \phi_1(t)] \end{aligned} \quad (31)$$

$$\begin{aligned} v_2(t) &= A_2(t) \cos[2\pi\nu_0 t + \Phi_2(t)] \\ &= [V_2 + \epsilon_2(t)] \cos[2\pi\nu_0 t + \phi_1 + \phi_2(t)] \end{aligned} \quad (32)$$

where $\epsilon_1(t)$ and $\epsilon_2(t)$ represent the amplitude fluctuations of the signals and $\phi_1(t)$ and $\phi_2(t)$ represent the phase fluctuations of the signals. For an ideal mixer, the signal $v_3(t)$ is equal to the product of signals $v_1(t)$ and $v_2(t)$. After some algebraic manipulation, we have

$$\begin{aligned} v_3(t) &= \frac{A_1(t)A_2(t)}{2} \{ \cos[4\pi\nu_0 t + \Phi_1(t) + \Phi_2(t)] \\ &\quad + \cos[\Phi_1(t) - \Phi_2(t)] \} \end{aligned} \quad (33)$$

At the output of the low-pass filter, the signal reduces to

$$v_4(t) = \frac{A_1(t)A_2(t)}{2} \{ \cos[\Delta\phi + \Delta\phi(t)] \} \quad (34)$$

where $\Delta\phi$ is the difference between the phase angles of the two input signals ($\phi_1 - \phi_2$) and $\Delta\phi(t) = \phi_1(t) - \phi_2(t)$. When $\Delta\phi$ is approximately equal to an odd multiple of $\pi/2$ and the

Figure 9. Block diagram for a heterodyne (two-oscillator) PM noise measurement system.

integrated phase noise $[\int \Delta\phi(f)^2 df]$ does not exceed 0.1 rad^2 , the two signals are in quadrature and the output voltage of the mixer is proportional to the difference of the phase fluctuations in the signals $v_1(t)$ and $v_2(t)$. When a double-balanced mixer is used, the amplitude fluctuations are suppressed by 25 to 40 dB (11,12). This is also called suppression of AM to PM conversion in a double-balanced mixer.

When the two input signals to the mixer are in phase or $\Delta\phi \cong 0$, the output voltage of the mixer is proportional to the amplitude fluctuations of the signals. The suppression of phase fluctuations when $\Delta\phi \cong 0$ is higher than 90 dB (11,12). The setup in Fig. 8 can be used in either AM noise or PM noise measurement systems by adjusting the phase shifter.

PM Noise Measurement Systems For Oscillators and Amplifiers

Heterodyne Measurements of PM Noise in Signal Sources (Two-Oscillator Method). Figure 9 shows a heterodyne PM noise measurement system for an oscillator. In this system, the signals from the test oscillator and a reference oscillator of similar frequency are fed into a double-balanced mixer. A phase-locked loop (PLL) is used to lock the reference frequency to the test oscillator frequency and to maintain quadrature between the two input signals to the mixer (13). The output voltage of the mixer is proportional to the difference between the phase fluctuations of the two sources. This voltage is amplified and its PSD is measured with a spectrum analyzer. Often this spectrum analyzer is of the fast Fourier transform (FFT) type. The voltage at the output of the amplifier is

$$v_o(t) = k_d G \Delta\phi(t) \quad (35)$$

where k_d is the mixer's phase-to-voltage conversion factor (or mixer sensitivity), G is the gain of the amplifying stage, and $\Delta\phi(t)$ is the difference between the phase fluctuations of the test oscillator and the reference $[\phi_A(t) - \phi_B(t)]$. The PM noise can be obtained from

$$S_{\phi}(f) = \frac{\text{PSD}[v_o(t)]}{(k_d G)^2} \quad (36)$$

The calibration factor or mixer sensitivity k_d can be found by turning off the PLL to obtain a beat frequency signal at the mixer output. The slope at the zero crossing and the period of

Figure 10. Sensitivity of a low-level double-balanced mixer at 5 MHz as a function of the intermediate frequency (IF) port termination for radio frequency (RF) and local oscillator (LO) inputs of +2 and +10 dBm (11).

this signal can be measured with an oscilloscope or another recording device. The calibration factor k_d in V/rad is

$$k_d = (\text{slope}) \times \frac{T}{2\pi} \quad (37)$$

Ideally this measurement should be made at the output of the amplifier because the measurement then yields $k_d G$, which includes the effect of amplifier input impedance on the performance of the mixer. The calibration of this PM noise measurement system using the beat-frequency method can introduce errors in the measurement if the mixer and the amplifier gains are frequency dependent, as is often the case. Figure 10 shows the variation of k_d with Fourier frequency for different mixer terminations. Capacitive terminations improve the mixer sensitivity, thereby improving the noise floor. However, the frequency response is not nearly as constant as the response obtained with resistive terminations, thus increasing the measurement error (11).

A calibrated Gaussian noise source centered about the carrier frequency can be used to calibrate the frequency-dependent errors (14,15). In this technique Gaussian noise is added to the reference signal by means of a low-noise power summer. Since the Gaussian noise is independent of the reference noise, equal amounts of PM and AM noise are added to the reference signal. When the Gaussian noise is “on,” the PSD of the output noise voltage $v_o(t)$ is equal to

$$\text{PSD}[v_{o,\text{on}}(t)] = (k_d G)^2 S_{\text{PMcal}} \quad (38)$$

where S_{PMcal} is the PM noise added by the Gaussian noise source. The calibration factor as a function of frequency is obtained by dividing $\text{PSD}[v_{o,\text{on}}(t)]$ by S_{PMcal} . A PSD measurement is then made with the Gaussian noise “off.” The calibrated PM

noise is obtained from

$$S_\phi(f) = \frac{\text{PSD}[v_{o,\text{off}}(t)]}{(k_d G)^2} = S_{\text{PMcal}} \frac{\text{PSD}[v_{o,\text{off}}(t)]}{\text{PSD}[v_{o,\text{on}}(t)]} \quad (39)$$

This approach greatly reduces the uncertainty of the measurement because it automatically takes into account the frequency-dependent errors. This approach also reduces the time necessary to make routine PM noise measurements as compared to traditional methods since the measurement is now reduced to a simple ratio measurement between noise on and noise off (14,15). The use of this calibration technique is illustrated in the cross-correlation measurements discussed in the following and shown in Fig. 11.

The confidence intervals for spectrum analyzers (swept and FFT) as a function of the number of measurements can be estimated from Table 1 (4,16–18). Biases in commonly used FFT window functions are discussed in Ref. 4.

Table 1. Approximate Statistical Confidence Interval for FFT and Swept Spectrum Analyzers (16–18). $\beta = N$ (the Number of Averages) for FFT Analyzers and $\beta = N(\text{RBW}/\text{VBW})$ for Swept Spectrum Analyzers. (RBW Refers to the Resolution Bandwidth of the Spectrum Analyzer and VBW refers to the video bandwidth).

Figure 11. Block diagram of a two-channel cross-correlation system for measuring PM noise in an oscillator. Calibration of the system is accomplished using a PM and AM noise standard (14,15).

One of the shortcomings of the single-channel, two-oscillator measurement system is that the measured noise includes noise contribution from the test source as well as that from the reference source. The noise terms included in $S_\phi(f)$ are

$$S_\phi(f) = S_{\phi,A}(f) + S_{\phi,B}(f) + \frac{v_n^2(f)}{k_d^2 BW} + S_{a,A}(f)\beta_A^2 + S_{a,B}(f)\beta_B^2 \quad (40)$$

where $S_{\phi,A}(f)$ is the PM noise of the test source, $S_{\phi,B}(f)$ is the PM noise of the reference, $v_n(f)$ is the noise added by the mixer, the amplifier, and the spectrum analyzer, $S_{a,A}(f)$ and $S_{a,B}(f)$ refer to the AM noise of the test source and the reference, and β_A and β_B are the factors by which the AM noise is suppressed. If the PM noise of the reference is higher than the PM noise of the test source, then the PM noise of the source cannot be measured accurately.

The last three terms of Eq. (40) constitute the noise floor of the measurement system. The noise floor can be estimated by using a single source (test source or reference) to feed the two inputs of the mixer. A phase shifter placed in one of the channels is used to adjust the phase difference to an odd multiple of 90° . The PM noise of the driving source is mostly canceled and the measured noise at the output is

$$S_\phi(f) = \frac{v_n^2(f)}{k_d^2 BW} + 2S_{a,A}(f)\beta_A^2 + \eta(f)S_{\phi,A}(f) \quad (41)$$

where the factor $\eta(f)$ is due to decorrelation of the source noise and is much smaller than 1 for small Fourier frequencies. [See the section on delay line measurements, especially Eq. (52), for a discussion of this effect.] Equation (41) is approximately

equal to the noise-floor components in Eq. (40). Equation (40) indicates that the AM noise of the source and the reference can affect PM noise measurements; thus sources with low AM noise should be used.

Cross-Correlation Heterodyne Measurements of PM Noise in Signal Sources. One of the limitations of the single-channel, two-oscillator method is that the PM noise of the reference contributes to the measured noise. If three different oscillators are available (A, test source; B, reference 1; C, reference 2), PM noise measurements of three different pairs of oscillators can be made and the PM noise of the source can be approximated by

$$S_{\phi,A}(f) \cong \frac{1}{2} [S_{\phi,AB}(f) + S_{\phi,AC}(f) - S_{\phi,BC}(f)] - 2S_{a,A}(f)\beta_A^2 - \frac{v_n^2(f)}{k_d^2 BW} \quad (42)$$

where $S_{\phi,AB}(f)$ includes the PM noise of sources A and B, $S_{\phi,AC}(f)$ includes the PM noise of sources A and C, and $S_{\phi,BC}(f)$ includes the PM noise of sources B and C. One problem with this approach is that small errors in any of the three measurements taken separately can result in large overall errors. Another problem is that the noise of the measurement system still contributes to the noise floor.

A more effective way of eliminating the PM noise from the reference is to use cross-correlation PM noise measurements. Figure 11 shows a two-channel, cross-correlation PM noise measurement system that uses two reference oscillators and two PM noise detectors operating simultaneously. Each individual channel is a simple heterodyne measurement system. Therefore the noise terms in $\text{PSD}[v_{o1}(t)]$ and $\text{PSD}[v_{o2}(t)]$ divided

Figure 12. Block diagram of a single-channel system for measuring PM noise in a pair of amplifiers.

by the respective calibration factors are described by Eq. (40). The PSD of the cross-correlation of the noise voltages $v_{o1}(t)$ and $v_{o2}(t)$ divided by the calibration factor is

$$S_{\phi}(f) = S_{\phi,A}(f) + S_{a,A}(f)\beta_A^2 + \frac{1}{\sqrt{N}} \left(S_{\phi,B}(f) + S_{\phi,C}(f) + \frac{v_n^2(f)}{k_d^2 BW} \right) + S_{a,B}(f)\beta_B^2 + S_{a,C}(f)\beta_C^2 \quad (43)$$

where $S_{\phi,A}(f)$ is the PM noise of the test source, $S_{\phi,B}(f)$ and $S_{\phi,C}(f)$ are the PM noise of the references, and N is the number of averages in the measurement (11,14,15,19,20). The contribution of the PM noise of the references and the noise in the detectors and amplifiers are reduced by $\sqrt{N}$, because they are independent. This results in a reduction of the unwanted PM noise in the references and the measurement system of 10 dB for 100 averages and 20 dB for 10,000 averages. This powerful measurement technique makes it possible to obtain an accurate measurement of the PM noise of a source that has lower noise than the references if the AM noise of the source can be neglected.

Heterodyne Measurements of PM Noise in Amplifiers. Figure 12 shows the block diagram of a PM noise measurement system for a pair of amplifiers. In this system an oscillator signal is split using a reactive power splitter. The outputs of the splitter drive two test amplifiers, and their outputs feed a double-balanced mixer. The mixer output is then amplified and measured by a spectrum analyzer. A phase shifter in one of the channels is used to maintain quadrature. The PM noise of the amplifier pair is obtained dividing the PSD of the noise voltage $v_o(t)$ by the calibration factor $(k_d G)^2$,

$$S_{\phi}(f) = \frac{\text{PSD}[v_o(t)]}{(k_d G)^2} = S_{\phi,\text{amp}}(f) + \frac{v_n^2(f)}{k_d^2 BW} + S_a(f)\beta^2 \quad (44)$$

where $S_{\phi,\text{amp}}(f)$ is the PM noise of the amplifier pair and $S_a(f)$ is the AM noise of the source. This system assumes that the noise of the amplifiers is higher than the noise floor of the measurement system. If this is not the case, cross-correlation measurement systems should be used. The calibration factor can be easily obtained by adding a Gaussian noise source to one of the channels and making measurements with the noise on and

the noise off, as discussed previously. Calibration can also be achieved by using a second source to drive one of the amplifiers to obtain a beat signal at the output of the mixer. An oscilloscope can then be used to measure the zero-crossing slope and the period of the beat signal, and the calibration factor can be computed using Eq. (37).

A similar measurement system can be used to measure the PM noise of a single amplifier if the delay across the amplifier is so small that decorrelation of the source noise is not important to the measurement. See Eq. (52) and associated text for a discussion of decorrelation effects.

Cross-Correlation Heterodyne Measurements of PM Noise in Amplifiers. Figure 13 shows a cross-correlation PM noise measurement system for a pair of amplifiers. It consists of two channels, each a separate heterodyne measurement system. The PSD of the cross-correlation of the noise voltages $v_{o1}(t)$ and $v_{o2}(t)$ divided by the calibration factor is

$$S_{\phi}(f) = \frac{\text{PSD}[v_{o1}(t)v_{o2}(t)]}{(k_d G)^2} = S_{\phi,\text{amp}}(f) + \frac{1}{\sqrt{N}} \frac{v_n^2(f)}{(k_d G)^2 BW} + S_{a,A}(f)\beta_A^2 \quad (45)$$

The noise added by the phase detectors is reduced by $\sqrt{N}$. The calibration factor $k_d G$ can be obtained by adding a calibrated Gaussian noise source about the carrier frequency as shown in Fig. 13. In this setup the noise floor is generally limited by the AM noise of the source. It is therefore important to select a source with low AM noise and to operate the mixer at the maximum point of AM rejection.

Delay-Line Measurements of PM Noise in Signal Sources. A PM noise measurement system that does not need a second source is the delay-line system shown in Fig. 14 (11,21). In this setup the oscillator signal is split, a delay line of time delay τ_d is placed in one channel, and a phase shifter is placed in the other channel. The two channels are fed into a double-balanced mixer. The phase fluctuations of the combined signal at the mixer output are given by

$$\phi_m(f) = [2 - 2 \cos(2\pi f \tau_d)]^{1/2} \phi(f) \quad (46)$$

Figure 13. Block diagram of a two-channel cross-correlation system for measuring PM noise in a pair of amplifiers.

where $\phi(f)$ are the rms phase fluctuations of the source at an offset frequency f (21,22). If the phase shifter is adjusted so that the phase difference between the two input signals is an odd multiple of 90° , then the output voltage of the mixer is proportional to the phase fluctuations of the source. For $2\pi f\tau_d \ll 1$,

$$v_m(f) \cong k_d \left[2 - 2 \left(1 - \frac{(2\pi f\tau_d)^2}{2} \right) \right]^{1/2} \phi(f) = k_d 2\pi f\tau_d \phi(f) \quad (47)$$

where $v_m(f)$ is the output voltage of the mixer at an offset frequency f . Equation (47) can also be expressed in terms of $y(f)$ by multiplying the right side by v_0/f :

$$v_m(f) \cong k_d 2\pi v_0 \tau_d y(f) \quad (48)$$

Equation (48) can be equivalently expressed in the time domain as

$$v_m(t) \cong k_d 2\pi v_0 \tau_d y(t) \quad (49)$$

Equation (49) indicates that the output voltage of the mixer is proportional to the frequency fluctuations in the source, and thus this system measures the FM noise of the test source. The

voltage at the output of the amplifier is given by

$$v_o(t) \cong k_d (2\pi v_0 \tau_d) G y(t) = v_0 k_v G y(t) \quad (50)$$

where k_v is the mixer sensitivity to frequency fluctuations and G is the voltage gain of the amplifier. The FM and PM noise of the source can then be obtained:

$$S_y(f) \cong \frac{\text{PSD}[v_o(t)]}{(2\pi v_0 \tau_d k_d G)^2} = \frac{\text{PSD}[v_o(t)]}{(v_0 k_v G)^2} \quad (51)$$

$$S_\phi(f) \cong \frac{\text{PSD}[v_o(t)]}{(2\pi f \tau_d k_d G)^2} = \left(\frac{1}{f} \right)^2 \frac{\text{PSD}[v_o(t)]}{(k_v G)^2} \quad (52)$$

Equations (51) and (52) are valid only for $f \ll 1/(2\pi\tau_d)$, where the approximation in Eq. (47) is valid. The calibration factor k_v can be found by stepping the source frequency up and down and measuring the corresponding voltage change at the output of the amplifier. The voltage change divided by the frequency change is equal to $k_v G$ in V/Hz. At $f > 1/(2\tau_d)$, the output of the mixer is approximately sinusoidal with maximums occurring at odd multiples of $1/(2\tau_d)$, and minimums occurring at even multiples of $1/(2\tau_d)$. The first minimum occurs at $f = 1/\tau_d$, and thus a measurement of this occurrence can be used to determine τ_d (21). A calibrated Gaussian noise source can be used to calibrate the system at Fourier frequencies

Figure 14. Block diagram of a PM noise measurement system that uses a delay line to measure PM noise in an oscillator.

Figure 15. Block diagram of a PM noise measurement system that uses a high-Q-factor cavity to measure PM noise in an oscillator.

higher than $1/(2\tau_d)$, thus extending the frequency range of this system (14,15).

The close-in noise floor of this measurement system is much larger than that of the two-oscillator system. From Eq. (47), the effective phase sensitivity of the mixer is multiplied by a factor of $2\pi f\tau_d$ and thus is less than the phase sensitivity of the two-oscillator method (21). As discussed previously, the noise floor of the two-oscillator measurement system is given by

$$S_{\phi, \text{floor}}(f) = \frac{1}{k_d^2} \frac{v_n^2(f)}{\text{BW}} + S_{a,A}(f)\beta_A^2 + S_{a,B}(f)\beta_B^2 \quad (53)$$

For $f \ll 1/(2\pi\tau_d)$, the noise contributions of the mixer, the amplifier, and the spectrum analyzer to the noise floor increase by a factor of $(2\pi f\tau_d)^{-2}$. The noise floor for the delay line measurement system is given by

$$S_{\phi, \text{floor}}(f) = \frac{1}{(2\pi f\tau_d)^2 k_d^2} \left(\frac{v_n^2(f)}{\text{BW}} \right) + S_{a,A}(f)\beta^2 \quad (54)$$

The first term usually limits the noise floor of this system. The term in large parentheses usually follows a $1/f$ power law at frequencies close to the carrier; thus the overall noise floor at these frequencies follows a f^{-3} dependence on Fourier frequency. In addition, the noise floor is inversely proportional to τ_d^2 ; therefore longer delays will result in lower noise floors, but also a smaller Fourier frequency span in which Eqs. (51) and (52) are valid. At very long delays, the attenuation of the signal is so large that the noise floor is adversely affected. The noise floor of this measurement system cannot be measured directly since a source is needed and the noise from the source cannot be easily separated from the noise of the measurement system. If the noise contribution of the measurement system (mixer, amplifier, and spectrum analyzer) are known, then the noise floor can be approximated using Eq. (54).

Cavity Discriminator Measurements of PM Noise in Signal Sources. Figure 15 shows a cavity discriminator measurement system (11). This system is similar to the delay-line system, but uses a high-Q cavity in place of the delay line. If the signal frequency and the cavity resonance frequency are close, the cavity causes a phase delay proportional to the signal frequency. In the linear region around v_0 , the fractional frequency fluctuations of the source are converted to phase fluctuations according to

$$\phi(t) \cong 2Qy(t) \quad (55)$$

If the phase shifter is adjusted so that the two input signals to the mixer are in quadrature, then the output voltage of the mixer is proportional to phase fluctuations of the source. After amplification, the output voltage is given by

$$v_o(t) \cong k_d(2Q)Gy(t) = v_0 k_v G y(t) \quad (56)$$

where the mixer sensitivity to frequency fluctuations k_v is equal to $2Qk_d/v_0$. (Figure 15 shows the output voltage of the amplifier as a function of input frequency.) The FM and PM noise of the source are therefore

$$S_y(f) \cong \frac{\text{PSD}[v_o(t)]}{(2Qk_dG)^2} = \frac{\text{PSD}[v_o(t)]}{(v_0 k_v G)^2} \quad (57)$$

$$S_\phi(f) \cong \left(\frac{v_0}{f} \right)^2 \frac{\text{PSD}[v_o(t)]}{(2Qk_dG)^2} = \left(\frac{1}{f} \right)^2 \frac{\text{PSD}[v_o(t)]}{(k_v G)^2} \quad (58)$$

Equations (57) and (58) are valid only for $f \ll v_0/(2Q)$, where the phase-to-frequency relation of the cavity is linear and k_v is a constant. The value of k_v can be found by stepping the frequency of the source up and down and measuring the corresponding voltage change at the output of the amplifier. The voltage change divided by the frequency change is equal to $k_v G$ in volts per hertz. At higher Fourier frequencies k_v changes

according to (11)

$$k_v \propto \frac{1}{1 + \left(\frac{2Qf}{v_0}\right)^2} \quad (59)$$

A calibrated Gaussian noise source can be added to the source to calibrate the system at Fourier frequencies higher than $v_0/(2Q)$, thus extending the range of this measurement system.

As in the delay-line measurement system, the effective phase sensitivity of the mixer is less than the phase sensitivity of the two-oscillator method. The noise floor is thus given by

$$S_{\phi, \text{floor}}(f) = \frac{1}{(2Qf)^2 k_d^2} \frac{v_n^2(f)}{\text{BW}} + S_{a,A}(f) \beta^2 \quad (60)$$

Close to the carrier the noise floor follows a f^{-3} dependence on Fourier frequency and is higher than the noise of the two-oscillator measurement system. In addition, the noise floor is inversely proportional to Q^2 . Therefore, higher Q cavities will result in lower noise floors, but also a smaller Fourier frequency span in which Eqs. (57) and (58) are valid. Other resonant circuits, such as multiple-pole filters, can be used in place of the cavity. The resonant circuit used can add noise to the system and thus limit the resolution or noise floor of the measurement system.

AM Noise Measurement Systems For Oscillators and Amplifiers

Simple AM Noise Measurements For Oscillators. Figure 16 shows a single-channel AM noise measurement system for a source. In this system a source drives an AM detector. The output voltage of the detector is then amplified and fed into a swept or FFT spectrum analyzer. AM detectors commonly used are the mixer detector discussed previously or a diode detector.

The voltage at the output of the mixer is given by

$$v_m(t) \cong k_a \frac{\epsilon(t)}{V_0} \quad (61)$$

where k_a is the detector's sensitivity to fractional amplitude fluctuations. The AM noise of the source is then

$$S_a(f) = \frac{\text{PSD}[v_o(t)]}{(k_a G)^2} \quad (62)$$

where $v_o(t)$ is the voltage into the spectrum analyzer and G is the gain of the amplifier. The sensitivity k_a can be measured by replacing the test source with a source with amplitude modulation capability (12,20). The power of the (calibration) source should be the same as the power of the test source, and it should be adjusted so that the dc voltage at the output of the mixer is

Figure 16. Block diagram of a single-channel AM noise measurement system for measuring AM noise in an oscillator.

the same as when the test source is used. The amplitude modulated input signal is given by

$$v(t) = V_0(1 + \text{AM}_{\text{in}} \cos \Omega t) \cos(2\pi v_0 t) \quad (63)$$

where AM_{in} is the peak fractional amplitude modulation and Ω is the modulation frequency. The magnitude of the amplitude modulation $S_a(f)$ at the input signal is $\frac{1}{2}(\text{AM})^2$, where AM is the modulation selected. The amplitude modulation at the output (AM_{out}) is then measured with the spectrum analyzer and the calibration factor is given by

$$(k_a G)^2 = \frac{2\text{AM}_{\text{out}}}{\text{AM}_{\text{in}}} \quad (64)$$

This measurement assumes that the calibration factor is a constant independent of the Fourier frequency. Many times k_a and G vary with frequency, and thus errors are introduced in the calibration. This is especially important for f higher than 100 kHz. To avoid this problem and speed the measurement of $k_a G$, a Gaussian noise source added to the test source can be used to calibrate the system (12,14,15). To calibrate the system, the PSD of $v_o(t)$ with the Gaussian noise on is measured with the spectrum analyzer. This curve will show any variation of $k_a G$ with Fourier frequency if it exists. The values of $(k_a G)^2$ as a function of Fourier frequency are obtained by dividing the measured $v_o(f)$ by the known calibrated noise power.

The confidence intervals for spectrum analyzer (swept and FFT) measurements, as a function of the number of measurements, can be estimated from Table 1 (4,16–18). Biases in commonly used FFT window functions are discussed in Ref. 4.

One problem of this simple measurement system is that the measured noise, given by Eq. (62), includes the AM noise of the source in addition to noise added by the detector, the amplifier, and the analyzer (noise floor of the system). The noise components included in $S_a(f)$ are

$$S_a(f) = S_{a,\text{src}}(f) + \frac{1}{(k_a)^2} \frac{v_n^2(f)}{\text{BW}} \quad (65)$$

where $S_{a,\text{src}}(f)$ is the AM noise of the source, and the second term represents the noise floor of the system. It is therefore difficult to separate the AM noise of the source from the noise floor.

Cross-Correlation AM Noise Measurements For Oscillators. The noise floor of the AM noise measurement system discussed

Figure 17. Block diagram of a two-channel cross-correlation system for measuring AM noise in an oscillator.

Figure 18. Block diagram of a single-channel system for measuring AM noise in an amplifier.

previously can be considerably reduced by using two-channel cross-correlation techniques as shown in Fig. 17. In this system $\text{PSD}[v_{o1}(t)]$ includes AM noise of the source plus noise in channel 1 (detector 1, amplifier 1). $\text{PSD}[v_{o2}(t)]$ includes AM noise of the source plus noise in channel 2 (detector 2, amplifier 2). The PSD of the cross spectrum divided by the calibration factor mainly includes the AM noise of the source since the noise that is not common between the two channels is reduced proportionally to $1/\sqrt{N}$, so

$$\frac{\text{PSD}[v_{o1}(t)v_{o2}(t)]}{(k_a G)^2} = S_{a,\text{src}}(f) + \frac{1}{\sqrt{N}} \left(\frac{v_{n1}^2(t)}{(k_{a1})^2 \text{BW}} + \frac{v_{n2}^2(t)}{(k_{a2})^2 \text{BW}} \right) \quad (66)$$

This measurement technique is very useful for separating the AM noise of the source from the system noise. This system can be calibrated with a source with AM capability or by using a calibrated Gaussian noise source (12,14).

Simple AM Noise Measurements For Amplifiers. Figure 18 shows a single-channel AM noise measurement system for an amplifier. A source is used to drive the amplifier under test, and the output signal of the amplifier is fed into an AM detector. The signal is amplified, and the output voltage is measured with a spectrum analyzer. The PSD of the noise voltage $v_o(t)$ divided by the calibration factor $(k_a G)^2$ is

$$\frac{\text{PSD}[v_o(t)]}{(k_a G)^2} = S_{a,\text{src}}(f) + S_{a,\text{amp}}(f) + \frac{1}{(k_a)^2} \frac{v_n^2(t)}{\text{BW}} \quad (67)$$

The first term in Eq. (67) represents the AM noise of the source, the second term is the noise of the test amplifier, and the third term is the noise floor of the measurement system. The calibration factor $k_a G$ can be obtained by using a source with AM capability or by using a calibrated Gaussian noise source to calibrate the system (12,14,20). If the AM noise of the source

or the system noise floor is comparable to the amplifier noise, accurate measurements of the amplifier AM noise cannot be made using this system.

Cross-Correlation AM Noise Measurements For Amplifiers.

Figure 19 shows a cross-correlation AM noise measurement system for an amplifier that reduces the noise floor of the measurement system. A reference source drives the test amplifier, the amplifier output is split, and each channel is fed into an AM detector. The output signals of the detectors are then amplified and measured with a two-channel FFT spectrum analyzer. The PSD of the cross-correlation $[v_{o1}(t)xv_{o2}(t)]$ divided by the calibration factor is

$$\frac{\text{PSD}[v_{o1}(t)v_{o2}(t)]}{(k_a G)^2} = S_{a,\text{src}}(f) + S_{a,\text{amp}}(f) + \frac{1}{\sqrt{N}} \left(\frac{v_{n1}^2(t)}{(k_a)^2 \text{BW}} + \frac{v_{n2}^2(t)}{(k_a)^2 \text{BW}} \right) \quad (68)$$

Equation (68) indicates that part of the noise floor in the system is reduced by a factor of $\sqrt{N}$. If the AM noise of the source dominates the measured noise, a limiter can be placed after the source to reduce its AM noise (6).

CARRIER SUPPRESSION MEASUREMENT SYSTEMS

The concept of carrier suppression was first introduced by Sann for measuring noise in amplifiers (23). Carrier suppression measurement systems use a bridge network to cancel the power at the carrier frequency, effectively enhancing the noise of the device under test (23–26). This results in a reduction of the noise floor of the measurement system, or in other words, in an increase of the detector sensitivity.

Carrier Suppression AM Noise Measurement Systems for Amplifiers

Figure 20 shows an AM noise measurement system for amplifiers that uses carrier suppression (25). The source signal is split, and the amplifier under test is placed in one of the channels. The variable attenuator is used to match the magnitudes of the two channels. The phase shifter is used to adjust the phase difference between the two channels to 0. When the two signals are combined in the hybrid, the carrier power is mostly cancelled. The degree of cancellation depends on how well the two channels are matched. An additional amplifier is placed at the output of the power summer to increase the power input to the AM detector. The effective AM noise of the device (as seen

Figure 19. Block diagram of a two-channel cross-correlation system for measuring AM noise in an amplifier.

Figure 20. Carrier suppression AM noise measurement system for amplifiers.

by the AM detector) is increased by the amount of carrier suppression. An AM noise standard is used to calibrate the gain of the system.

Carrier Suppression PM Noise Measurement System for Amplifiers

Figure 21 shows a carrier suppression PM noise measurement system for amplifiers (25,26). A bridge circuit is used to effectively increase the PM noise of the amplifier with respect to the noise floor of the system. A PM noise standard is used to calibrate the gain of the system.

Carrier Suppression PM Noise Measurement Systems for Oscillators

Carrier suppression can also be used in PM measurement systems for oscillators. Figure 22 shows a two-oscillator PM noise measurement system with carrier suppression (25). In this system a bridge is used to raise the magnitude of the PM noise of the two oscillators with respect to the noise in the phase noise detector. A PM noise standard is used to calibrate the gain of the system. Carrier suppression can also be applied to delay line measurement systems (27).

The advantage of carrier suppression measurement systems over cross-correlation systems is that similar noise floors can be achieved at smaller measurement times. The disadvantage is that a very good amplitude and phase match of the bridge channels is required to suppress the carrier power. Furthermore, the match changes with temperature, and thus careful calibrations should be performed before and after a measurement to ensure

Figure 21. Carrier suppression PM noise measurement system for amplifiers.

Figure 22. Two-oscillator PM noise measurement system with carrier suppression.

that the amount of suppression has not changed. The use of a PM/AM noise standard will ease the calibration process. In some specific systems, like AM measurement systems for amplifiers, carrier suppression systems are superior. The reason is that in these systems, the AM noise of an amplifier with lower or comparable noise to the source can be accurately measured. In cross-correlation measurement systems for amplifiers it is difficult to cancel the AM noise of the source, which is often comparable or larger than the noise in the amplifier under test.

POWER AND ENERGY

POWER MEASUREMENT

Power measurement has a wide variety of applications. It is of importance primarily for the testing, monitoring, and maintenance of the energy supply network and of electrical equipment. It is also required in high-frequency and low-power circuits.

A wide variety of instruments and transducers are available for the measurement of power in ac and dc circuits. Analog instruments are available, but the recent trend has been toward digital instruments, because of their better performance and remote communication capabilities.

This article reviews the state and the trends of power measurement. The concept of electric power is first introduced; then common measurement methods and instruments adopted in different situations are discussed.

DEFINITION OF THE MEASURED QUANTITIES

Power can be defined as the time rate of energy transfer or energy dissipation in a load. It is dimensionally expressed as [J/s]. The electric power in a circuit, at any instant, equals the product of the current in the circuit and the voltage across its terminals at that instant. Dimensionally we have

$$[\text{J/s}] = [\text{J/C}][\text{C/s}] = [\text{V}][\text{A}] = [\text{W}] \quad (1)$$

Dc Circuits

In a dc circuit, if the voltage and current are constant, the electrical power P dissipated by a load (L) fed by a power supply (E) is the product of the voltage V_L across the load and the current I_L flowing in it:

$$P = V_L I_L \quad (2)$$

Ac Circuits

In the case of ac-fed circuits, the instantaneous rate of energy flow, or *instantaneous power*, is defined as the product of the instantaneous voltage drop across the load and the instantaneous current flowing through it:

$$p(t) = v(t)i(t) \quad (3)$$

It changes continuously, because of the cyclic variations in current and voltage. For this reason, its mean value over a defined time interval is generally considered.

Sinusoidal Circuits. The simplest case is that of a sinusoidal supply feeding a purely resistive load, where there is no phase difference between voltage $v(t)$ and current $i(t)$. The instantaneous power $p(t)$ is given by

$$p(t) = VI(1 - \cos 2\omega t) \quad (4)$$

in which V and I are the rms values of $v(t)$ and $i(t)$, respectively, and ω is the power supply angular frequency.

The instantaneous power is a unidirectional pulsating energy flow, given by a sum of two terms: a constant value VI ,

representing the average power, which gives the net energy transfer, and an oscillating component with a doubled angular frequency. In circuits fed by periodic ac voltages, it is then relevant to define the *average power* P dissipated in one period T (also called the *real* or *active power*):

$$P = \frac{1}{T} \int_0^T p(t) dt \quad (5)$$

In the case of purely reactive loads the phase difference between the voltage drop across the load and the current flowing through it is of 90° . The instantaneous power $p(t)$ is given by

$$p(t) = VI \cos 2\omega t \quad (6)$$

so there is no active power consumption in a reactive load. This is because energy is stored in the reactive load as electromagnetic or electrostatic energy for a certain time, and then returned to the power supply.

In the case of a sinusoidal supply, the resistive and purely reactive loads can be expressed by a real or a pure imaginary number, respectively. Since the load generally is not a pure element, it can be represented by a complex quantity, the impedance value. In this situation, the waveforms of the voltage $v(t)$, current $i(t)$, and instantaneous power $p(t)$ are shown in Fig. 1. The load impedance can also be represented by an equivalent circuit, such as a pure resistance R_{EQ} and a pure reactance X_{EQ} in series (Fig. 2). In this case the electrical power dissipated in the load Z_L can be expressed as the sum of the two power components dissipated on the resistance and reactance of the equivalent circuit. Because there is no active power dissipation in the reactance X_{EQ} , the average power is as follows:

$$P = V_{REQ} I_L = V_L I_L \cos \phi \quad (7)$$

The factor $\cos \phi$ appearing in Eq. (7) is referred as the *power factor*, because it yields the amount of power consumed as a fraction of $V_L I_L$. In fact, only a fraction of the voltage V_L contributes to the average power, because the component V_{XEQ} (the drop across the reactance) does not produce any active power dissipation, as it is orthogonal to the current I_L flowing into the load (Fig. 2).

Figure 1. Waveforms of instantaneous power (p), voltage (v), and current (i).

Figure 2. Voltage drop across the load and across its equivalent components.

The quantity

$$Q = V_{XEQ} I_L = V_L I_L \sin \phi \quad (8)$$

—called, by analogy, the *reactive power*—is introduced as a consequence of the voltage drop across a pure reactance. It is a term with zero mean value, representing an energy oscillating equally in both directions, and therefore does not give any contribution to the active power.

The product of the load voltage and current rms values,

$$P_A = V_L I_L \quad (9)$$

—called the *apparent power*—is a figure of merit representing the maximum energy transfer capability of a system and used to express the power consumption of various electrical devices.

Both apparent power and reactive power are dimensionally homogeneous with power and thus might be expressed in watt. But they have a different nature. While relationships involving instantaneous power and real power satisfy the principle of conservation of energy, apparent power and reactive power do not satisfy any conservation principles. To stress the different physical meaning of P_A and Q , their units are called voltampere (VA) and reactive voltampere (var), respectively.

The relationship existing between apparent power, active power and reactive power is given by

$$P_A = \sqrt{P^2 + Q^2} \quad (10)$$

Nonsinusoidal Circuits. A case of great interest is that of the power measurement on distorted waveforms. As an example, advanced systems for electric power production in industrial applications are commonly based on solid-state power components. They have proved to be extremely effective and useful, but, unfortunately, the waveforms that these devices produce on the power line have characteristics far different from the sinusoidal waveforms.

In this case, obviously, the above symbolic representation can no longer be applied. In the general case of distortion of both voltage and current waveforms, we have

$$\begin{aligned} v(t) &= \sum_{h=0}^M V_h \sin h\omega t \\ &= V_0 + V_1 \sin \omega t + V_2 \sin 2\omega t + V_3 \sin 3\omega t + \dots \\ i(t) &= \sum_{k=0}^M I_k \sin(k\omega t - \phi_k) \\ &= I_0 + I_1 \sin(\omega t - \phi_1) + I_2 \sin(2\omega t - \phi_2) \\ &\quad + I_3 \sin(3\omega t - \phi_3) + \dots \end{aligned} \quad (11)$$

Figure 3. Voltage waveform in both time and frequency domains.

The active power, always defined as the mean power dissipated in one fundamental period, is then

$$\begin{aligned} P &= \frac{1}{T} \int_0^T \sum_{h=0}^M V_h \sin h\omega t \sum_{k=0}^M I_k \sin(k\omega t - \phi_k) dt \\ &= \frac{1}{T} \int_0^T \sum_{h=0}^M \sum_{k=0}^M V_h I_k \sin h\omega t \sin(k\omega t - \phi_k) dt \\ &= \frac{1}{T} \int_0^T \sum_{h=0}^M \sum_{k=0}^M V_h I_k \\ &\quad \times \frac{\cos[(h-k)\omega t + \phi_k] - \cos[(h+k)\omega t - \phi_k]}{2} dt \\ &= V_0 I_0 + \sum_{h=1}^M V_h I_h \cos \phi_h \\ &= V_0 I_0 + V_1 I_1 \cos \phi_1 + V_2 I_2 \cos \phi_2 + V_3 I_3 \cos \phi_3 + \dots \end{aligned} \quad (12)$$

—that is, the sum of the active powers of the various frequency components contained in the voltage and current. As an example, voltage and current waveforms in both time and frequency domains are shown in Figs. 3 and 4, respectively. Voltage components of order 1 (fundamental), 3, 5, 7, and 9 and current components of order 1, 5, and 11 are present. In this situation the active power is expressed as

$$P = V_1 I_1 \cos \phi_1 + V_5 I_5 \cos \phi_5$$

—that is, the actual power measurement is not affected by the 3rd, 5th, and 9th voltage harmonics or by the 11th current harmonic. In case of absence of distortion on either the voltage or the current, only the multiplication of the two fundamental waves must be performed.

Figure 4. Current waveform in both time and frequency domains.

The apparent power of nonsinusoidal waves is the product of the load voltage and current rms values:

$$P_A = V_L I_L = \sqrt{\sum_{h=0}^M V_h^2 \sum_{k=0}^M I_k^2} = \sqrt{V_0^2 I_0^2 + \sum_{h=1}^M V_h^2 I_h^2 + \sum_{\substack{h=1 \\ (h \neq k)}}^M \sum_{k=1}^M V_h^2 I_k^2} \quad (13)$$

where every voltage frequency component is separately combined with every current frequency component; the total apparent power then is not equal to the sum of the components related to the separate harmonics.

In the absence of the dc term, the difference $P_A^2 - P^2$ is

$$\begin{aligned} P_A^2 - P^2 &= \sum_{h=1}^M V_h^2 I_h^2 + \sum_{\substack{h=1 \\ (h \neq k)}}^M \sum_{k=1}^M V_h^2 I_k^2 - \sum_{h=1}^M V_h^2 I_h^2 \cos^2 \Phi_h \\ &\quad - \sum_{\substack{h=1 \\ (h \neq k)}}^M \sum_{k=1}^M V_h I_h V_k I_k \cos \Phi_h \cos \Phi_k \\ &= \sum_{h=1}^M V_h^2 I_h^2 \sin^2 \Phi_h + \sum_{\substack{h=1 \\ (h \neq k)}}^M \sum_{k=1}^M V_h^2 I_k^2 \\ &\quad - \sum_{\substack{h=1 \\ (h \neq k)}}^M \sum_{k=1}^M V_h I_h V_k I_k \frac{\cos(\Phi_h - \Phi_k) + \cos(\Phi_h + \Phi_k)}{2} \\ &= \sum_{h=1}^M V_h^2 I_h^2 \sin^2 \Phi_h + \sum_{\substack{h=1 \\ (h \neq k)}}^M \sum_{k=1}^M V_h^2 I_k^2 \\ &\quad + \sum_{\substack{h=1 \\ (h \neq k)}}^M \sum_{k=1}^M V_h I_h V_k I_k \\ &\quad \times \frac{\cos(\Phi_h - \Phi_k) - \cos(\Phi_h + \Phi_k) - 2 \cos(\Phi_h - \Phi_k)}{2} \\ &= \sum_{h=1}^M V_h^2 I_h^2 \sin^2 \Phi_h + \sum_{\substack{h=1 \\ (h \neq k)}}^M \sum_{k=1}^M V_h^2 I_k^2 \\ &\quad + \sum_{\substack{h=1 \\ (h \neq k)}}^M \sum_{k=1}^M V_h I_h V_k I_k [\sin \Phi_h \sin \Phi_k - \cos(\Phi_h - \Phi_k)] \\ &= \left(\sum_{h=1}^M V_h I_h \sin \Phi_h \right)^2 \\ &\quad + \sum_{\substack{h=1 \\ (h \neq k)}}^M \sum_{k=1}^M [V_h^2 I_k^2 - V_h I_h V_k I_k \cos(\Phi_h - \Phi_k)] \quad (14) \end{aligned}$$

The first part of this relation contains terms involving the product of component of the same frequency; by analogy with the

sinusoidal case, they can be expressed as

$$Q = \sum_{h=1}^M V_h I_h \sin \Phi_h \quad (15)$$

and called reactive power. This relation has no physical meaning, but it is a convenient analytical component introduced for its duality with the physical relation Eq. (8). This mathematical decomposition can be given various interpretations. Many other analytical decompositions are possible.

The second part of the relation contains the summation of the products of current and voltage harmonics with different frequencies, expressed in terms of a further analytical expression

$$D = \sqrt{P_A^2 - (P^2 + Q^2)} \quad (16)$$

and called the *distortion power*.

While in sinusoidal conditions the reactive power is entirely related to the energy storage, and in a system their components can be summed algebraically, this is not true in nonsinusoidal conditions. In the case of voltage components of order 1, 3, 5 and current components of order 1, 5, and 11,

$$\begin{aligned} P_A^2 &= (V_1^2 + V_3^2 + V_5^2)(I_1^2 + I_5^2 + I_{11}^2) \\ P^2 &= V_1^2 I_1^2 \cos^2 \phi_1 + V_5^2 I_5^2 \cos^2 \phi_5 + 2V_1^2 I_1^2 V_5^2 I_5^2 \cos \phi_1 \cos \phi_5 \\ P_A^2 - P^2 &= V_1^2 I_1^2 + V_3^2 I_1^2 + V_5^2 I_1^2 + V_1^2 I_5^2 + V_3^2 I_5^2 + V_5^2 I_5^2 + V_1^2 I_{11}^2 \\ &\quad + V_3^2 I_{11}^2 + V_5^2 I_{11}^2 - V_1^2 I_1^2 \cos^2 \phi_1 - V_5^2 I_5^2 \cos^2 \phi_5 \\ &\quad - 2V_1^2 I_1^2 V_5^2 I_5^2 \cos \phi_1 \cos \phi_5 \\ &= V_1^2 I_1^2 \sin^2 \phi_1 + V_5^2 I_5^2 \sin^2 \phi_5 + V_3^2 I_1^2 + V_5^2 I_1^2 + V_1^2 I_5^2 \\ &\quad + V_3^2 I_5^2 + V_1^2 I_{11}^2 + V_3^2 I_{11}^2 + V_5^2 I_{11}^2 - 2V_1^2 I_1^2 V_5^2 I_5^2 \\ &\quad \times \cos \phi_1 \cos \phi_5 \end{aligned}$$

Voltage and current harmonics produce annoying effects in electrical power systems and also cause problems in industrial and communication apparatus. It is thus frequently necessary, or useful, to measure and analyze the power components in nonsinusoidal conditions.

High-Frequency Circuits. At low frequencies the power measurement is derived from voltage and current measurements. As the frequency increases, the wavelength become comparable to or lower than the circuit dimensions. In this case current and voltage become hard to measure, because they vary with the position along the transmission line, while the power remains constant. For this reason the power level is the most important factor in the design of high-frequency devices.

Power transmitted from a supply to a load at radio or microwave frequencies is generally measured by attaching a power sensor to the transmission-line port under measurement. The sensor output is connected to a power meter.

While an ideal sensor absorbs all the incident power (P_I), the actual impedance mismatch between the characteristic impedance of the radio frequency (RF) transmission line and the RF sensor input produces a partial reflection of the incoming power toward the supply. For this reason, the meter connected to the sensor does not account for the total amount of reflected power (P_R). The relationship among power dissipated

in the load (P_L), power incident, and power reflected is obviously $P_L = P_I - P_R$.

Directional couplers allow separate measurement of incident and reflected power by means of power meters applied, respectively, on the right and on the left side of the secondary waveguide. Directional couplers are also used to determine the reflection coefficient ρ of the sensor, which takes into account mismatch losses and is defined by

$$P_R = \rho^2 P_I \quad (17)$$

In order to take into account also the absorptive losses due to dissipation in the conducting walls of the sensor, leakage into instrumentation, power radiated into space, and so on, beside the reflection coefficient, the *effective efficiency* η_C of the sensor should also be considered. Generally, the reflection coefficient and effective efficiency are included in the *calibration factor* K , defined as

$$K = \eta_C(1 - \rho^2) \times 100\% \quad (18)$$

For instance, a calibration factor of 90% means that the meter will read 10% below the incident power. Generally calibration factors are specified by sensor manufacturers at different values of frequency.

GENERAL METHODS AND INSTRUMENTATION

As far as methods and instruments for power measurements are concerned, the problems involved change as the frequency of the power supply increases. Therefore, in the following, power measurement is discussed by considering general methods and instrumentation for dc and ac circuits. The ac circuits will be classified as (1) line-frequency circuits, (2) low- and medium-frequency circuits (up to a few megahertz), and (3) high-frequency circuits (up to a few gigahertz). Line-frequency circuits will be discussed separately from low-frequency circuits principally because of the existence of problems related specifically to three-phase power of the main.

Dc Circuits

A power measurement in a dc circuit can be generally carried out by using a voltmeter (V) and an ammeter (A), according to one of the connections shown in Fig. 5.

Both the connections introduce a systematic error, generally referred to as insertion error. In the connection of Fig. 5(a) the ammeter measures the current flowing into the voltmeter, I_V , as well as that flowing into the load, I_L . In the connection of Fig. 5(b) the voltmeter measures the voltage drop across the

Figure 5. Two arrangements for dc power measurement circuits.

load, V_L , in addition to that dropping across the ammeter, V_A . So both connections give an excess of measured power, representing the power absorbed by the instrument connected closer to the load.

The analysis of the circuits of Fig. 5(a,b) provides the relations between the measurand, the electrical power P in the load, and the measured voltage V and current I , expressed as

$$P = V_L I_L = V(I - I_V), \quad P = V_L I_L = I(V - V_A) \quad (19)$$

By neglecting R_L (compared with the voltmeter internal resistance R_V) for the connection of Fig. 5(a) and the ammeter resistance R_A (compared with R_L) for the connection of Fig. 5(b), we have the respective approximations

$$I_V = I \frac{R_L}{R_V + R_L} \approx I \frac{R_L}{R_V}, \quad V_A = V \frac{R_A}{R_A + R_L} \approx V \frac{R_A}{R_L} \quad (20)$$

Consequently, the equations (19) become respectively

$$P = VI \left(1 - \frac{R_L}{R_V}\right) = VI \frac{R_V - R_L}{R_V} \quad (21)$$

$$P = VI \left(1 - \frac{R_A}{R_L}\right) = VI \frac{R_L - R_A}{R_L}$$

From Eqs. (20) and (21) analytical corrections of the insertion errors can be easily derived.

In a dc circuit the electrical power can also be measured by a wattmeter. The instrument most commonly used is the dynamometer. It is made of two fixed coils, positioned coaxially with space between them, and a moving coil, placed between the fixed coils and equipped with a pointer [Fig. 6(a)]. The fixed coils, commonly known as *current coils*, are connected in series with the load, to carry the load current. The moving coil (*voltage coil*), with a resistor R_V in series, is connected in parallel with the load R_L , to carry a current proportional to the voltage across it. When each coil carries a current, the interaction between the magnetic fields produced by the fixed and moving coils supplies a torque to move the pointer, which is proportional to the product of the two currents flowing into the coils. As a consequence, the deflection of the moving coil is proportional to the power dissipated in the load.

Insertion errors are also present in the dynamometer power measurement. In particular, on connecting the voltage coil

Figure 6. Power measurement with a dynamometer: (a) working principle, (b) measurement circuit.

between A and C [Fig. 6(b)], the current coils carry both the current through the load and that taken by the voltage coil. Consequently, the power P_L dissipated in the load can be obtained from the dynamometer reading P as

$$P_L = P - \frac{V^2}{R_V} \quad (22)$$

where $R_V = R_V + R_{VC}$ is the overall resistance of the voltage circuit (R_{VC} is the resistance of the voltage coil). By connecting the moving coil between B and C, this current error can be avoided, but now the voltage coil measures the excess voltage drop across the current coils. In this case the power in the load is

$$P_L = P - I^2 R_C \quad (23)$$

where R_C is the resistance of the current coil.

Ac Circuits

Active power in ac circuits can be measured by a dynamometer. Since its moving system cannot follow the rapid torque variations, it works as an intrinsic integrator of the instantaneous power, showing the average power according to Eq. (5). The insertion errors can be derived by simple considerations, in analogy with the previously discussed dc case, by replacing voltages and currents by the corresponding rms values.

However, a phase uncertainty due to the self-inductance of the voltage circuit arises in ac measurements. In sinusoidal conditions, if e_ω (in radians) is the phase defect angle (departure from exact quadrature) of the voltage circuit and $\cos \phi$ the load power factor, the relative uncertainty in active power measurements can be shown to be equal to $-e_\omega \tan \phi$. The phase uncertainty depends on the frequency. By using more complex circuits to compensate for this source of error, the frequency range of the dynamometer can be extended up to a few tens of kilohertz.

The reactive power measurement can be carried out by using special instruments (varmeters or reactive meters) with the same arrangements described for the active power. These are instruments whose response is proportional to $V_L I_L \sin \phi = V_L I_L \cos(90^\circ - \phi)$, where $\cos \phi$ is the load power factor. It can be measured with a wattmeter, by shifting the line voltage into quadrature.

In a polyphase system reactive power can be derived from the readings of wattmeters connected in a special way (Barbagelata's and Righi's insertions; see "Symmetrical Power Systems Supplying Unbalanced Loads" below). Also the apparent power, which is important for determining the line and supply capacity, can be measured by using a voltmeter and an ammeter. Electronic instruments, such as sampling wattmeters, can generally process the acquired data to supply all the different power quantities.

Line Frequency

For applications where the power is directly derived from the mains, the assumption of infinite power source can be reliably made and at least one of the two quantities voltage and current

Figure 7. Single-phase power measurement with voltage (VT) and current (CT) transformers.

can be considered as sinusoidal. In this case only the power at the fundamental frequency should be examined (1).

Single-Phase Measurement. The power measurement at line frequency in single-phase circuits is generally carried out by a dynamometer, though the use of electronic instruments has become common. In practical applications, the case of a voltage greater than 1000 V is very common. Then the measurement must be carried out by using voltage and current transformers, inserted as shown in Fig. 7. In this case, the relative measurement uncertainty is equal to

$$\frac{\Delta P}{P} = (\eta_w + \eta_a + \eta_v) + (\epsilon_w + \epsilon_a + \epsilon_v) \tan \Phi_c \quad (24)$$

where η_w and ϵ_w are the instrumental and phase uncertainty of the wattmeter, η_a and η_v are the ratio uncertainties of the current (CT) and voltage (VT) transformers, and ϵ_a and ϵ_v are their phase uncertainties, respectively. If the load current exceeds the current range of the wattmeter, a current transformer has to be used, even in the case of low voltages.

Polyphase Power Measurement. In the following, the general case of power measurements on polyphase systems is analyzed. The common case of three-phase systems is treated, and different solutions are considered.

Measurements on Systems with Several Wires. Let a network with sinusoidal voltages and currents composed of n wires be considered. Among the currents flowing in such wires the following relation is established:

$$\sum_{i=1}^n I_i = 0 \quad (25)$$

The network can be thought as composed of $n-1$ single-phase independent systems, with the common return on one of the wires (say the s th wire). Then the total power can be measured as the sum of the readings of $n-1$ wattmeters, each one inserted with the current circuit in a different wire and the voltmeter

Figure 8. Power measurement on systems with several wires.

circuit between that wire and the s th one (Fig. 8):

$$P = \sum_{i \neq s}^n \dot{V}_{is} \dot{I}_i \quad (26)$$

The load power can also be measured by referring to a generic point O external to the network, as the sum of the readings of n wattmeters, each inserted with the ammeter circuit in a different wire and the voltmeter circuit connected between that wire and the point O :

$$P = \sum_{i=1}^n \dot{V}_{iO} \dot{I}_i \quad (27)$$

Power Measurements on Three-Wire Systems. The active power in a three-phase power system can generally be evaluated with three wattmeters connected as shown in Fig. 9. On each instrument, the current system is connected to carry the line current, while the voltmeter system is connected between the same wire and an artificial neutral point O , whose position is fixed by the voltmeter impedance of wattmeters or by suitable external impedances.

Figure 9. Insertion of three wattmeters for three-wire three-phase systems.

In these conditions the power in the load is the sum of the three wattmeters' indications:

$$P = \sum_{i=1}^3 \dot{V}_{iO} \dot{I}_i \quad (28)$$

If the three-phase system is provided by four wires (three phases with a neutral wire), the neutral wire is utilized as the common wire.

Analogously to the single-phase case, for medium-voltage circuits the three-wattmeter insertion is modified as in Fig. 10.

Symmetrical and Balanced Systems. The supply system is symmetrical and the three-phase load is balanced if

$$\begin{aligned} V_1 &= V_2 = V_3 \\ I_1 &= I_2 = I_3 \end{aligned} \quad (29)$$

In Fig. 11 the three possible kinds of insertion of an instrument S (active or reactive power meter) are illustrated, by using the following convention: S_{ijk} indicates a reading performed with the current leads connected to line i and the voltmeter leads connected between phases j and k . If i is equal to j , one is omitted, for example, P_{12} [Fig. 11(b)]. The active power related to a single phase is usually referred to as P_1 .

In the first case [Fig. 11(a)] S is inserted between the phase and the artificial point O . By Eq. (29), the overall active power is

Figure 10. Insertion of three wattmeters for medium voltage.

Figure 11. The three modes of insertion of a power meter.

given by three times the indication of the wattmeter S ; similarly for the overall reactive power if S is a reactive power meter. Notice that a pair of twin resistors with the same resistance R as that of the voltage circuit of S are placed on the other phases in order to balance the load.

The wattmeter reading corresponding to Fig. 11(c) can be expressed as

$$P_{1(23)} = I_1 \dot{V}_{23} \quad (30)$$

But $CIV_{12} + CIV_{23} + CIV_{31} = 0$ and $CIV_{13} = -CIV_{31}$; thus

$$P_{1(23)} = I_1(-\dot{V}_{12} - \dot{V}_{31}) = -I_1 \dot{V}_{12} + I_1 \dot{V}_{13}$$

where the last two terms are $I_1 CIV_{12} = P_{12}$ and $I_1 CIV_{13} = P_{13}$, which lead to the final relation, and to corresponding relations for the other phases, valid for any kind of supply and load:

$$\begin{aligned} P_{1(23)} &= P_{13} - P_{12} \\ P_{2(31)} &= P_{21} - P_{23} \\ P_{3(12)} &= P_{32} - P_{31} \end{aligned} \quad (31)$$

If the supply system is symmetrical, we have $P_{1(23)} = \sqrt{3} Q_1$. In fact, starting from the relationship

$$P_{1(23)} = I_1 \dot{V}_{23} = I_1 V_{23} \cos \beta \quad (32)$$

where $\beta = 90^\circ - \phi_1$ (Fig. 12), we have

$$P_{1(23)} = \sqrt{3} E_1 I_1 \sin \phi_1 = \sqrt{3} Q_1$$

with Q_1 the reactive power involved in phase 1. The three final relationships are

$$\begin{aligned} P_{1(23)} &= \sqrt{3} Q_1 = P_{13} - P_{12} \\ P_{2(31)} &= \sqrt{3} Q_2 = P_{21} - P_{23} \\ P_{3(12)} &= \sqrt{3} Q_3 = P_{32} - P_{31} \end{aligned} \quad (33)$$

Hence, in the case of symmetrical and balanced systems, the overall reactive power is given by

$$Q = 3Q_1 = 3P_{1(23)}/\sqrt{3} = \sqrt{3}P_{1(23)} \quad (34)$$

Figure 12. Phasor diagram for a three-phase symmetrical and balanced system.

Power Measurements Using Two Wattmeters. The overall active power in a three-wire system can be measured by using only two wattmeters. In fact, Aron's theorem states the following relationships:

$$\begin{aligned} P &= P_{12} + P_{32} \\ P &= P_{23} + P_{13} \\ P &= P_{31} + P_{21} \end{aligned} \quad (35)$$

Analogously, the overall reactive power can be measured by using only two reactive power meters:

$$\begin{aligned} Q &= Q_{12} + Q_{32} \\ Q &= Q_{23} + Q_{13} \\ Q &= Q_{31} + Q_{21} \end{aligned} \quad (36)$$

To prove one of the previous statements, say $P = P_{12} + P_{32}$, refer to Fig. 13, where the two wattmeters furnish P_{12} and P_{32} . Hence the sum of the two readings gives

$$\begin{aligned} P_{12} + P_{32} &= I_1 \dot{V}_{12} + I_3 \dot{V}_{32} = I_1(E_1 - E_2) + I_3(E_3 - E_2) \\ &= I_1 E_1 - I_1 E_2 + I_3 E_3 - I_3 E_2 \\ &= I_1 E_1 + I_3 E_3 - (I_1 + I_3) E_2 \\ &= I_1 E_1 + I_3 E_3 + I_2 E_2 = P_1 + P_2 + P_3 = P \end{aligned} \quad (37)$$

Provided that the system has only three wires, Aron's theorem applies to any kind of supply and load. In the case of symmetrical and balanced systems, it also allows the reactive power to

Figure 13. Power measurements using two wattmeters.

be evaluated as

$$Q = \sqrt{3}(P_{32} - P_{12}) \quad (38)$$

By using Eqs. (35) and (38) the power factor is seen to be

$$\begin{aligned} \cos \phi &= \frac{P_{12} + P_{32}}{\sqrt{(P_{12} + P_{32})^2 + 3(P_{32} - P_{12})^2}} \\ &= \frac{P_{12} + P_{32}}{\sqrt{4P_{12}^2 + 4P_{32}^2 - 4P_{12}P_{32}}} \\ &= \frac{1 + (P_{12}/P_{32})}{2\sqrt{(P_{12}/P_{32})^2 - (P_{12}/P_{32}) + 1}} \end{aligned} \quad (39)$$

Aron's insertion presents a limitation for low power factors. In fact, considering the functions

$$\begin{aligned} \cos(\phi + 30^\circ) &= \frac{P_{12}}{VI} \\ \cos(\phi - 30^\circ) &= \frac{P_{32}}{VI} \end{aligned} \quad (40)$$

(Fig. 14), it can be argued that for $\phi \leq 60^\circ$, P_{12} and P_{32} are both greater than zero, while for $\phi > 60^\circ$, $\cos(\phi - 30^\circ)$ is still greater than zero and $\cos(\phi + 30^\circ)$ is less than zero. The absolute error in the active power is

$$\Delta P = \frac{\partial(P_{12} + P_{32})}{\partial P_{12}} \Delta P_{12} + \frac{\partial(P_{12} + P_{32})}{\partial P_{32}} \Delta P_{32} = \Delta P_{12} + \Delta P_{32} \quad (41)$$

This corresponding relative error is greatest when P_{12} and P_{32} have values close to each other and opposite in sign; in particular, for $\cos \phi = 0$ ($\phi = 90^\circ$) the error is infinite.

If η_w and ϵ_w are the wattmeter amplitude and phase errors, the error in the active power is

$$\frac{\Delta P}{P} = \frac{(\eta_w + \epsilon_w \tan \phi_{12})P_{12} + (\eta_w + \epsilon_w \tan \phi_{32})P_{32}}{P_{12} + P_{32}} = \eta_w + \epsilon_w \frac{Q}{P} \quad (42)$$

Let two wattmeters with nominal values V_0 , I_0 , $\cos \phi_0$ and accuracy class c be considered. The maximum absolute error in

Figure 14. Sign of powers in Aron's insertion.

each reading is

$$\Delta P = \frac{c V_0 I_0 \cos \phi_0}{100} \quad (43)$$

Therefore, the percentage error related to the sum of the two indications is

$$\frac{\Delta P}{P} = \frac{c V_0 I_0 \cos \phi_0}{\sqrt{3} V I \cos \phi} = 1.11 \frac{c V_0 I_0 \cos \phi_0}{V I \cos \phi} \quad (44)$$

equal approximately to the error of only one wattmeter inserted in a single-phase circuit with the same values of I , V , and $\cos \phi$. Consequently, under the same conditions, the use of two wattmeters involves a measurement uncertainty rather lower than the use of three wattmeters. If the Aron's insertion is performed via current and voltage transformers, characterized by ratio errors η_a and η_v and phase errors ϵ_a and ϵ_v respectively, the active power error is

$$\begin{aligned} \frac{\Delta P}{P} &= \frac{(\eta_{TOT} + \epsilon_{TOT} \tan \phi_{12})P_{12} + (\eta_{TOT} + \epsilon_{TOT} \tan \phi_{32})P_{32}}{P_{12} + P_{32}} \\ &= \eta_{TOT} + \epsilon_{TOT} \frac{Q}{P} = \eta_{TOT} + \epsilon_{TOT} \tan \Phi_c \end{aligned} \quad (45)$$

where $\cos \phi_c$ is the conventional power factor, and

$$\eta_{TOT} = \eta_w + \eta_a + \eta_v$$

$$\epsilon_{TOT} = \epsilon_w + \epsilon_a + \epsilon_v$$

the error sums, with η_w , ϵ_w the wattmeter errors.

Symmetrical Power Systems Supplying Unbalanced Loads. If the load is unbalanced, the current amplitudes are different from each other and their relative phase is not equal to 120° . In this situation two wattmeters and one voltmeter have to be connected as proposed by Barbagelata (1) (Fig. 15). The first wattmeter gives P_{12} and P_{13} (changing the switch position), and the second one gives P_{31} and P_{32} .

From Aron's theorem the active power is

$$P = P_{12} + P_{32} \quad (46)$$

and then the reactive power Q is

$$Q = Q_1 + Q_2 + Q_3 = \frac{1}{\sqrt{3}}(P_{13} - P_{12} + \underline{P_{21}} - \underline{P_{23}} + P_{32} - P_{31}) \quad (47)$$

Figure 15. Barbagelata's insertion for symmetrical and unbalanced systems.

Figure 16. Righi's insertion for symmetrical and unbalanced systems.

For the underlined terms, from Aron's theorem it follows that

$$P = P_{13} + P_{23} = P_{12} + P_{32} = P_{21} + P_{31} \quad (48)$$

Then

$$P_{13} + P_{23} = P_{21} + P_{31} \quad \text{so} \quad P_{21} - P_{23} = P_{13} - P_{31}$$

Then we have

$$Q = \frac{1}{\sqrt{3}} [2(P_{13} - P_{31}) + P_{32} - P_{12}] \quad (49)$$

Hence, from only four power measurements, the overall active and reactive powers can be obtained.

The main disadvantage of this method is that the four measurements are not simultaneous; therefore, any load variations during the measurement will cause a loss in accuracy. In this case, a variation proposed by Righi (1) may be used, with three wattmeters connected as shown in Fig. 16 to measure P_{12} , P_{32} , and $P_{2(31)}$ simultaneously. The reactive power is

$$Q = \frac{1}{\sqrt{3}} (P_{13} - P_{12} + P_{21} - P_{23} + P_{32} - P_{31}) \quad (50)$$

As above, from Aron's theorem it follows that

$$P_{21} - P_{23} = P_{13} - P_{31} \quad \text{and} \quad P_{2(31)} = P_{21} - P_{23} = P_{13} - P_{31}$$

Then

$$Q = \frac{1}{\sqrt{3}} (P_{32} - P_{12} + 2P_{2(31)}) \quad (51)$$

For symmetrical and unbalanced systems another two-wattmeter insertion can be carried out (Fig. 17). The wattmeters give

$$\begin{aligned} P_{1(30)} &= E_3 I_1 = j \frac{\dot{V}_{12}}{\sqrt{3}} I_1 = -\frac{Q_{12}}{\sqrt{3}} \\ P_{3(10)} &= E_1 I_3 = j \frac{\dot{V}_{23}}{\sqrt{3}} I_3 = \frac{Q_{32}}{\sqrt{3}} \end{aligned} \quad (52)$$

Hence, the overall reactive power is

$$Q = Q_{12} + Q_{32} = \sqrt{3}(-P_{1(30)} + P_{3(10)}) \quad (53)$$

Figure 17. Insertion of two wattmeters for symmetrical and unbalanced systems.

Method Selection Guide. For three-wire systems, the flux diagram of Fig. 18 leads to selecting the most suitable method according to system characteristics.

Low- and Medium-Frequency Power Measurements

In the following, the main methods and instruments for power measurements at low and medium frequencies are considered.

Three-Voltmeter Method. The power dissipation in the load L can be measured by using a non-inductive resistor R and three voltmeters, as shown in Fig. 19 (2). Though one of the voltmeters may appear redundant on a first analysis of the circuit, in actual fact three independent data are needed in order to derive the power from Eq. (7). In particular, from the voltage drops v_{AB} and v_{BC} , the load current and load voltage can be directly derived; then, v_{AC} is used to retrieve information about their relative phase. If the currents drawn by the voltmeters are neglected and the current i_L flowing into the load L is assumed to be equal to that flowing into the resistor R, the statement can be demonstrated as follows:

$$\begin{aligned} v_{AC} &= Ri_L + v_L \\ v_{AC}^2 &= R^2 i_L^2 + v_L^2 + 2Rv_L i_L \end{aligned} \quad (54)$$

where the lowercase letters indicate instantaneous values. By computing rms values (indicated with capital letters) we obtain the power P_L :

$$\begin{aligned} \frac{1}{T} \int_0^T v_{AC}^2 dt &= \frac{1}{T} \int_0^T R^2 i_L^2 dt + \frac{1}{T} \int_0^T v_L^2 dt + \frac{1}{T} \int_0^T 2Rv_L i_L dt \\ V_{AC}^2 &= R^2 I_L^2 + V_L^2 + 2RP_L \\ P_L &= \frac{V_{AC}^2 - R^2 I_L^2 - V_L^2}{2R} = \frac{V_{AC}^2 - V_{AB}^2 - V_{BC}^2}{2R} \end{aligned} \quad (55)$$

The expression (55) is also applicable to dc on replacing rms values with dc ones. Since the result is obtained as a difference, problems arise from relative uncertainty when the three terms have a sum near zero.

Such a method is still used for high-accuracy applications.

Thermal Wattmeters. The working principle of thermal wattmeters is based on a pair of twin thermocouples whose output

Figure 18. Method selection guide for power measurements on three-wire systems.

voltage is proportional to the square of the rms value of the currents flowing into the thermocouple heaters (3).

The essential circuit of a thermal wattmeter is shown in Fig. 20(a). Without the load, if the two heaters have equal resistance ($r_1 = r_2 = r$), in the limit $S \ll r$ they are connected in parallel and carry the same current i_p , proportional to the supply voltage:

$$i_1 = i_2 = i_p = \frac{v}{2R + r} \quad (56)$$

In this case, the output voltages of the two thermocouples turn out to be equal ($e_1 = e_2$), thus the voltage Δe measured by the voltmeter is null. In Fig. 20(b) this situation is represented by

Figure 19. Three-voltmeter method.

the working point T , the same for both thermocouples. By applying a load L with a corresponding current i_L , a voltage drop across S arises, determining an imbalance between currents i_1 and i_2 (i_1 increases and i_2 decreases). In the limit $r \ll R$, the two heaters are in series; thus the current imbalance i_u through them is proportional to the load current:

$$i_u = i_1 - i_2 = \frac{S}{2R} i_L \quad (57)$$

Therefore, the working points of the two thermocouples change: to A for the thermocouple that carries the current i_1 , and to B for the other one [Fig. 20(b)].

Because the thermocouple response time is higher than the period of the heater current, it produces an emf proportional to the average squared value of this current. In this situation, in the above limits, the voltmeter measures a voltage imbalance Δe proportional to the active power absorbed by the load (except for the excess given by the powers dissipated in R , S , r_1 , and r_2):

$$\begin{aligned} \Delta e &= k(\overline{i_1^2} - \overline{i_2^2}) = k[\overline{(i_p + i_L)^2} - \overline{(i_p - i_L)^2}] = k \\ \overline{4i_p i_L} &= k_1 \overline{v(t) i(t)} = k_1 P \end{aligned} \quad (58)$$

where the overbars indicate time averages.

If the two thermocouples cannot be considered as matched and linear, the power measurement accuracy will obviously be

Figure 20. (a) Thermal wattmeter based on twin thermocouples; (b) working characteristic in ideal conditions.

compromised. This situation is shown in Fig. 21, where the two thermocouples are supposed to have two quite different nonlinear characteristics. In this case, the voltage measured by the voltmeter will be Δe_n instead of Δe .

Wattmeters based on the thermal principle allow high accuracy to be achieved in critical cases of highly distorted wideband signals.

Wattmeters Based on Multipliers. The multiplication and averaging processes involved in power measurements can be undertaken by electronic circuits (Fig. 22). Wattmeters of this kind fall into two categories, depending on whether the multiplication and averaging operations are performed in a continuous or a discrete way. In the first case multiplication is usually carried out by means of an analog electronic multiplier, while averaging is carried out by a low-pass filter or by an averaging reading instrument. In the other case (sampling wattmeters), simultaneous samples of voltage and current waveforms are taken, digitized, and then multiplied and averaged by using digital techniques.

In multiplier methods also, the resistances of the voltage and current circuits have to be taken into account, analogously to the case of dynamometers [see Eqs. (22) and (23)]. Furthermore, phase errors of both current circuits ($e_{\omega c}$) and voltage circuits ($e_{\omega v}$) increase the relative uncertainty of power measurement [in the case of sinusoidal conditions by $(e_{\omega c} - e_{\omega v}) \tan \phi$].

Wattmeters Based on Analog Multipliers. The main analog multipliers are based on a transistor circuit, such as a four-

Figure 21. Ideal and actual characteristics of thermal-wattmeter thermocouples.

quadrant multiplier (4), which is fed by voltage and current signals to give the instantaneous power, and an integrator to provide the mean power (Fig. 23). More effective solutions are based on the time-division multiplier (TDM) and on Hall-effect-based multipliers.

TDM-Based Wattmeters. The block diagram of a wattmeter based on a TDM is shown in Fig. 24 (5). A square wave v_m [Fig. 25(a)] with constant period T_g , and with duty cycle and amplitude determined by $i(t)$ and $v(t)$, respectively, is generated. T_g is much smaller than the period of the measurands $v_x(t)$ and $v_i(t)$, so that one can consider these voltages constant during that time interval.

The duty cycle of v_m is set by the impulse duration modulator circuit (Fig. 24). The ramp voltage $v_g(t)$ [Fig. 25(b)], compared with the voltage $v_i(t)$ proportional to $i(t)$, produces a square-wave output, which drives the switch SW, fixing a time interval t_2 of the output $v_m(t)$ proportional to $v_i(t)$. If

$$v_g(t) = \frac{4V_{g0}}{T_g} t \quad \text{when } 0 \leq t \leq \frac{T_g}{4} \quad (59)$$

from simple geometrical considerations we obtain

$$t_2 = 2 \left(\frac{T_g}{4} - \frac{T_g}{4} \frac{v_i}{V_{g0}} \right) \quad (60)$$

and

$$t_1 - t_2 = \frac{T_g}{V_{g0}} v_i \quad (61)$$

The amplitude of $v_m(t)$ is set by the impulse amplitude

Figure 22. Block diagram of a multiplier-based wattmeter.

Figure 23. Block diagram of a four-quadrant multiplier-based wattmeter.

modulator circuit to be equal to $+v_x$ during the time interval t_1 , and to $-v_x$ during the time interval t_2 [Fig. 25(a)].

After an initial transient, the output voltage $v_{out}(t)$ of the low-pass filter (integrator) is the mean value of $v_m(t)$:

$$\begin{aligned} V_{out} &= \frac{1}{RC} \int_0^t v_m(t) dt = K' \left(\int_0^{t_1} v_x(t) dt - \int_{t_1}^{t_1+t_2} v_x(t) dt \right) \\ &= K' v_x(t_1 - t_2) = K v_x v_i \end{aligned} \quad (62)$$

The frequency range is generally between 200 Hz and 20 kHz, but can reach 100 kHz. Uncertainties are typically 0.01% to 0.02% (6).

Hall-Effect Based Wattmeters. As is known, in a Hall-effect transducer the output voltage $v_H(t)$ is proportional to the product of two time-dependent quantities, the current $i(t)$ through the transducer and the magnetic induction $B(t)$ (7):

$$v_H(t) = R_H i(t) B(t) \quad (63)$$

where R_H is the Hall constant. In the circuit of Fig. 26(a), the power P is determined by measuring $v_H(t)$ through a high-input-impedance averaging voltmeter, and by considering that $v_x(t) = ai(t)$ and $i_x(t) = bB(t)$, with a and b proportionality factors:

$$P = \frac{1}{T} \int_0^T v_x(t) i_x(t) dt = ab \frac{1}{T} \int_0^T i(t) B(t) dt = ab \frac{V_H}{R_H} \quad (64)$$

where T is the measurand period, and V_H the mean value of $v_H(t)$.

In the usual realization of the Hall multiplier (accuracy 0.1% up to a few megahertz), shown in Fig. 26(a), the magnetic induction is proportional to the load current i_L and the optimal polarizing current i_v is set by the resistor R_v . For frequencies over the megahertz range, an alternative arrangement is shown in Fig. 26(b), in which the load current i_L , or a suitable amount of it reduced by inserting the shunt R_s , flows directly into the Hall device, acting as a polarizing current, and the magnetic field is generated by the voltage v_x . In this way, the influence of temperature is reduced for line-frequency applications with constant-amplitude voltages and variable load currents.

Standard wattmeters for high frequency, use probes in waveguides with rectifiers.

Wattmeters Based on Digital Multipliers

Sampling Wattmeters. The most important wattmeter operating on discrete samples is the sampling wattmeter (Fig. 27). It is essentially composed of two input channels, each constituted by a conditioner (C), a sample-and-hold (S/H), and an analog-to-digital converter (ADC). Digital multiplier (MUL), summing (SUM), dividing (DIV), and displaying (DISP) units are also included. The architecture is handled by a processing unit, not shown in the figure.

The uniform sampling of input signals allows the active power to be evaluated as the mean of the sequence of

Figure 24. Block diagram of a TDM-based wattmeter.

Figure 25. Waveform of TDM-based power measurement: (a) impulse amplitude-modulator output, (b) ramp-generator output.

instantaneous power samples $p_j(k)$:

$$P = \frac{1}{N} \sum_{k=0}^{N-1} p_j(k) = \frac{1}{N} \sum_{k=0}^{N-1} v_j(k) i_j(k) \quad (65)$$

where N is the number of samples in one period of the input signal. A previous estimation of the measurand fundamental period is made to adjust the summation interval of Eq. (65) and/or the sampling period in order to carry out synchronous sampling (8). The sampling period can be adjusted by using a frequency multiplier with a PLL circuit driven by the input signal (9). Alternatively, the contribution of the sampling error is reduced by averaging over a large number of periods of the input signal.

In the time domain, estimation of the period of highly distorted signals, as in pulse width modulation (PWM), is made difficult by the numerous zero crossings present in the waveform. Some types of digital filters can be used for this purpose. An efficient digital way to estimate the period is the discrete integration of the PWM signal. In this way, the period of the

Figure 27. Block diagram of the sampling wattmeter.

fundamental harmonic is estimated by detecting the sign changes of the cumulative sum function (10):

$$S(k) = \sum_{i=1}^k v_i, \quad k = 1, 2, \dots, N \quad (66)$$

If the summation interval is extended to an integer number of periods of the function $S(k)$, then *quasisynchronous* sampling (11) is achieved through a few simple operations (cumulative summation and sign detection), and the maximum synchronization error is limited to a sampling period. Through relatively small increases in computational complexity and in memory size, the residual error can be further reduced through a suitable data-processing algorithm, that is, the multiple convolution in the time domain of triangular windows (10). Hence, the power measurement can be obtained as

$$P_{(B)} = \frac{1}{\sum_{k=0}^{2B(N-1)} w(k)} \sum_{k=0}^{2B(N-1)} w(k) p(k) \quad (67)$$

where $p(k)$ is the k th sample of the instantaneous power and $w(k)$ the k th weight corresponding to the window obtained as the convolution of B triangular windows (11).

Another way to obtain the mean power is through the consideration of the harmonic components of voltages and currents in the frequency domain by using the discrete Fourier transform (12). In particular, a fast Fourier transform algorithm is used in order to improve the efficiency. A two-step search for the harmonic peaks is then carried out: (1) the indices of the frequency samples corresponding to the highest spectral peaks

Figure 26. Configurations of the Hall-based wattmeter.

Figure 28. Working principle of the thermistor-based power meter.

provide a rough estimate of the unknown frequencies when the wideband noise superimposed on the signal is below threshold; (2) a more accurate estimate of the harmonic frequencies is carried out to determine the fractional bin frequency (i.e. the harmonic determination up to the frequency resolution); to this aim, several approaches such as zero padding, interpolation techniques, and flat-top window-based techniques can be applied (13).

High-Frequency Power Measurements

High-frequency power measurements can be classified as follows: *low power*, up to 10 mW; *medium power*, from 10 mW to 1 W; and *high power*, greater than 1 W. Meters used for power measurements at radio or microwave frequencies are generally classified as *absorption type* (containing their own load, generally 50 Ω for radio frequencies) and *transmitted or through-line type* (where the load is remote from the meter). Independently of the type, power meters are mainly based on thermistors, thermocouples, diodes, or radiation sensors.

Thermal Methods. In this sub-subsection, the main methods based on power dissipation will be examined, namely: (1) thermistor-based, (2) thermocouple-based, and (3) calorimetric.

Figure 29. Manual bolometer.

Figure 30. Manual bolometer with substitution method.

Thermistor-Based Power Meters. A thermistor is a resistor made up of a combination of highly temperature-sensitive metallic oxides (14). If it is used as a sensor in a power meter, its resistance becomes a function of the temperature rise produced by the applied power.

The working principle of the thermistor power meter is illustrated in Fig. 28 (15): two thermistors (R_{T1} and R_{T2}) are connected (1) in parallel, for measurand signals appearing at the RF input (P_{RF}) and (2) in series, for the following measuring circuit (e.g. a bridge). The capacitance C_1 prevents the dc power component from flowing to the thermistors; C_2 excludes the RF power from the bridge.

A bridge with a thermistor or a barretter in one arm is called a *bolometer*. Bolometer-based measurements are mainly performed with (1) a manual bolometer with variation of the bias current, (2) a manual bolometer with the substitution method, or (3) a self-balancing bolometer.

The *manual bolometer with a variation of the bias current* is illustrated in Fig. 29. Its working principle consists of two steps. In the first, no RF power is applied to the sensor; the equilibrium is obtained by varying the dc power supply E until the sensor resistance R_B , related to the dc power flowing in it, is equal to R . In this condition let the current I flowing into the

Figure 31. Self-balancing bolometer.

Figure 32. Power meter based on two self-balancing bridges.

circuit be equal to I_1 . In the second step, RF power P_{RF} is fed to the sensor; the power increase must be compensated by a dc power decrease, which is performed by lowering the bridge dc supply voltage E ; in this case, let I be equal to I_2 . Since the power dissipated in the sensor has been maintained constant in both steps, the power P_{RF} can be evaluated as

$$P_{RF} = \frac{R}{4}(I_1^2 - I_2^2) \quad (68)$$

The *manual bolometer with the substitution method* (Fig. 30) involves two steps. In the first, both RF power (P_{RF}) and dc power (P_{dc}) are present, and the power (P_d) necessary to bring the bridge to the equilibrium is

$$P_d = P_{dc} + P_{RF} \quad (69)$$

During the second step, P_{RF} is set to zero and an alternating voltage V_{ac} is introduced in parallel with the dc power supply. In this case, the power P_d necessary to balance the bridge,

$$P_d = P_{dc} + P_{ac} \quad (70)$$

is obtained by varying V_{ac} . Since P_d is the same in both cases,

the power supplied by the ac generator is equal to

$$P_{RF} = P_{ac} = \frac{V_{ac}^2}{4R} \quad (71)$$

Equation (71) implies that the RF power can be obtained by a voltage measurement.

The *self-balancing bolometer* (Fig. 31) automatically supplies a dc voltage V to balance the voltage variations due to changes in the sensor resistance R_B for an incident power P_{RF} . At equilibrium, R_B is equal to R , and the RF power will then be

$$P_{RF} = \frac{V^2}{4R} \quad (72)$$

As mentioned above, the thermistor resistance depends on the surrounding temperature. This effect is compensated in an instrument based on two self-balancing bridges (15). The RF power is input only to one of these, as shown in Fig. 32.

The equilibrium voltages V_c and V_{RF} feed a chopping and summing circuit, whose output $V_c + V_{RF}$ goes to a voltage-to-time converter. This produces a pulse train V_1 , whose width is proportional to $V_c + V_{RF}$. The chopping section also generates a signal with an amplitude proportional to $V_c - V_{RF}$ and

Figure 33. Power meter with thermocouple-based sensor.

Figure 34. Calorimetric method based on a substitution technique.

a frequency of a few kilohertz, which is further amplified. The signals V_1 and V_2 enter an electronic switch, whose output is measured by a medium-value meter M . This measure is proportional to the RF power, because

$$P_{RF} = \frac{(V_c + V_{RF})(V_c - V_{RF})}{4R} = \frac{V_c^2 - V_{RF}^2}{4R} \quad (73)$$

Owing to the differential structure of the two bolometers, this device is capable of performing RF power measurements independent of the surrounding temperature. In addition, an offset calibration can be carried out when P_{RF} is null and V_c is equal to V_{RF} .

These instruments can range from 10 mW to 1 μ W and utilize sensors with frequency bandwidths ranging from 10 kHz to 100 GHz.

Thermocouple-Based Power Meters. Thermocouples (14) can be also used as RF power meters up to frequencies greater than 40 GHz. In this case the resistor is generally a thin-film type.

The sensitivity of a thermocouple can be expressed as the ratio between the dc output amplitude and the input RF power. Typical values are 160 μ V/mW for a minimum power of about 1 μ W.

The measurement of voltages of some tens of millivolt requires strong amplification, such that the amplifier does not introduce any offset. For this purpose, a chopper microvoltmeter is utilized (16), as shown in the Fig. 33. The thermocouple output voltage V_{dc} is chopped at a frequency of about 100 Hz; the resulting square wave is filtered to its mean value and then input to an ac amplifier to further reduce offset problems. A detector, synchronized to the chopper, and a low-pass filter transform the amplified square-wave voltage to a dc voltage, which is finally measured by a voltmeter.

Figure 35. Calorimetric method based on a comparison technique.

Figure 36. Circuit for diode-sensor-based power measurement.

Calorimetric Method. For high frequencies a substitution technique based on a calorimetric method is utilized (Fig. 34) (17). First, the unknown RF power P_{RF} is sent to the measuring device t , which measures the equilibrium temperature. Then, once the calorimetric fluid has been cooled to its initial temperature, dc power P_{dc} is applied to the device and regulated until the same temperature increase occurs in the same time interval. In this way, a thermal energy equivalence is established between the known P_{dc} and the measurand P_{RF} .

A comparison version of the calorimetric method is also used for lower-frequency power measurements (Fig. 35). One measures the temperature difference ΔT in a cooling fluid between the input (1) and the output (2) sections of a cooling element where the power P to be measured is dissipated. In this case, the power loss will correspond to P :

$$P = C_p \rho Q \Delta T \quad (74)$$

where C_p is the specific heat, ρ the density, and Q the volume flow of the refreshing fluid.

Diode-Sensor-Based Power Measurements. Very sensitive (down to 0.10 nW, -70 dBm) high-frequency (10 MHz to 20 GHz) power measurements are carried out through a diode sensor by means of the circuit in Fig. 36 (18). In particular, by a suitable selection of the components in this circuit, either true-average power measurements or peak power measurements can be performed.

The basic concept underlying *true-average power measurements* exploits the nonlinear (quadratic) region of the characteristic of a low-barrier Schottky diode (nonshaded area in Fig. 37). In this region, the current flowing through the diode is proportional to the square of the applied voltage; thus the diode acts as a quadratic-characteristic sensor.

In the essential circuit of diode sensor-based wattmeters shown in Fig. 36, the measurand v_x , terminated on the

Figure 37. Characteristic of a low-barrier Schottky diode.

matching resistor R_m , is applied to the diode sensor D_s working in its quadratic region in order to produce a corresponding output current i_c in the bypass capacitor C_b . If C_b has been suitably selected, the voltage V_c between its terminals, measured by the voltmeter amplifier V_a , is proportional to the average of i_c , that is, to the average of the squares of instantaneous values of the input signal v_x , and hence to the true-average power.

In the true-average power measurement of nonsinusoidal waveforms having the biggest components at low frequency, as in RF amplitude modulation (AM), the value of C_b must also satisfy another condition. The voltage v_d on the diode must be capable of holding the diode switched on (conducting) even for the smallest values of the signal. Otherwise, in the valleys of the modulation cycle, the high-frequency modulating source is disconnected by the back-biased diode and the measurement is therefore misleading.

On the other hand, for the same signal but for a different selection of the C_b value, the circuit can act as a peak detector for *peak power measurements*. As a matter of fact, the voltage v_c on the bypass capacitor C_b during the peak of the modulation cycle is so large that in the valleys the high-frequency peaks are not capable of switching the diode into conduction; thus these peaks do not contribute to the measured power level.

If higher power levels have to be measured (10 mW to 100 mW), the sensing diode is forced to operate outside the quadratic region, in the linear region (shaded area in Fig. 37). In this case, the advantage of true-average power measurements for distorted waveforms is lost, and for peak power measurements, since the diode input-output characteristic is nonlinear and the output is quadratic, spectral components different from the fundamental introduce significant measuring errors.

POWER METERS

Several kinds of power meters are employed in electrical and electronics engineering. Depending on the specific application, a unique power meter must be used. A description of the main kinds of power meters (dc power meters, ac power meters for electric power applications, and power meters for high-frequency electronic systems) follows. In electronic circuits, for the frequency range of approximately 1 Hz to 500 kHz, depending on the nature of the signal, power may be measured with instruments implementing methods similar to those employed in ac power meters for electric power applications or power meters for high-frequency.

DC POWER METERS

The direct current (dc) power dissipated in a load resistance R_L may be calculated from measured voltage across R_L (with a dc voltmeter) and measured current flowing through R_L (with a dc ammeter). This task may be performed in the two circuit configurations that are shown in Fig. 1. In the circuit of Fig. 1(a), the voltmeter measures the voltage drop V_L across

R_L , while the ammeter measures the sum of two currents, I_L , flowing through R_L , and I_V , flowing through the voltmeter. If no correction associated with I_V is made, then the dc power is calculated as

$$P_{(a)} = IV_L = (I_L + I_V)V_L \quad (1)$$

If a correction for I_V is made, then the power dissipated in the load, P_L , is calculated as

$$P_L = I_L V_L = IV_L - I_V V_L = P_{(a)} - P_V \quad (2)$$

where $P_V = I_V V_L$ is the power dissipated in the voltmeter. The worst-case relative error with which the P_L is measured in the circuit of Fig. 1(a) while correction for I_V is made is

$$\delta_{PL(a)} = \frac{I}{I_L} \delta_I + \delta_{VL} + \frac{I_V}{I_L} \delta_{IV} \quad (3)$$

where δ_I is the relative measurement error of I (error of the ammeter), δ_{VL} is the relative measurement error of V_L (error of the voltmeter), and δ_{IV} is the relative error with which the I_V has been estimated (calculated from known voltmeter resistance R_V and measured V_L). If the power calculated from Eq. (1) is taken as the result of a measurement (no correction is applied), then the error of the P_L in the circuit shown in Fig. 1(a) is

$$\delta_{PL(a)} = \frac{I}{I_L} \delta_I + \delta_{VL} + \frac{I_V}{I_L} \quad (4)$$

If the circuit of Fig. 1(b) is used to measure P_L , then the ammeter measures the current I_L flowing through R_L , while the voltmeter measures the sum of two voltage drops, V_L across R_L , and V_A across the ammeter. If no correction related to V_A is made, then the dc power is calculated as

$$P_{(b)} = I_L V = I_L (V_L + V_A) \quad (5)$$

If a correction for V_A is made, then the power dissipated in the load, P_L , is calculated as

$$P_L = I_L V_L = I_L V - I_L V_A = P_{(b)} - P_A \quad (6)$$

where $P_A = I_L V_A$ is the power dissipated in the ammeter. The worst case relative error with which the P_L is measured in the circuit of Fig. 1(b) while correction for V_A is made is

$$\delta_{PL(b)} = \delta_{IL} + \frac{V}{V_L} \delta_V + \frac{V_A}{V_L} \delta_{VA} \quad (7)$$

where δ_{IL} is the relative measurement error of I_L (error of the ammeter), δ_V is the relative measurement error of V (error of the voltmeter), and δ_{VA} is the relative error with which the V_A has been estimated (calculated from known ammeter resistance R_A and measured I_L). If the power calculated from Eq. (5) is taken as the result of a measurement (no correction is applied) then the error of the P_L is

$$\delta_{PL(b)} = \delta_{IL} + \frac{V}{V_L} \delta_V + \frac{V_A}{V_L} \quad (8)$$

Figure 1. Dc power measurement using a voltmeter and an ammeter. There are two possible measurement circuits: (a) direct V_L measurement, where the voltage drop across the load is measured directly but the ammeter measures a sum of load current and voltmeter's current, and (b) direct I_L measurement. The result of power measurement needs to be computed from the measured voltage and current.

To decide which of the two circuits is preferable, errors $\delta_{PL(a)}$ and $\delta_{PL(b)}$ need to be compared. The circuit that gives a lower measurement error is preferred. The key criterion obtained from this comparison is: which of the two ratios is smaller, I_V/I_L or V_A/V_L ?

Power meters process the information of I_L and V_L and display the measured power with given accuracy. Block diagrams of two dc power meters are shown in Fig. 2. The circuit shown in Fig. 2(a) implements analog multiplication of signals proportional to V and I_L . The output voltage of an analog multiplier, V_O , is proportional to the product of two input voltages. In the circuit of Fig. 2(a), V_O is proportional to the power dissipated in R_L and may be converted to a digital form with an analog-to-digital converter (ADC), or displayed in an analog form. Analog multipliers are integrated circuits and they allow the presence

of a limited voltage at their inputs. Therefore, when the input voltage V is equal or exceeds the full scale value, a voltage attenuator needs to be employed. Or else, if V is too small to be processed with the smallest possible error, an amplifier needs to be used. In circuits of Fig. 2, current I_L is converted to voltage with a current sensor that has a low-pass frequency response (includes dc in its frequency range). The benefit of this type of current to voltage conversion is a small equivalent R_A resistance. Also, the current sensor may be of clamp-on type, that makes the connection of the power meter to the circuit under test very easy. Output voltage from current sensors is always a small value and requires amplification before it is applied to the input of the analog multiplier. Integrated circuits specially designed for applications in power measurement circuits are available. An example of such a device is the AD7750 product-to-frequency converter from the Analog Devices company (World Wide Web Site: <http://www.analog.com>).

The circuit depicted in Fig. 2(b) shows block diagram of a digital power meter. Instead of using the analog multiplier, voltages proportional to V and I_L are converted to a digital form with ADCs. Digital values D_V and D_I proportional to V and I_L are then processed by the digital part of the power meter. The circuit shown in Fig. 2(b) uses two ADCs, but sometimes one DAC and an analog multiplexer in front of it may be used.

Measurement errors of circuits shown in Fig. 2 are computed similarly as errors for the circuit shown in Fig. 1(b); see Eqs. (5) to (8). An equivalent voltage V_A (or equivalent R_A) may be specified for the current sensor as for an ammeter.

AC POWER METERS USED IN ELECTRIC POWER APPLICATIONS

Instantaneous power p is a product of current i and voltage v that are functions of time t

$$p(t) = i(t)v(t) \quad (9)$$

Fig. 3(a) shows sinusoidal $i(t)$ and $v(t)$ as functions of phase angle ωt . In the graph, the phase shift of v is assumed to be 0° and current i lags the voltage by 50° (inductive-resistive load). The power p for these v and i is shown in Fig. 3(b). In cases when the instantaneous power is the signal that carries the desired information, circuits like those shown in Fig. 2 are used. An example of using the instantaneous power as a medium for fault detection of electric motors is described in the paper of

Figure 2. Dc power meters provide the value of measured power. One of two methods of computing the power may be employed: (a) analog power computation, (b) digital power computation.

Figure 3. Ac voltage, current, and instantaneous power, (a) sinusoidal $v(t)$ and $i(t)$, (b) instantaneous power $p(t)$. Instantaneous power is a function of time and may take positive or negative values.

Legowski, Ula, and Trzynadlowski (1). In order to update the circuits shown in Fig. 2 to ac applications, an ac voltage source with Thévenin equivalent impedance $Z_S(s)$ needs to be used in place of the dc voltage source. As the load in ac circuits an impedance $Z_L(s)$, rather than R_L , needs to be used. All symbols of voltages and currents need to be changed to those that represent ac signals. In these modified circuits, the output voltage from the block “Attenuator or Amplifier” is proportional to $v(t)$ and the output voltage from the block “Amplifier” is proportional to $i_L(t)$. In the ac circuit similar to the one shown in Fig. 2(a), the output voltage from the analog multiplier is $v_o(t)$ and is proportional to $p(t)$. While using this circuit, the $v_o(t)$ is further processed in an analog circuit or sampled with an ADC and processed digitally. In the ac circuit similar to the one shown in Fig. 2(b), output voltages from the “Attenuator or amplifier” and “Amplifier” are sampled with ADCs at a sampling frequency suitable for the digital signal processing of the $p(t)$. In both circuits, the bandwidth of the current sensor, “Attenuator or amplifier,” and “Amplifier” must match the bandwidths of $v(t)$ and $i_L(t)$. In order to recall the other definitions of power in ac circuits, assume that the excitation is sinusoidal and the circuit is linear. Thus phasor analysis may be used. Definition

Figure 4. Phasor diagram of voltage, current, and power.

of the complex power is

$$\underline{S} = \frac{1}{2} \underline{V} \underline{I}^* \quad (10)$$

which results in

$$\underline{S} = P + jQ \quad (11)$$

where P is the active power (or real power, or average power), and Q is the reactive power. A phasor diagram that shows a superposition of current, voltage, and power phasors is shown in Fig. 4. This phasor diagram shows a specific case for which the phase shift of the voltage is equal zero. The active power and reactive power are

$$P = \frac{1}{2} V_p I_p \cos \Theta \quad [\text{W}] \quad (12)$$

and

$$Q = \frac{1}{2} V_p I_p \sin \Theta \quad [\text{VAR}] \quad (13)$$

where V_p is the peak value of the voltage, I_p is the peak value of the current, and Θ is

$$\Theta = \phi_V - \phi_I$$

In the last equation, ϕ_V is the phase shift of the voltage, and ϕ_I is the phase shift of the current. The apparent power is the magnitude of CBISul;

$$|\underline{S}| = \sqrt{P^2 + Q^2} = \frac{1}{2} V_p I_p \quad [\text{VA}] \quad (14)$$

A graph of various components of ac power in the time domain (as functions of phase shift ωt) is shown in Fig. 5. As before, $\phi_V = 0^\circ$ and $\phi_I = -50^\circ$ have been chosen for the figure. In this figure, two components of $p(t)$ are shown, $p_p(t)$ representing the energy

Figure 5. Components of ac power in time domain.

flow into the load impedance, and $p_Q(t)$ which characterizes the energy borrowed and returned by the load impedance. The real power P is at the same time the average value of $p(t)$ and also the average value of $p_p(t)$. The reactive power Q is the peak value of $p_Q(t)$, while the average value of $p_Q(t)$ equals zero. The apparent power $|S|$ equals one half of the peak-to-peak value of $p(t)$. A description of power in ac circuits may be found in the book by Cunningham and Stuller (2).

Ac power meters are designed to measure individual components of the ac power (including power factor, $PF = \cos\Theta$) or given sets of these components. The electrodynamic instrument (or dynamometer, or electrodynamicometer) is the moving coil instrument that measures active power. The main parts of its mechanism are shown in Fig. 6(a). Between 1843 to 1910, the work of researchers like Wilhelm E. Weber, Lord Kelvin, James P. Joule, Andre Marie Ampere, and the brothers Werner and William Siemens made possible the development of a reliable electrodynamic instrument that started to be mass manufactured. In it, the magnetic field is produced by a two-part fixed coil conducting current i_f . This magnetic field and current i_m in the moving coil produce a torque that turns the moving mechanism of the meter. Fig. 6(b) depicts a circuit in which ac power is measured [similarly as shown in Fig. 1(b)] with the electrodynamic instrument. The average value of the torque is

$$T_m = \frac{1}{T} \int_0^T i_m i_f \frac{dM}{d\alpha} dt \quad (15)$$

where M is the mutual inductance between the moving and fixed coils, α is the angular deflection of the moving coil, and T is the period of i_f and i_m . In series with the moving coil is connected a reference resistor R_V that makes the current i_m proportional to the voltage v . Current i_m is carried to the moving coil by two control springs (that produce the reference restoring torque) and the shaft of the moving mechanism. The position of the pointer that is attached to the shaft of the moving mechanism is read from a scale in watts. The electrodynamic instrument can measure dc power. When ac power is measured, the averaging effect of the T_m is produced by the inertia of the moving mechanism. Therefore, it is not possible to measure the power at frequencies below 10 Hz or so, because the averaging effect is not in place yet. On the other hand, the electrodynamic

Figure 6. Electrodynamic power meter. Inductance L_f is formed by a series connection of two inductors. Rotating inductor L_m is placed in the middle of these two inductors.

instrument may be used for frequencies up to 400 Hz. These instruments are optimized for measurements at 50 Hz or 60 Hz and may be used for sine wave signals with limited nonlinear distortions (harmonics of the line current up to the seventh harmonic are included in their frequency range). Measurement error of these instruments is usually in the range from 1% to 5% when the measured power equals the full scale value. When smaller than full scale values are measured, the measurement error increases accordingly. Other types of power meters that convert electric power to deflecting torque, for example, electrostatic wattmeters or moving-iron wattmeters, were also developed. Meters of other components of electric power, for example, power-factor meters and reactive power meters (varmeters), have been developed too. More information on torque based measurement instruments may be found in books by Kidwell (3) and Kinnard (4).

Figure 7 shows the block diagram of single phase electronic power meter. This instrument measures a set of components of the ac power that includes true rms values of line current and line voltage and the active power. The electronic power meter shown in Fig. 7 uses analog integrated circuits to convert the line current and voltage to their rms values and to produce a signal proportional to the instantaneous power. The ADCs in this type of wattmeter are of the integrating type (similar to

Figure 7. Single-phase electronic power meter with analog computation circuit. The output voltage from the multiplier is proportional to the instantaneous power. Digital output of the integrating analog-to-digital converter is proportional to the average power.

those used in digital multimeters). The integrating ADC converts the output voltage from the analog multiplier, that is, proportional to the instantaneous power, to its average value over the time of integration, that is, to the active power. The power factor may be computed from these measurements using Eq. (12) if v_{line} and i_{line} are sinusoidal. Also, reactive power and apparent power may be computed.

Electronic power meters are digital instruments. An example of this class of power meters are the instruments developed by Valhalla Scientific (5) and Fluke (6,7). They are more accurate than electrodynamic instruments, measure more than one component of power, and have several ranges of measured quantities. Electronic power meters may measure active power in the range from 1 mW to 12 kW, voltage from 1 V to 600 V, current from 0.1 mA to 20 A. They have much better frequency characteristic than the electrodynamic instrument. Electronic wattmeters can be used for measuring dc power and ac power from 20 Hz to 500 kHz. They have the total measurement uncertainty from 0.1% to 0.5% of reading for frequencies up to 5 kHz or 10 kHz. For frequencies larger than that the uncertainty deteriorates, and is from 2% to 5% at 20 kHz. It worsens

further for increasing frequencies. Electronic power meters may be used when the current's crest factor is in the range from 2.5:1 to 50:1, depending on the ratio of the rms value of the measured current to the full scale value. The smaller this ratio is, the larger the crest factor may be.

In the circuit of Fig. 7, a Hall effect current sensor is used. There are three types of current sensors: (1) resistive shunt (for currents lower than 500 A), (2) current transformer, and (3) Hall effect device. Two kinds of resistive shunts are made, for frequencies up to 100 Hz and for frequencies exceeding 500 kHz. Among the advantages of the resistive shunt current sensors are: they convert dc and ac current, are very reliable, do not produce offset voltage, and those made for frequencies below 100 Hz are not expensive. To the disadvantages of these current sensors belong: a lack of electrical isolation from the line voltage, significant power loss, they require amplification of the output voltage, those made for frequencies exceeding 500 kHz are expensive. Current transformer type sensors may sense currents up to 100 kA and their output current may be easily converted to voltage. Their advantages include: electrical isolation from the line voltage, they are very reliable, and

Figure 8. Three-phase power measurement circuits: (a) circuit for Δ connected load or two power meter circuit, and (b) circuit for Y connected load with neutral line or three power meter circuit.

low cost. The disadvantages are: they sense ac current only, the power loss is not negligible, their output current is frequency dependent, and they are susceptible to stray ac magnetic fields. The Hall effect current sensors can measure dc and ac currents. They provide electrical isolation from the line voltage, may measure large currents (3 kA or so), some have bandwidth from dc to 200 kHz, and they are very reliable. The disadvantages include: they require external power supply and the output signal includes an offset that needs to be compensated. An electronic power meter may include resistive shunt current sensors. In such a case, the range of the current input may be increased up to a few kiloamperes by using additional current transformers. However, use of current transformers increases the measurement error by about 1% or 2% and the frequency range will be limited to a range from 40 Hz to about 400 Hz. More information on current sensors is provided in the paper written by Drafts (8).

Figure 8 shows circuits for three phase power measurements with single-phase power meters. The circuit shown in Fig. 8(a) is used when the load is Δ connected and only three phase lines are used. In such a case two power meters are used. Inputs to "Power meter 1" are i_A and v_{AB} , while inputs to "Power meter 2" are i_B and v_{CB} . Power delivered to the three phase load is

$$P_{3\phi 3W} = P_1 + P_2 \quad [W] \quad (16)$$

where $P_{3\phi 3W}$ is the total active power measured in the three-phase, three-wire circuit, P_1 and P_2 are the active powers measured by "Power meter 1" and "Power meter 2", respectively. Figure 8(b) shows the measurement circuit used when in addition to the three phase lines the neutral conductor is used. Three power meters are used in such a case. Inputs to the "Power meter 1" are i_A and v_{AN} , inputs to the "Power meter 2" are i_B and v_{BN} , and inputs to the "Power meter 3" are i_C and v_{CN} . The power delivered to the three phase load is

$$P_{3\phi 4W} = P_1 + P_2 + P_3 \quad [W] \quad (17)$$

where $P_{3\phi 4W}$ is the total active power measured in the three-phase, four-wire circuit, P_1 , P_2 , and P_3 are the active powers measured by "Power meter 1", "Power meter 2", and "Power meter 3", respectively.

In many cases, for example, when adjustable speed drives are used to drive electric motors, the line current is not sinusoidal at all. An adjustable speed drive may be supplied from a single phase line (this is not a typical case), as it is shown in Fig. 9(a), or from a three-phase line, as shown in Fig. 9(b). An adjustable speed drive contains a rectifier with a huge capacitance at its output and an inverter that converts the dc supply to

Figure 9. Adjustable speed motor drives: (a) motor drive with single-phase input or single-phase or three-phase converter, (b) motor drive with three-phase input or three-phase to three-phase converter.

Figure 10. Line current of an adjustable speed drive, (a) timing diagram, (b) spectrum.

adjustable frequency three-phase supply. Because of this huge capacitance the line current i_{line} has a form of relatively narrow pulses. An oscillogram of i_{line} of a single phase inverter is shown in Fig. 10(a) and spectrum of it is shown in Fig. 10(b). Because i_{line} may be of the nature shown in Fig. 10(a), one of the important parameters of a power meter is the maximum acceptable crest factor of the current. A power meter usually has an indicator in the form of a light-emitting diode (LED) that warns the user when the current has too large of a crest factor and the measurements are unreliable. An example of waveforms on the output from the "Adjustable speed drive" that drove a 60 hp induction motor are shown in Fig. 11(a) and (b). The inverter used in the adjustable speed drive that produced these signals was a voltage source type and the direct torque control was used in it. Line-to-line voltages at the output of this drive are pulse trains, as shown in Fig. 11(a). Because an inductive load is driven by the drive, the current waveform is similar to the integral of the voltage and are sinusoidal with a ripple component, as shown in Fig. 11(b). Figure 11(c) shows the spectrum of the line current. An analysis of the graphs shown in Fig. 11 makes it clear that high-bandwidth instruments must be used

Figure 11. Line-to-line voltage and line current of an adjustable speed drive, (a) line-to-line voltage, (b) line current, (c) spectrum of line current.

to measure the output power of the “Adjustable speed drive” shown in Fig. 9. Electronic instruments called power analyzers are used to make these measurements. They are capable to measure power delivered to the “Adjustable speed drive” (rectifier with a large capacitor on its output), as well as the output power of the “Adjustable speed drive.” A block diagram

of a power analyzer is shown in Fig. 12. It has three input channels, but it may be used in any configuration, from single-phase power meter to three-phase, three-wattmeter measurement system. Current inputs accept various current sensors. Signal-processing methods are used to compute all components of three phase power, including spectrum analysis of line currents. Every channel has a “Programmable attenuator” and “Programmable amplifier” for matching the signal levels with the ranges of ADCs. These ADCs sample the signals with sampling frequency that is required for processing signals like these shown in Figs. 10 and 11. Every programmable attenuator/amplifier with its ADC is supplied by a floating power supply, because its input is connected to a three-phase system. Digital signals from every programmable attenuator/amplifier are transmitted through isolation circuits to the digital signal processing (DSP) system, where the signal processing takes place. Power analyzers may be used as instruments in a measurement system using the IEEE-488 Bus or connected to a computer using the RS-232-C transmission line. Power analyzers measure active power, reactive power, apparent power, power factor, rms value of voltages and currents, peak values of voltages and currents, crest factor of voltages and currents, peak inrush current, impedance, spectrum of voltages and currents (fundamental frequency, up to 99th harmonic, and total harmonic distortion), and integrals of active and reactive power (Whr and Varhr). Active power range is from 25 mW to 400 kWp, voltage range is from 0.5 V to 2 kVp, current range is from 50 mA to 200 Ap, frequency range from 0.1 Hz to 500 kHz. Measurement uncertainty is usually in the range from 0.05% to 0.2% of the reading. An example of this kind of instrument is the Voltech power analyzer (9).

Example of a measurement circuit for efficiency measurements of induction motors driven by the “Adjustable speed drive” is shown in Fig. 13. This kind of measurements must follow requirements described in appropriate standards, for example, IEEE Std. 112, and it is feasible to make these measurements in a computer-controlled system, as shown in Fig. 13. In this system, as the load of the motor under test a programmable dynamometer made of a dc generator with digitally controlled field current is used. The dynamometer is adjusted to the required power range by changing the load of the dc generator. The input power is measured with the power analyzer, while the mechanical power is measured with the torque measurement system. Measurement of temperature in up to 8 points of the motor under test is necessary in some measurement protocols.

MECHANICAL POWER METERS

A block diagram of a mechanical power meter used in the measurement system of Fig. 13 is shown in Fig. 14. A torque transducer is inserted in the shaft connecting the motor under test with the dynamometer. The torque transducer consists of a reference part of the shaft (reference diameter and material) with a strain gauge bridge (R_1 , R_2 , R_3 , and R_4) affixed to its surface in such a way that the output signal from the bridge is proportional to the torque. The bridge is used as an ac bridge at carrier frequency in the range from 1 kHz to 20 kHz. Supply voltage to this bridge and the output signal from the bridge are transmitted between the stationary measurement system and

Figure 12. Three-phase electronic power analyzer using digital computation method. Successive approximation digital-to-analog converters are used to acquire samples of phase voltages and phase currents. Signal processing is used to compute parameters of a three-phase system.

Figure 13. Automatic system for measuring efficiency of electric motors. The dc generator is used as a programmable load for the motor under test. Various test programs may be carried out in this system.

Figure 14. Mechanical power meter for measurement of power transmitted by a shaft. A torque transducer that includes a rotating strain gauge bridge needs to be installed in the shaft.

the rotating shaft with two rotary transformers. The ac bridge is used because of very large interference of noise to the sensing part of the meter. The output voltage from the bridge is a very low level signal, hence a large voltage gain amplifier must be used before the signal can be rectified with the synchronous demodulator. The synchronous demodulator uses a reference voltage from the same oscillator that produces the excitation for the bridge and has the ability of rejecting dc offset and the noise, and passing only the signal of frequency of the oscillator. As the synchronous demodulator the integrated circuit AD630 from Analog Devices, described in the Analog Devices databook (10), may be used. The signal from the oscillator that is used as the reference for the synchronous demodulator must have its phase shift adjusted accordingly with the phase of the output signal from the bridge. The dc value of the output voltage from the synchronous demodulator (average value of the output voltage) carries the information of changes of resistances of the bridge. The dc value of the output voltage from the synchronous demodulator is obtained by using a low-pass filter. The AD630 with ease allows the measurement of change of bridge resistances of 0.5 ppm, which corresponds to a 3.2 mV change in the output voltage from the low-pass filter. The dc output voltage from the low-pass filter is proportional to torque. This output voltage is converted to a corresponding digital value with the ADC. In addition to torque, the velocity of the shaft is measured and the results are stored in the microprocessor system. Mechanical power is computed in the microprocessor system based on the measured torque as

$$P_m = \frac{V_{avg} T}{63025} \quad (18)$$

where P_m is the mechanical power in horsepower, T is the torque in pounds per inch, and V_{avg} is the average shaft velocity in revolution per minute. An example of the mechanical power meter is the torque transducer and mechanical power instrument from the Himmelstain company (11).

POWER METERS FOR HIGH FREQUENCY (HF) ELECTRONIC SYSTEMS

Electronic systems employ a very wide frequency range, from dc to hundreds of gigahertz, and a great variety of waveforms,

ranging from continuous wave (CW unmodulated and modulated sinewaves) to complex pulse trains. Values of measured power range from tenths of picowatt to several kilowatts. A number of measurement methods are used to measure the power of these diverse signals. In electronic systems that operate in the radio frequency (RF) and microwave frequency ranges from about 100 kHz to 110 GHz, active power is the most frequently measured quantity. In this frequency range, power meters belong to the group of typical instruments used for evaluating electronic systems. An HF power meter consists of a power sensor, which converts active power of a RF or microwave signal to a dc or low-frequency signal proportional to the active power and a power meter (also called an RF meter). For a given kind of signal and its range of frequency, a right power sensor must be selected from a set of more than twenty different kinds of power sensors. One power meter may work with a few power sensors that were designed specifically for this power meter. Therefore, power sensors and the power meter must be of the same brand, say Hewlett-Packard or Rhode & Schwartz. Three methods of power sensing are used and they are described below. Results of power measurements are expressed as absolute power in watts (W) or as relative power in dBm. The definition of dBm is

$$\text{dBm} = 10 \log_{10} \left(\frac{P}{1\text{mW}} \right) \quad (19)$$

where the active power P is expressed in milliwatts. The active (or average) power in RF and microwave power measurements is averaged over many periods of the signal and is defined as

$$P_{avg} = \frac{1}{nT_1} \int_{t_0}^{t_0+nT_1} v(t)i(t) dt \quad (20)$$

where T_1 is the period of the lowest frequency component of $v(t)$ and $i(t)$. The averaging time is typically in the range from several hundredths of a second to a few seconds and is much greater than T_1 ; therefore it is not essential to integrate over an integer number of periods of $v(t)$ and $i(t)$. For pulse type signals,

Figure 15. Envelopes of power pulses, (a) rectangular power pulses, (b) sinusoidal power pulses.

the pulse power is defined as

$$P_P = \frac{1}{\tau} \int_{t_0}^{t_0+\tau} v(t)i(t) dt \quad (21)$$

where τ is the pulse width, defined as a time from the instance when the rising edge rises to 50% of the pulse amplitude to the instance when the falling edge falls to 50% of the pulse amplitude. Two envelopes of power pulses are shown in Fig. 15. The envelope of power shown in Fig. 15(b) represents a pulse train of single periods of the function $[1 - \cos(\omega t)]$. This shape of pulses has been chosen because it is easy to envision the three values of power for this signal [which are depicted in Fig. 15(b)]. Measurements of pulse power as defined by Eq. (21) are difficult to perform, therefore another definition of the pulse power is also used:

$$P_{Pa} = \frac{P_{avg}}{DT} \quad (22)$$

where DT is the duty cycle defined as

$$DT = \frac{\tau}{T} \quad (23)$$

Only for a rectangular power envelope $[p_e(t)]$ such as the one shown in Fig. 15(a) will the definitions described by Eqs. (21) and (22) give the same result. For the particular power envelope shown in Fig. 15(b), the peak value of $p_e(t)$ equals P_{Pa} . For many practical kinds of power envelopes, as for example, Gaussian pulse shape used in certain navigation systems, the peak value of $p_e(t)$ is not equal P_{Pa} . Power meters for many other kinds of complex signals, like fast digital phase-shift-keyed modulation

or multiple carrier signals, are also available. Proper selection of a power sensor and power meter adequate for the specific kind of measured signal is a critical factor in accurate power measurements.

The measured power may be the terminating power, that is the power absorbed in a load, or directional power, that is forward or reflected power. For measuring the terminating power, the measurement usually made, the power sensor is used in place of the load. The readout from the power meter is affected by errors related to inaccuracies of:

1. the HF part of the circuit, because the HF power dissipated in the power sensor is slightly different from the power that would be dissipated there if everything in the circuit is perfect (in the description that follows, the perfect parameters are called "ideal")
2. the circuit that produces dc or low frequency power equal to the HF power dissipated in the power sensor (this function is performed by a closed loop control system)
3. the measurement circuit of the dc or low frequency power

Denote the HF power actually dissipated in the load (the HF power dissipated in the power sensor) as P_1 and the ideal amount of power that would be dissipated there when the HF part of the circuit is perfect as $P_{l,ideal}$. The relationship between P_1 and $P_{l,ideal}$ is

$$P_1 = \frac{1 - |\Gamma_1|^2}{|1 - \Gamma_s \Gamma_1|^2} P_{l,ideal} \quad (24)$$

where Γ_1 is the reflection coefficient of the load (a complex number with magnitude ρ_1 and phase shift ϕ_1) and Γ_s is the reflection coefficient of the source (a complex number with magnitude ρ_s and phase shift ϕ_s). Denote the dc or low frequency power that substitutes the HF power as P_{sub} . Inaccuracy of the substitution process is represented by the effective efficiency η_e

$$\eta_e = \frac{P_{sub}}{P_1} \quad (25)$$

Recalling that

$$P_1 = P_i - P_r \quad (26)$$

where P_i is the incident power and P_r the reflected power, and that the calibration factor κ_{cal} is

$$\kappa_{cal} = \frac{P_{sub}}{P_i} \quad (27)$$

the following relationship between the effective efficiency and calibration factor may be written

$$\kappa_{cal} = \eta_e(1 - |\Gamma_1|^2) \quad (28)$$

If the result of the HF power measurement displayed by the power meter is denoted as P_m , its departure from the $P_{m,ideal} = P_{sub}$ is expressed by the equation

$$P_m = \xi P_{m,ideal} + P_{m,os} \quad (29)$$

where ξ represents the gain coefficient (ideally $\xi = 1$) and $P_{m,os}$ represents the offset error ($P_{m,os}$ may be a positive or negative number, ideally $P_{m,os} = 0$). Hence, the relationship between the readout from the power meter and the ideal value of HF power delivered to the power sensor is

$$P_m = \xi \kappa_{cal} \frac{P_{l,ideal}}{|1 - \Gamma_s \Gamma_l|^2} + P_{m,os} \quad (30)$$

A more detailed description of the accuracy of HF power measurement may be found in the Hewlett-Packard Application Note 64-1A (12).

Power sensor circuits are quite complex and only basic principles of their operation are described below. Every power sensor is characterized by a set of calibration coefficients that may be stored in an EEPROM installed in the power sensor unit. The power meter reads these calibration coefficients and automatically implements them in computations of the result of a measurement. Peak power analyzers for power measurements in pulsed RF and microwave electronic systems are also available. A broader description of RF and microwave power measurements may be found in Hewlett-Packard's Application Notes 64-1A (12) and 64-4A (13). Parameters of power sensors and power meters currently available from the Hewlett-Packard company may be found in the product catalog (14) and listed there publications. Power sensors and RF meters offered by the Rhode & Schwartz company may be found in the Tektronix company's catalog of measurement products (15). The author also referred to unpublished materials written by Barp (16).

Thermistor Power Sensors and Power Meters

Bolometers are power sensors that implement devices whose resistance is a function of temperature. The increment of temperature of such a device is proportional to the increment of active power dissipated in it, no matter what kind of signal (ac or dc) is delivering the power. Hence, bolometers possess a power substitution ability that is beneficial in transferring standards. There are two types of bolometers, barretters and thermistors. A barretter is a very small power (about 10 mW) metallic resistor. Power sensors using barretters are not manufactured any more because the allowed overload of a barretter is small and its damage may readily occur. Power sensors employing thermistors are still fabricated, but they are not typical power sensors now. Their frequency range is limited and their impedance matches are not good. The main use of thermistor power sensors is as power transfer standards to references, for example, at the National Institute of Standards and Technology (NIST) in Boulder, CO, and in the round robin procedures. Thermistors are mounted in either coaxial or waveguide structures. Figure 16 shows the circuit of the RF thermistor power sensor and Fig. 17 shows the measurement circuit of the power meter. Thermistors TRF1 and TRF2 are heated by the input RF signal, v_{RFin} , and a portion of the dc supply voltage of the measurement circuit, V_{RF} . The RF signal is applied through the coupling capacitor C_C to thermistors TRF1 and TRF2 connected in parallel (for the RF signal, the bypass capacitor C_{b1} connects the terminal RFB2 to the ground). Thermistors TRF1 and TRF2 are connected to the dc bridge measurement circuit using terminals RFB1 and RFB2, therefore in the dc bridge they are connected in series. Equivalent resistance of the parallel connection of R_{TRF1} and R_{TRF2} equals a matching impedance

Figure 16. HF thermistor power sensor. Two thermistors TRF are used to convert HF power to an equivalent dc or low frequency voltage. Two thermistors TC are used to compensate for changes of ambient temperature.

for the transmission line (50Ω or 75Ω). This equivalent resistance is maintained constant (temperature of TRF1 and TRF2 is maintained constant) and independent of the amount of RF power delivered to it as well as of ambient temperature variations. The dc voltage across thermistors TRF1 and TRF2 equals $0.5V_{RF}$. The power meter keeps the sum of the RF power and dc power dissipated in R_{TRF1} and R_{TRF2} at a constant value. In order to simplify the description, first ignore the presence of R_{TC1} and R_{TC2} in the circuit. For $v_{RFin} = 0$, the V_{RF} has its largest value (the whole power dissipated in R_{TRF1} and R_{TRF2} is delivered from the dc voltage source) corresponding to the full scale power. When v_{RFin} produces in R_{TRF1} and R_{TRF2} one half of the full scale power, then V_{RF} delivers one half of the full scale power. When the v_{RFin} delivers the full scale power, then the $V_{RF} = 0$. The second pair of thermocouples, TC1 and TC2, is used to compensate for variations of ambient temperature. All four thermistors are mounted on a thermal conducting substrate and they are in the same temperature. The bypass capacitor C_{b2} ensures that there is no RF signal between terminals CB2 and CB1. Thermistors TC1 and TC2 are a part of the compensation bridge supplied by the dc voltage V_C . For $I_{AZ} = 0$, the voltage across thermistors TC1 and TC2 connected in series equals $0.5 V_C$. Voltage V_C changes when the ambient temperature changes. The resistance temperature coefficient of thermistors is negative, thus if the ambient temperature

Figure 17. Thermistor HF power meter. This simplified circuit diagram shows a power measurement system formed by the power meter and the power sensor.

Figure 18. HF thermocouple power sensor. A pair of thermocouples is used to convert the HF power to an equivalent dc or low frequency voltage.

increases, the R_{TC1} and R_{TC2} would like to decrease. However, instead of that the V_C decreases, less power is delivered from the V_C and the R_{TC1} and R_{TC2} remain constant. The same mechanism changes V_{RF} when the ambient temperature varies. Because of that, V_{RF} must be larger than initially was assumed. The readout of the power meter is proportional to the difference ($V_C - V_{RF}$), hence V_{RF} may be made larger than the full scale V_{RFIn} (rms value of v_{RFIn}). To adjust the zero of the power meter, at $v_{RFIn} = 0$ the auto-zero circuit sets the auto-zero current I_{AZ} to a value for which the output voltage from the power meter, V_{OUT} , that is proportional to the difference ($V_C - V_{RF}$), equals zero. For increasing v_{RFIn} the V_{RF} decreases and V_{OUT} increases in proportion with the increase of V_{RFIn} .

Thermocouple Power Sensors and Power Meters

Thermocouples exhibit an inherent square-law transfer characteristic, where square-law means that the dc output voltage is proportional to the square of the input rms voltage across a reference resistance, that means to the input RF power. Thermocouple sensors are heat-based devices, consisting of a resistor that dissipates the measured power of any kind of an electric signal and the thermocouple that converts its temperature to a dc voltage. Thermocouple sensors allow power meters to be made with full scale power from $0.3 \mu\text{W}$ and with a small SWR (standing wave ratio). Thermocouple sensors are fabricated using combined thin-film and semiconductor technologies. A simplified circuit diagram of a thermocouple sensor is shown in Fig. 18. The bypass capacitor C_b is a short circuit for RF signal, thus the v_{RF} is applied to the two pairs of resistor-thermocouple connected in parallel. The equivalent resistance of this parallel connection constitutes the 50Ω or 75Ω termination resistance of the RF transmission line. However, from

the standpoint of the dc output voltage V_{OUT} , these thermocouples are connected in series, hence the V_{OUT} equals two times a voltage from a single thermocouple. Typical thermocouples' sensitivities are $250 \mu\text{V}/^\circ\text{C}$ and $160 \mu\text{V}/\text{mW}$. The transfer characteristic of the thermocouple sensor (V_{OUT} as a function of P_D) is slightly nonlinear, because its sensitivity is a little lower for large powers. The thermocouple sensor's V_{OUT} is approximately 160 nV for $1 \mu\text{W}$ of power dissipated in it, consequently the power sensor and power meter are considerably complex. Figure 19 shows a simplified block diagram of the power sensor attached to the power meter. Dc signals at such a low level as the V_{OUT} cannot be transmitted over a cable. Also, in the power meter they need to be amplified significantly. A chopper amplifier is used to obtain the required large amplification of the V_{OUT} . One-half of the gain is provided by the ac amplifier located in the power sensor enclosure, and the other one half of the gain is furnished by an ac amplifier located in the power meter enclosure. The ac output voltage from the amplifier is demodulated synchronously with the chopping signal. An auto-zero feature is implemented in the measurement scheme too. Thermocouple sensors do not have the dc substitution feature; hence it is necessary to provide a reference RF power source for calibration purposes. The output power of this reference power source is controlled with total uncertainty better than $\pm 1\%$.

Diode Sensors and Power Meters

Schottky diodes are used to build diode sensors. $P-N$ junction diodes have much smaller bandwidth than Schottky diodes, without bias have extremely high impedance, and when biased they produce a large amount of noise and thermal drift. Schottky diodes specially designed for applications in power sensors have a low potential barrier of the metal-semiconductor junction, which results in a forward voltage of about 0.3 V . They have a very large bandwidth that is within the microwave frequency range. Current-voltage ($I-V$) characteristic of these diodes may be divided into three regions: (1) the square-law region for very small voltages across the junction, (2) a linear region for large voltages, and (3) the transition region from the square-law region to the linear region. The $I-V$ characteristic is described by the approximate equation

$$I = I_S \left[\exp \left(\frac{V}{nV_T} \right) - 1 \right] \quad (31)$$

where I_S is the saturation current, n is a coefficient specific for a given type of a Schottky diode that compensates the weak

Figure 19. Thermocouple HF power meter. This simplified block diagram illustrates functions of the power meter that together with a HF thermocouple power sensor forms a power measurement system.

dependence of the saturation current on voltage V in the accurate equation, and V_T is the thermal voltage

$$V_T = \frac{kT}{q} \quad (32)$$

In Eq. (32), k is Boltzmann's constant, T is the temperature in kelvins, and q is the charge of an electron. Derivation of the Schottky diode equation may be found in the book by Muller and Kamins (17). Figure 20(a) shows the I - V characteristic of a Schottky diode designed for power sensor applications. The constant n is slightly greater than 1 and for making the graph $n = 1.07$ has been used. Schottky diodes fabricated for applications in power sensors have much larger I_S than typical Schottky diodes. The exponential term in Eq. (31) may be expanded into the infinite series form

$$\exp\left(\frac{V}{nV_T}\right) - 1 = \frac{1}{1!} \frac{V}{nV_T} + \frac{1}{2!} \left(\frac{V}{nV_T}\right)^2 + \frac{1}{3!} \left(\frac{V}{nV_T}\right)^3 + \dots \quad (33)$$

For $V \ll nV_T$ Eq. (31) may be approximated as

$$I_q = I_S \left[\frac{V}{nV_T} + \frac{1}{2} \left(\frac{V}{nV_T}\right)^2 \right] \quad (34)$$

where I_q is the current I approximated by the quadratic Eq. (34). Figure 20(b) shows graphically the error of this approximation (δ) for $-20 \text{ mV} < V < +20 \text{ mV}$, defined as

$$\delta = \frac{I_q - I}{I} 100\% \quad (35)$$

Figure 20. I - V characteristic of a diode power sensor, (a) I - V characteristic of a Schottky diode, (b) error of the square-law relationship.

Figure 21. HF diode power sensor.

Figure 21 shows the simplified circuit of an unbiased diode for detecting low level RF and microwave signals. A matching resistor is used to obtain the right termination impedance for a transmission line. In practical circuits two diodes are used in the circuit of a power sensor. When the diode power sensor detects the smallest power level (limited by noise of the diode) of 100 pW the dc output voltage $V_{OUT} = 50 \text{ nV}$. To handle this extremely small signal, a high-gain chopper amplifier is used in the power meter. Part of this amplifier is located in the enclosure of the power sensor, as well as circuitry for temperature compensation and the EEPROM that stores calibration constants of the power sensor. The diode power sensors do not have the dc substitution feature, hence it is necessary to provide a reference RF power source for calibration purposes. More information on RF and microwave power sensors and power meters may be found in Hewlett-Packard Journal papers (18–20).

Uncertainty of a HF power measurement is associated with circuit imperfections of the power sensor and the power meter. Because of the complexity of these circuits, usually main partial uncertainties are specified for a power sensor and for a power meter. It is up to the user of this equipment to decide which partial uncertainties need to be considered for a specific measurement and how the total uncertainty needs to be computed. The total uncertainty may be computed as the worst case uncertainty, root sum of the squares (RSS), or according to the ANSI/NCSL 540Z-2 guide. Typical range of combined uncertainty of power sensors is from 3% to 8%, and the range of combined instrumentation uncertainty is from 1% to 5%.

Optical Power Sensors and Optical Power Meters

A simplified block diagram of an optical power sensor and its connection to an optical power meter is shown in Fig. 22. In the optical power sensor, the optical power, P_O , of the measured lightwave is converted to an electrical current, I_D , following to the relationship

$$I_D = r_D(\lambda) P_O \quad (36)$$

where $r_D(\lambda)$ is the conversion factor or responsivity, that is, a function of wavelength, λ . The output current of the photodetector is very small and needs to be significantly amplified and conditioned before the result of the measurement may be displayed. It is necessary to place a suitable preamplifier (usually two preamplifiers must be used in order to cover the entire dynamic range) in the enclosure of the optical power sensor. One of these preamplifiers has smaller gain but wide bandwidth, while the other has large gain and therefore must have small bandwidth. Depending on measured optical signal level and specific kind of power (average optical power, peak

Figure 22. Optical power sensor and optical power meter. An optical power meter and optical power sensor create an optical power measurement system. The optical power meter works with a set of dedicated optical power sensors.

optical modulation power), the control system of the optical power meter chooses the proper preamplifier, its gain and bandwidth. In order to keep the photodetector at a constant temperature, the detector is placed in a thermostat (both heating and cooling techniques are used). If a chopper amplifier is used in an optical power meter, then an optical chopper is used. Disadvantages of optical choppers include reduced bandwidth, slow sampling rate, and possible reflection effects from the chopper. If a dc amplifier is used, constant temperature of the amplifier needs to be secured too. The lightwave may be completely cut off from the optical-to-electrical transducer, which is necessary for zeroing the measurement system. Dynamic range of the optical power meter increases with the use of a reference optical attenuator that may be inserted across the light ray. Typical attenuation of the optical attenuator is -10 dB. Optical power meters cover power ranges from $+27$ to -110 dBm, with total uncertainty range from 2.5% to 5%, and operate in the wavelength range of 400 nm to 1750 nm (contingent to use of a set of optical power sensors). More characteristics of optical power meters may be found in catalogs of Hewlett-Packard company (14,21), and Tektronix company (15). There are ordinary optical power meters, typically in the form of hand-held instruments, or lightwave multimeters that include a power measurement mode of operation. Measurements may be made in lightwave systems that implement lasers or light-emitting diodes (LED). Optical power meters are used to make measurements of absolute power of active components such as lasers or LEDs, insertion losses, and reflections in optical systems. Relative power measurements (with two-channel optical power meters or in single-channel optical power meters related to a specific measurement result) are also possible. Typically the average value of optical signals is measured, but other measurements, like peak power (high and low levels) over a large bandwidth from dc to 250 MHz, are also offered. Optical power meters are broadband receivers, integrating power levels over the wavelength specific for the optical power sensor that is applied. For optical component characterization at specific wavelength, a selective wavelength source must be used. Typical photodetectors used in optical power meters include large-area photodiodes, thermopiles, and pyroelectric crystals. To cover the entire fiber

optic wavelength range, three semiconductor materials are used to make photodetectors. Silicon detectors operate in the range from 400 nm to 1020 nm, germanium detectors cover the range from 900 nm to 1650 nm, and indium gallium arsenide (InGaAs) detectors handle the range from 800 nm to 1700 nm. Detectors made of these materials have some characteristics superior over the other two materials, hence selection of the best detector for a given application is essential. A broad description of topics related to optical power meters may be found in Hewlett-Packard publications (22–27) and in Derickson's book (28).

WATTMETERS

The wattmeter is an instrument that measures the average power P_0 entering a one-port. Under periodic conditions, P_0 is defined according to the following relationship:

$$P_0 = \frac{1}{T_1} \int_{t_A - T_1}^{t_A} v(t)i(t) dt \quad (1)$$

where $i(t)$ denotes the instantaneous current entering the port, $v(t)$ represents the instantaneous voltage across the port, and T_1 represents the period of the instantaneous power $p(t) = v(t)i(t)$. Under nonperiodic conditions, Eq. (1) can be generalized by introducing the limit for T_1 tending to infinity. Equation (1) suggests a method for measuring the mean power P_0 by applying the product of the input signals $v(t)$ and $i(t)$, to a linear time invariant (LTI) circuit whose impulse response $h(t)$ is shown in Fig. 1(a) (1). Recalling the modulus of the Fourier transform $H(fT_1)$ of $h(t)$ [Fig. 1(b)], when the condition $fT_1 = k$, with k an integer, is satisfied, only the direct component P_0 of the instantaneous power is present at the output, and it can be measured easily. In order to avoid this synchronization requirement, a low pass filter (LPF) that properly attenuates all the alternate spectral components is normally used instead of the circuit with impulse response $h(t)$. The input conditioning circuits are necessary in order to convert the input signals, both in type and amplitude, so that they can be compatible with the multiplier to optimize the multiplier performance and to insulate the operator from the measurement section when needed. These circuits, together with the multiplier and the LPF, characterize the sensitivity, the bandwidth, and the accuracy of the instrument. Accuracy and sensitivity are also influenced by the instrument which measures P_0 .

The electrodynamic wattmeter is an electromechanical implementation of the block diagram of Fig. 2. In fact, the instantaneous operating torque of the moving system is proportional to the product of the instantaneous currents in the fixed and moving coils. The effect of the couples that oppose the motion (the restoring torque, the mechanical and electromagnetic damping torques, and the inertial torque of the moving system) is equivalent to a low-pass filter with a natural frequency on the order of 1 Hz. This instrument is particularly suitable for ac power measurements at line frequency and usually has

Figure 1. (a) Impulse response and (b) its Fourier transform in modulus of the linear time-invariant (LTI) circuit after the multiplier of a wattmeter.

an uncertainty of 0.5% at full scale. Precision electrodynamic wattmeters, having an uncertainty lower than 0.01% at line frequency, are also available, along with wide-band wattmeters characterized by a frequency range up to a few kilohertz and uncertainty of 0.1%. Other techniques of multiplication were recently introduced (2), and some of them have been implemented in these instruments. One of them is the quarter-square technique. When both the quantities at the output of the conditioning circuits are currents, P_0 can be derived by measuring two root-mean-square (rms) values. In fact, by recalling the relationship

$$i_1 i_2 = \frac{1}{4} [(i_1 + i_2)^2 - (i_1 - i_2)^2] \quad (2)$$

when the currents i_1 and i_2 to be multiplied are a function of the quantities that the instantaneous power depends on, the mean power can be deduced from the difference of the rms values at the output of two thermal converters to which the quantities $(i_1 + i_2)$ and $(i_1 - i_2)$ are applied (3,4,5). However, the most common multiplier technique used in mean power measurement is time division (6–10). Both accuracy and bandwidth featured by

Figure 2. Functional block diagram of a wattmeter, showing that this instrument is basically made of input conditioning circuits, a multiplier, and a low-pass filter (LPF).

Figure 3. Block diagram of the sampling wattmeter.

commercial instruments using this technique do not substantially differ from those of the best electrodynamic instruments. The dc output is normally applied to a digital voltmeter in order to obtain a digital output.

The integral in Eq. (1) can be approximated by a weighted sum of the product of successive N samples of $v(t)$ and $i(t)$:

$$\hat{P}_k = \sum_{i=0}^{N-1} a_i v(t_{k-i}) i(t_{k-i}) \quad (3)$$

where the integer k identifies a generic discrete output $\hat{P}_k$, t_{k-i} is the i th sampling instant (x), and a_i is the value of the weighting function (11,12). This equation leads to a power meter implemented according to the block diagram of Fig. 3: The outputs of the two input conditioning circuits are simultaneously sampled through a sampling time generator (STG), digitized, and latched. The acquisition process is controlled by a digital signal processor (DSP). The two digital values are then acquired by the DSP to estimate the mean power in real time. In a digital environment, the multiplication does not present particular accuracy problems when a 32 bit floating-point DSP is used; therefore the measurement accuracy is influenced by both the adopted sampling strategy and the filtering algorithms, along with the characteristics of the S/H-ADC (sample/hold analog-to-digital converter) circuits, in particular by the frequency response of the S/Hs when they operate in the sample mode and by the resolution of the ADCs. The adopted sampling strategies are either of an equally spaced type (which can be divided into synchronous, quasi-synchronous, and asynchronous) or a random asynchronous one. The latter represents a convenient solution when a large bandwidth and high resolution are both required and relatively long measurement times are acceptable. The errors arising from the sampling strategy and the filtering procedures will be dealt with in the following sections separately from those associated with the input conditioning circuits.

Clearly, a power instrument based on Eq. (1) or (3) can also be used to implement the measurement of the rms value of each input signal.

The instruments described by the previous block diagrams can be also defined as transmission-type wattmeters, since they are designed to be connected between a source and a load. Another type of wattmeter is the absorption type, which utilizes a power sensor to terminate the transmission line in a prefixed load (usually 50 Ω) and convert the dissipated power into a dc value, which is then measured. Absorption-type wattmeters can be classified according to the type of power sensor

(thermistor, thermocouple, or diode) (13). These instruments can measure power values ranging from less than 1 nW up to some tens of watts in the frequency range from dc up to some tens of gigahertz.

EQUALLY SPACED SAMPLING WATTMETERS

If the N samples of Eq. (3) are taken at equally spaced instants T_s we can write

$$t_{k-1} = \tau_0 + (k-i)T_s \quad (4)$$

where τ_0 is the shift between the initial sampling instant and the time origin of both $v(t)$ and $i(t)$. The minimum value of the time interval T_s depends on which is the greater: the acquisition time of the S/H-ADC devices or the processing time of the digital hardware. Since the uncertainty arising from digital multiplication can be neglected, Eq. (3) can be rewritten as follows:

$$\hat{P}_k = \sum_{i=0}^{N-1} a_i p(t_{k-i}) \quad (5)$$

The periodic instantaneous power $p(t)$ can be represented by the Fourier series:

$$p(t) = \sum_{q=-\infty}^{+\infty} P_q e^{j2\pi q f_1 t} = P_0 + \sum_{\substack{q=-\infty \\ q \neq 0}}^{+\infty} P_q e^{j2\pi q f_1 t} \quad (6)$$

where $f_1 = 1/T_1$, $P_{-q} = (P_q^*)$ being the conjugate of P_q , and P_0 is the mean value of $p(t)$, that is the value of the measurand. By substituting Eqs. (6) and (4) into Eq. (5) we can write

$$\begin{aligned} \hat{P}_k &= \sum_{q=-\infty}^{+\infty} P_q \sum_{i=0}^{N-1} a_i e^{j2\pi q f_1 t_{k-i}} = P_0 \sum_{i=0}^{N-1} a_i \\ &+ \sum_{\substack{q=-\infty \\ q \neq 0}}^{+\infty} P_q e^{j2\pi q f_1 (\tau_0 + kT_s)} H(qf_1 T_s) \end{aligned} \quad (7)$$

where

$$H(fT_s) = \sum_{i=0}^{N-1} a_i e^{-j2\pi i f T_s} \quad (8)$$

Figure 4. Frequency response in modulus of a rectangular-window finite-impulse response (FIR) filter used in a sampling wattmeter to estimate the average power.

is the frequency response of the finite impulse response (FIR) filter. The filter has a periodic response of period f_s ; moreover, for $fT_s = u$, with u an integer, it results in $H(fT_s) = \sum_{i=0}^{N-1} a_i$. In order to obtain a unity scale factor in Eq. (7), the sum of the N coefficients a_i must be unity. Plainly, the coefficients a_i must be selected to obtain a frequency response which adequately attenuates the contribution to $\hat{P}_k$ [see Eq. (3)] of each spectral component of $p(t)$. By assuming $a_i = 1/N$ (that is a rectangular window) we obtain the well-known Dirichlet–Kernel formula:

$$H(fT_s) = e^{-j\pi fT_s(N-1)} \frac{\text{sinc}(NfT_s)}{\text{sinc}(fT_s)} \quad (9)$$

where the sinc function is defined as follows: $\text{sinc } x = (\sin \pi x)/\pi x$. The frequency response of the FIR filter used is therefore a periodic function that assumes a unity value for fT_s integer and null values for $fT_s = r/N$, r being an integer which is not a multiple of N . Figure 4 shows the shape of $|H(fT_s)|$ when $N = 10$ (this low value of N was chosen only for the sake of simplicity). Therefore, if a synchronous sampling strategy is used in which f_1T_s coincides with one of the zeros of $H(fT_s)$, it follows that

$$f_1T_s = \frac{r}{N} \quad (10)$$

where r is a positive integer with no common submultiple with N , and only the spectral components of $p(t)$ whose harmonic order is an integer multiple of N contribute to the output (14–16). In fact, when $q = zN$ (z integer) in Eq. (7), we obtain

$$\hat{P}_0 = P_0 + \sum_{\substack{z=-\infty \\ z \neq 0}}^{\infty} (-1)^{zr(N-1)} P_{zN} e^{j2\pi zNf_1\tau_0} \quad (11)$$

The output $\hat{P}_0$ is a constant and therefore becomes independent of k ; also, the instrument bandwidth, referred to $p(t)$, becomes equal to $(N-1)f_1$. In fact, the first spectral component of $p(t)$ that gives a contribution to $\hat{P}_0$ is the Nf_1 one ($z = 1$). The quantities T_s and N in Eq. (10) can be independently selected, provided that both signals are under steady-state conditions in the observation (or summation) interval NT_s . This interval, in which the N samples are taken, is also called the response time

of the instrument. According to Eq. (10), this interval must be equal to an integer number of periods T_1 ($NT_s = rT_1$); therefore one of the input signals must drive the sampling time generator in order to synchronize the sampling interval T_s with the period T_1 . This is the most common solution adopted in commercial digital wattmeters. The frequency bandwidth (from dc to some hundreds of kilohertz) is obviously much greater than that of the traditional instruments based on the analog multiplication, while the accuracy is usually of the same order of magnitude (0.1%). Moreover, the availability of the sampled values of the input signals readily allows further computations to be performed to extend the number of quantities measured (for example apparent power, power factor, and so on) and to make the spectral analysis. In this case the instrument is called a power analyzer.

If, instead of the synchronization condition (Eq. 10), the following condition is imposed:

$$|H(qf_1T_s)| \leq \frac{1}{N} \quad (12)$$

for any $q \neq zN$, the contribution to $\hat{P}_k$ of the each corresponding spectral component qf_1 is not zero, as occurs in the synchronous sampling, but can be neglected if N is adequately high. Since Eq. (11) is still approximately valid, this sampling strategy is called quasi-synchronous (17). It can be shown (18) that, on the hypothesis of $f_1T_s < 0.5$, Eq. (12) is verified when

$$|NT_s - r_1T_1| \leq T_s \quad \text{for } f_1T_s \leq 0.5 \quad (13)$$

where r_1 is the nearest integer to NT_s/T_1 . In the quasi-synchronous case, the value of N must therefore be adjusted so that the observation interval NT_s results close enough to an integer number of periods T_1 to satisfy Eq. (13). A prototype implementing this procedure featured an uncertainty of less than ± 50 ppm in the frequency range 50 Hz to 1 kHz (19).

On the contrary, in the asynchronous case the product fT_s can assume any value; therefore the bandwidth is limited by the periodicity of the function $H(fT_s)$, or f_s , and the FIR filter must be selected in such a way to minimize $|H(fT_s)|$ within this interval (20).

RANDOM SAMPLING WATTMETERS

The need for synchronization to overcome the bandwidth limitations of the equally spaced sampling strategy may restrict the possible applications of wattmeters. In fact, synchronization can be conveniently used only when dealing with strictly periodic waveforms, while many applications of practical interest must deal with almost periodic “multitone” signals, which are characterized by a discrete spectrum with nonharmonically related frequencies of the spectral components. Asynchronous sampling may also be more convenient in strictly periodic cases whenever synchronization is a difficult task, either because the signals have a very broad spectrum or because the period is relatively long. The bandwidth of a wattmeter based on an asynchronous equally spaced sampling strategy is limited by the conversion time of the ADC. On the other hand, high resolution and short conversion time are two opposing requirements of an ADC. To build an asynchronous wattmeter whose bandwidth is not limited by the sampling frequency, two different

Figure 5. Time allocation of the impulse train in the case of (a) a nonrecursive and (b) a recursive random sampling technique.

random strategies (or more precisely pseudorandom, since the mean sampling time is constant), have been proposed. The first one is defined by the expression (20).

$$t_{k-i} = \tau_0 + (k-i + X_{k-i})T_s \quad (14)$$

where any sampling instant t_{k-i} is given by the sum of a periodic component $(k-i)T_s$ (k and i are integers) and a random component $X_{k-i}T_s$ [(Fig. 5(a)]. The previously introduced quantity T_s [Eq. (4)] is not correlated with any spectral component of the instantaneous power (this sampling strategy is of an asynchronous type), while X_{k-i} is the $(k-i)$ th of a set of random independent variables having a continuous uniform distribution in the interval 0 to $\pm b$. It is noteworthy that Eq. (14) includes, as a special case, the equally spaced sampling strategy [Eq. (4)]. Under the assumption of $b = 0.5$, the successive sampling instants are distributed in consecutive nonoverlapping intervals equal to T_s . Since the distance between two consecutive sampling instants can be small without limitation, while the time interval between the first and the last of a consecutive triplet of samples can never be smaller than T_s , this strategy has the drawback of requiring a pair of S/H-ADC for each input channel.

In the other random strategy, called *recursive random sampling strategy* (21), every sampling instant t_{k-i} is obtained by adding to the preceding t_{k-i-1} a predetermined constant lag T_s plus a random increment $X_{k-i}T_s$ [Fig. 5(b)]

$$t_{k-i} = t_{k-i-1} + (1 + X_{k-i})T_s \quad (15)$$

where X_{k-i} is the $(k-i)$ th of a set of random independent variables having continuous uniform distribution in a prefixed interval 0 to b . The lag time T_s has been devised so that the time interval between two successive samples is never smaller than T_s . Therefore, if its value is not less than the maximum data acquisition and processing time of the digital hardware used, a real-time instrument can be realized by using only one S/H-ADC for each channel.

PERFORMANCE ANALYSIS OF SAMPLING WATTMETERS

By substituting Eqs. (14) or (15) and (6) into Eq. (5), we obtain the output quantity $\hat{P}_k(\tau_0, \overline{CIX}_k)$, which is a function of the index k marking any output state of the instrument, of the shift τ_0 between the initial sampling instant and the time origin of $p(t)$, and of the vector of the successive N sampling random

variables $\overline{CIX}_k = \{X_k, X_{k-1}, \dots, X_{k-N+1}\}$. The incidental quantities k and τ_0 occur as nuisance parameters because they locally condition the evaluation of $\hat{P}_k(\tau_0, \overline{CIX}_k)$ by restricting it to the choice of a particular pair of values of k and τ_0 . To eliminate the influence of these nuisance parameters, we can follow the Bayesian approach (22) by regarding any pair of possible values (k, τ_0) as a realization of a bivariate random variable (k, τ_0) , with a priori probability distribution which must be selected by their intrinsic relationship to the prior information available. As far as k is concerned, it should be considered that every output state of the instrument has an equal chance of being selected. Therefore, the enumerable sets of the labels, in general with $2h+1$ values, which mark the sequence of the output states of the instrument, can be treated as a discrete random variable, uniformly distributed within the whole time interval in which these states are available. As far as τ_0 is concerned, we must distinguish between the synchronous sampling techniques and the asynchronous ones. In the asynchronous cases, the sampling time generator of Fig. 4 is not controlled by any input signal; therefore any realization of τ_0 is independent of the instantaneous power $p(t)$, and since it is strictly related to the turn-on instant of the instrument, it belongs to a continuous set of possible equiprobable values distributed within any time interval. In the synchronous sampling technique, τ_0 depends on the synchronizing circuit that generates the sequence of the sampling instants as a function of one of the input signals. As a consequence, τ_0 is a function not only of the synchronizing circuit used but also of $p(t)$. If we want to take into account all possible states of τ_0 , we should have to foresee all the possible synchronizing operations for the same unknown signal and establish the possible functional relations which connect τ_0 to the signal itself. Obviously, this is practically utopian, and it is convenient to simulate an equivalent configuration in which τ_0 may be assumed as a realization of a continuous set of values distributed within some time interval T . To sum up, the a priori ignorance concerning the nature of the parameter τ_0 can be overcome in both techniques by postulating a uniform distribution in a generic time interval T (23,24).

An appropriate characterization of the output uncertainty of the sampling wattmeters can be obtained by evaluating the statistical parameters of the output $\hat{P}_k$, i.e., the mean value $E\{\hat{P}_k\}$ and the mean square error $E\{(\hat{P}_k - P_0)^2\}$. To incorporate all the possible a priori chances and also to avoid the influence of the conventional time origin on the instrument performance, the number $2h+1$ of the output states, and the excursion T of the initial shift τ_0 must be sufficiently large and must theoretically tend to infinite. Therefore we consider the asymptotic statistic parameters, that is the asymptotic mean

$$\bar{P} = \lim_{\substack{h \rightarrow \infty \\ T \rightarrow \infty}} E\{\hat{P}_k\} \quad (16)$$

and the asymptotic mean square error

$$e^2 = \lim_{\substack{h \rightarrow \infty \\ T \rightarrow \infty}} E\{(\hat{P}_k - P_0)^2\} \quad (17)$$

It can be shown (20,21,23,24) that the output of the instruments set up with one of the previously described sampling strategies is asymptotically unbiased ($\bar{CIP} = P_0$), and consequently, the asymptotic mean square error coincides with the asymptotic variance $e^2 = \sigma^2$, whose final expression can always

be expressed as follows:

$$\sigma^2 = 2 \sum_{q=1}^{\infty} |P_q|^2 W^2(qf_1 T_s) \quad (18)$$

According to the superposition principle, this equation shows that the contribution of the squared rms value $2|P_q|^2$ of each harmonic component of the instantaneous power to the asymptotic variance is weighted by the coefficient $W^2(qf_1 T_s)$. The sequence of the weighting coefficients $W^2(f_1 T_s)$, $W^2(2f_1 T_s)$, ... can be derived from a continuous weighting function $W^2(f T_s)$ by determining its values at the successive occurrence points $f_1 T_s$, $2f_1 T_s$, ..., that is the products between each instantaneous-power spectral frequency and the constant lag T_s . Since Eq. (18) is always valid, we can conclude that a corresponding weighting function can be associated with any sampling strategy, recursive or nonrecursive, random or equally spaced, asynchronous or synchronous. Hence the behavior of the weighting function $W^2(f T_s)$ as a function of $f T_s$ and the possible occurrence points at which the weighting coefficients are evaluated completely describe the performance of any selected sampling strategy with the associated filtering algorithm.

By considering an N -point rectangular window to realize the FIR filter, it can be shown that the weighting function for the sampling strategy defined by Eq. (14) can be expressed as follows:

$$W^2(f T_s) = \frac{1}{N} + \text{sinc}^2(2bf T_s) \left[|H(f T_s)|^2 - \frac{1}{N} \right] \quad (19)$$

where $|H(f T_s)|$ is the modulus of the frequency response of the rectangular window [Eq. (9)]. When $f = 0$ it results in $W^2(0) = 1$. For $b = 0$, an equally spaced sampling, we obviously obtain $W^2(f T_s) = |H(f T_s)|^2$; therefore all the previous considerations of this sampling strategy can be deduced also considering the weighting function. For $b > 0$ and $f T_s \geq 1$, the shape of $W^2(f T_s)$ depends significantly on the given value of b . By selecting $b = 0.5$, when the random sampling is distributed within an interval equal to the time constant T_s , we obtain

$$W^2(f T_s) \cong \frac{1}{N} \quad \text{for } f T_s \geq 1 \quad (20)$$

The shape of the weighting functions for $b = 0$ and $b = 0.5$ are represented in Fig. 6(a) on the hypothesis of $N = 10$. This very low value of N has been chosen only to show the shape of the weighting function more clearly. We can therefore conclude that the bandwidth of this random sampling strategy with $b = 0$ is not limited by the average sampling frequency $f_s = 1/T_s$, but solely by that of the S/H circuit used. It has been shown that these theoretical findings strongly agree with the experimental ones (25).

The weighting function for the sampling strategy defined by Eq. (15) is the following (26):

$$W^2(f T_s) = \frac{1}{N} + \frac{2}{N^2} \sum_{r=1}^{N-1} (N-r) \cos \left[2\pi r \left(1 + \frac{b}{2} \right) f T_s \right] \times \text{sinc}^r(bf T_s) \quad (21)$$

The plot of this function for different values of b ($b = 0.5, 1, 2$) and for $N = 10$ is reported in Fig. 6(b). For $f = 0$ we obtain

Figure 6. Weighting functions with $N = 10$ of (a) the equally spaced sampling strategy ($b = 0$) and of the random strategy defined by Eq. (14) with $b = 0.5$; (b) the random recursive strategy defined by Eq. (15). Comparison of the three weighting functions shows that neither of the considered random strategies introduces any frequency limitation.

$W^2(0) = 1$, while for $f \rightarrow \infty$ it results in $W^2(f T_s) \rightarrow 1/N$. The shape of this weighting function differs from that of the nonrecursive one only for the presence of a ripple around $1/N$ whose amplitude decreases as b , the range of the random increments X_{k-i} in Eq. (15), increases. Clearly, the overshoot above $1/N$ must not exceed an acceptable threshold in order to contain the contribution of each spectral component to the asymptotic variance through the corresponding weighting coefficients. On the other hand, higher values of b increase the mean response time of the wattmeter, and consequently b must be selected as small as possible. An optimum value is $b = 1.5$, but in any case the value of b is not critical. The theoretical study has been confirmed by the experimental results with a prototype implementing this sampling strategy (27).

It is interesting to note that the standard error associated with the sampling strategy and filtering algorithm of both these asynchronous random strategies results in $1/\sqrt{N}$ while that of the quasisynchronous equally spaced one is $1/N$; therefore a large bandwidth in an asynchronous sampling can be obtained only with a decrease in accuracy. Since the bandwidth of the proposed asynchronous random strategies is not limited by the sampling frequency but only by the bandwidth of the S/H, a

high resolution ADC can be adopted in order to implement a wattmeter characterized both by a large bandwidth and high resolution. A prototype based on the strategy defined by Eq. (4) was used to evaluate the power losses in electronic devices used in switching converters. Modern power devices are characterized by low losses and high switching speed. Therefore, the instrument required to measure their power losses must have a bandwidth from dc to several megahertz and a resolution so high that its performance is still acceptable when the power factor is of a percent order. The accuracy of the experimental results was of some percent in comparison with that of the calorimetric method (28).

TIME-JITTERED EQUISPACED SAMPLING WATTMETERS

The random fluctuations with respect to the nominal sampling instants are commonly called time jitter; since they are present both in the voltage and current channels, the effect of time jitter on the performance of the wattmeter must be considered (29). For instance, the unpredictable temporal variations of the aperture delay of each channel S/H produce different random effects in the sampling instants: The noise associated with the clock generator can instead cause common random independent fluctuations in the sampling instants. Therefore, the effect of time jitter must be analyzed by considering the sampling instants of the two channels separately, and each of them can be determined by adding to the right side of Eq. (4) two quantities: $X_{k-i}T_s$, common to the two channels, and $X'_{k-i}T_s$ for the voltage channel or $X''_{k-i}T_s$ for the current channel respectively:

$$t'_{k-i} = \tau_0 + (k-i + X_{k-i} + X'_{k-i})T_s \quad (22)$$

$$t''_{k-i} = \tau_0 + (k-i + X_{k-i} + X''_{k-i})T_s \quad (23)$$

Obviously, t'_{k-i} and t''_{k-i} are mutually interdependent due to the common component X_{k-i} . Each of the three random variables X_{k-i} , X'_{k-i} , and X''_{k-i} is the i th element of three independent sets of random variables having a continuous distribution with mean value equal to zero. The two variables X'_i and X''_i can be assumed to be characterized by the same distribution.

In the special case of only common time jitter having a uniform distribution in a certain interval $\pm b$, the effect of time jitter can be evaluated by considering the random sampling strategy defined by Eq. (14). Therefore Eq. (19) also represents the weighting function for this case when b has a small value. The shape of the weighting functions $W^2(fT_s)$ of an equally spaced sampling strategy with a jitter uniformly distributed within $\pm b = \pm 0.1$, or $\pm b = \pm 0.05$, and $N = 10$ are shown in Fig. 7 (18). This figure shows that time jitter leads to values of the relative minima increasing with frequency and values of the relative maxima decreasing with frequency. Therefore, in the presence of time jitter, the contribution of the spectral components that meet the condition $q \neq zN$ must also be investigated in order to limit the asymptotic mean square error. By imposing a maximum value on the weighting function, the upper limit of the wattmeter frequency caused by a given time jitter can be deduced from Eq. (19) or Fig. 7.

Separate time jitters for the current and voltage channels generate an asymptotic bias which, under the assumption of periodic input signals and a uniform distribution of the random

Figure 7. Weighting function with $N=10$ of an equally spaced sampling technique in the case of a common time jitter affecting the two input channels. The function shows that this kind of time jitter increases the relative minima and decreases the relative maxima.

variables in the interval $\pm b_1$, can be expressed as follows (29):

$$\text{Bias} \rightarrow \sum_{\substack{m=-\infty \\ m \neq 0}}^{+\infty} V_m I_m^* (1 - \text{sinc}^2(2b_1 m f_1 T_s)) \quad (24)$$

where V_m and I_m with $V_{-m} = V_m^*$ and $I_{-m} = I_m^*$ are the spectral components in the exponential form of the input signals and $m f_1$ the corresponding frequencies. By Parseval's theorem, the average power P_0 can be expressed as a sum of the average power associated with each individual Fourier component of the input signals:

$$P_0 = \sum_{\substack{m=-\infty \\ m \neq 0}}^{+\infty} V_m I_m^* \quad (25)$$

Therefore the asymptotic bias can be obtained by weighting the contribution of each spectral component with the average power and summing over the whole spectrum. Figure 8(a) shows the plot of the weight $(1 - \text{sinc}^2(2b_1 f T_s))$ in Eq. (24) as a function of fT_s for $\pm b_1 = \pm 0.05$ or $\pm b_1 = \pm 0.1$. Therefore, the bias introduces another bandwidth limitation when it becomes comparable with the instrument's accuracy.

The expression of the asymptotic mean square error in the presence of both common and separate time jitter is rather complex. A simpler result can be deduced when the effect of the common time jitter is negligible and under the assumption of two sinusoidal input signals at frequency $m f_1$. In this case the asymptotic variance can be expressed as follows (28):

$$\begin{aligned} \sigma^2 \rightarrow & 2|V_m I_m^*|^2 \left\{ \frac{2}{N} (1 - \text{sinc}^4(2b_1 m f_1 T_s)) \right. \\ & \left. + \text{sinc}^4(2b_1 m f_1 T_s) |H(2m f_1 T_s)|^2 \right\} \\ & + \frac{P_0^2}{2} \left\{ \frac{1}{N} [\text{sinc}^2(4b_1 m f_1 T_s) - \text{sinc}^4(2b_1 m f_1 T_s)] \right\} \end{aligned} \quad (26)$$

Figure 8(b) shows the shape of the normalized quantity $\sigma_N^2 = \sigma^2 / 2|V_m I_m^*|^2$ for in-phase input signals as a function of fT_s , under the assumption of sampling instants uniformly distributed

Figure 8. The estimate of the average power in the presence of different time jitters occurring in the voltage and current channels is affected by bias and variance. Plot (a) enables the bias to be deduced according to Eq. (24), while the normalized variance in the case of in-phase input signals can be deduced from plot (b).

over the interval $\pm b_1 T_s$ with $\pm b_1 = \pm 0.05$ or $\pm b_1 = \pm 0.1$ and $N = 10$. The shape of this function is very similar to that of the weighting function in the presence of only common time jitter (Fig. 7); therefore a further bandwidth limitation is introduced.

In conclusion, the effect of time jitter in an equally spaced time sampling must be evaluated, since it introduces an asymptotic variance, and if different time jitters exist in the two channels, it also introduces a bias. The instrument bandwidth must therefore be adequately limited in order to make these effects negligible. When one of the two previously described random sampling strategies is considered instead [Eqs. (14) and (15)], only the different time-jitters introduce a further bandwidth limitation.

INPUT-CONDITIONING CIRCUITS

The conditioning circuits of Fig. 2 must convert the voltage and current, which the power to be measured depends on, into signals acceptable by the multiplier. When the line voltage is hazardous to the operator, these circuits must also ensure insulation between the instrument and the power system.

The input signals of the multiplier must usually be of the same type, either current or voltage, according to the multiplier operating principle. As a consequence, voltage-to-current ($V-I$) and current-to-voltage ($I-V$) transducers are necessary. The multiplier input signals must also have proper amplitude. This calls for current-to-current ($I-I$) and voltage-to-voltage ($V-V$) transducers.

All the above transducers could easily be implemented by means of impedances. In this case, the $V-I$ and $I-V$ transducer transfer functions depend on an admittance or an impedance, respectively; while the transfer function of $I-I$ and $V-V$ transducers depend on the ratio between impedances. It is worth recalling that it is easier to know and keep constant the value of an impedance ratio than the value of an impedance. $I-I$ and $V-V$ transducers can be also implemented by means of instrument transformers, which is the most common solution when electrical safety is the main requirement. Broadband thermal rms/dc converters based on thermocouples are used in wattmeters that implement the quarter-square technique. However, the instrument frequency bandwidth is limited at several orders of magnitude below that of these converters because of the analog circuits that provide the currents $(i_1 + i_2)$ and $(i_1 - i_2)$ shown in Eq. (2).

Power measurement accuracy depends on the characteristics featured by all the signal conditioning chain, hence those of the transducers external to the instrument also must be considered.

The choice of the transducer frequency bandwidth depends on the wattmeter application. For instance, in many industrial processes, where large amounts of power at high currents and voltages are utilized, the active power is substantially transmitted at industrial frequency, even under nonsinusoidal conditions. Indeed, the difference $(P - P_1)$ between the active power P and that at industrial frequency is usually lower than a few parts per thousand of P_1 (30). In particular, the active power associated with the direct voltage and current components can be neglected. In these cases, the use of passive instrument transformers can therefore be quite satisfactory. In other industry applications power measurement may require transducers featuring wider frequency bandwidths (31).

Resistors

Resistors are a simple and cheap solution for the implementation of the above variety of transducers. Their frequency bandwidth includes a direct component and may range up to about 100 MHz. This means that the output of a resistor-based transducer may feature a phase shift of about 0.1 mrad at 10 kHz. The frequency bandwidth is limited by the nominal power of the resistor. Indeed, if the thermal drift is stressed to remain constant, the component sizes must increase as the dissipated power increases, and this increases the component time constant. The power dissipation also sets a limit to the use of resistors in self-contained instruments. For this reason, external series resistors have been used in electrodynamic wattmeters to extend the voltage range.

The stray capacitances may significantly affect the time constants of the resistive voltage divider components. When the two sections of a divider are characterized by different time constants, its transfer function differs from the dc ratio. This is described by means of the ratio and phase-angle errors. The ratio error increases with the product of the

Table 1. Characteristics of Two I - V Wide-Bandwidth Transducers.

Transducer Type	Full-Scale Input (A)	Full-Scale Output (V)	Cut-off Frequencies	Accuracy (%)
Noninductive shunt resistor	100	0.1	1.5 MHz	± 0.1
CT with resistive burden	65	6.5	1 Hz to 20 MHz	$-0/+1$

stray reactances; their difference determines the phase-angle error. The time constants can be compensated by means of capacitors.

Resistor-based transducers do not ensure electrical insulation between the power system and the instrument.

Current and Voltage Transformers

The upper cut-off frequency of instrument transformers is limited by the stray capacitances; hence, a current transformer (CT), even for high-voltage applications, features a wider frequency bandwidth than a voltage transformer (VT). Usually CTs show satisfactory frequency response in the audio frequency range, while ferrite core CTs may feature upper cut-off frequencies of tens of megahertz. Broadband I - V transducers can therefore be implemented by means of CTs with resistive burden. Their output, contrary to that of shunt resistors, does not require amplification. The upper cut-off frequency of the VTs depends on their nominal voltage and is usually lower than 1 kHz.

Table 1 compares some characteristics of two commercial I - V transducers of similar price. Active instrument transformers based on the Hall effect are used when the input signal bandwidth includes the direct component.

Capacitive Dividers

Capacitive voltage dividers are often used to extend the amplitude range of the multiplier for alternating voltages. Capacitors are the passive components that best approach the ideal behavior over a wide frequency bandwidth limited by stray resistances and inductances. The phase shifts exhibited by capacitive dividers depend on the difference between the capacitor loss angles and may be less than 0.1 mrad up to hundreds of kilohertz. At frequencies sufficiently lower than the resonance frequency f_0 depending on the stray inductance, the capacitance of a capacitor is a linear function of the squared ratio of the frequency to the resonant frequency f_0 . Therefore, if the capacitors possess different resonance frequencies, the voltage division accuracy depends on frequency. Moreover, for direct voltages and for alternating voltages at very low frequency, capacitive dividers cannot be used because of stray phenomena. The dc voltage division is independent of the capacitance values of the two sections and is determined only by their equivalent parallel resistances. Moreover, at low frequency the voltage division can also be affected by the occurrence of interfacial polarization.

Like all impedance dividers, capacitive dividers do not ensure the isolation of the instrument from the power system; however, high-voltage transducers based on them are usually built, given that voltage transformers are too expensive for voltage values greater than about 150 kV. Since the divider output voltage commonly ranges between 5 and 20 kV, they are

coupled with a VT that therefore limits the frequency response of the whole conditioning chain.

WATTMETER CALIBRATION

Calibration is the process of deducing or checking the instrument's accuracy. It can be performed by using either a dedicated calibration equipment (direct comparison) or a similar test instrument of known accuracy used as a reference (indirect comparison). The calibration procedure must meet the traceability condition. This means that the individual measurement results must be referred to national standards through an unbroken chain of calibration. Wattmeter calibration is performed at $\cos(\phi) = 1$ for different amplitude and frequency values, in addition, power factor effects must be taken into account. For the latter effect, at least four operating conditions are tested: unity, 0.5 lead and lag, and zero power factors. For the comparison of the results of wattmeter calibration between different Bureaus of Standards, more complex approaches are followed. They provide an estimate of three error coefficients, related to the magnitude and phase errors of the voltage and current circuits, and also of the zero offset (32).

The first method for calibration (direct comparison) requires synchronized sources of ac voltage and current. To this end, voltage and current should be known in amplitude and phase. Moreover, an adequate range of voltages, currents, and phase angle values at different frequencies must be available (33,34). A single instrument may replace the complex combinations of individual voltage and current sources. If the current and voltage circuits of the wattmeter are supplied by separate sources (phantom loading), the source must provide only the power dissipated into the instrument under test. In order to generate accurate reference signals and separate voltage and current channels, synthesized generators are normally used. A frequency range from 20 Hz up to 10 kHz and a best long-term accuracy of less than 100 ppm (referred to the apparent power) are normally provided in commercial calibrators.

The second method (indirect comparison) compares the readings of the unit under test with those of a reference unit. Also in this case it is preferable that the current and voltage circuits of the wattmeter are supplied from separate sources (phantom loading). If only one power source is available, the calibration can be performed by connecting the voltage channels of the two wattmeters in parallel, and connecting the current channels in series with a short-term stable load.

The issues related to electric-power quality have increased the interest in harmonic-power analyzers. Their calibrators offer accuracy and frequency ranges lower than those of the above-mentioned wattmeter calibrators. For instance, a calibration system characterized by an uncertainty of 500 ppm over a frequency bandwidth of about 2 kHz was described in Ref. 35.

VOLT-AMPERE METERS

Volt-ampere meters are multipurpose electric measuring instruments that display the values of active, reactive, and apparent electric power. Some of them also measure other electric quantities, such as current, voltage, and energy.

Before presenting some of the basic ideas that support the operating and implementing principles of volt-ampere meters, it is worth discussing the concepts of active power, reactive power, and apparent power.

Power is the rate at which energy is transferred or transformed into a different form. Active power P , also called true power, is physically related to the energy nonreversibly converted to heat (Joule effect) in the resistive components of electric circuits. Thus, in a resistor R with current i , P is given by

$$P = RI_{\text{rms}}^2 = \frac{U_{\text{rms}}^2}{R} = (ui)_{\text{av}} = \frac{1}{T} \int_T (ui) dt = (p)_{\text{av}} \quad (1)$$

where rms stands for root-mean-square, u is the voltage drop in R , p is the instantaneous power, T is the period of p , u and i represent instantaneous values, and U_{rms} and I_{rms} represent constant values.

Equation (1) is the basic definition of active power in a circuit. Active power is the time average of the product of instantaneous voltage and current (instantaneous power). When, and only when, voltage and current are sinusoidal, Eq. (1) yields the known relationship

$$P = U_{\text{rms}} I_{\text{rms}} \cos \phi \quad (2)$$

where ϕ is the phase angle between u and i . The unit of active power is the watt (W).

Contrary to the active power which has a physical meaning, reactive power (R) and apparent power (S) are electrical quantities that have the dimensions of power but have significance only when voltage and current are sinusoidal or near sinusoidal. These two quantities are related to the behavior of the reactive components of circuits and their meanings result from interpreting the complex Poynting theorem (1). For a circuit under a sinusoidal regime,

$$R = U_{\text{rms}} I_{\text{rms}} \sin \phi \quad (3)$$

$$S = U_{\text{rms}} I_{\text{rms}} = \sqrt{P^2 + R^2} \quad (4)$$

Reactive power is expressed in volt-ampere reactive (VAR) and apparent power in volt-ampere (VA).

TYPES OF VOLT-AMPERE METERS

Nowadays, because of the widespread use of personal computers (PCs) and PC data acquisition boards (DAQs), the design of multipurpose measuring instruments that function in particular as volt-ampere meters is a problem of software as well as hardware. And because the implementation of the hardware to digitize several electric voltages and currents is trivial in many situations, the measurement capacity of a PC with a DAQ depends mainly on the software component of such a measuring instrument, usually designated by a virtual instrument (VI). The use of object-oriented languages and the existence of commercial software packages supported and supporting visual programming has made life easier for VI designers and also for users, because those programming tools facilitate the implementation of instruments with user-friendly interfaces. It is our belief that in the near future PC-based virtual instrumentation will render obsolete many dedicated analog and digital instruments still in use now, particularly in the laboratory. Volt-ampere meters will be no exception. Model TPZ 303 from ZERA Electric GmbH is an example of this type of instrumentation already available. It is a multifunction, high-accuracy (200 ppm for active power) measuring system based on the digitization of the input quantities and signal processing. Designed to be a portable stand-alone instrument, the processing unit is not an external PC but an internal digital signal processor (DSP). However, an overview of some of the other types of volt-ampere meters is justified, because instruments based on different operating principles are still manufactured and used, particularly in industry.

The presentation of volt-ampere meters that follows is organized according to the power measurement principles they use.

According to the measuring method, power meters may be divided into analog and digital types. In analog power meters, the measurement is obtained by an electric quantity that is proportional to the power. This quantity is produced by analog means and is displayed in either analog or digital format. In digital power meters, voltage and current are digitized and the measurement of power is obtained upon adequate reduction of the resulting data. Presentation of the results is usually digital. A VI power meter is an example of a digital power meter.

From Eqs. (1), (3) and (4), one may conclude that any idea that yields the analog product of two voltages or currents supports a power measuring principle and the design of an analog power meter (analog multiplication power meter). Those expressions also clearly identify the operations that the software of digital power meters must implement to produce the measurements.

In the case of active power, some analog meter designs are based on the physical meaning of active power. Examples of methods used are (1) measurement of the voltage or current in a known noninductive resistor by a thermogalvanometer or a thermocouple ammeter; (2) measurement by comparing the brightness of an incandescent lamp driven by the source of power to be measured by using a voltmeter, an ammeter, an incandescent lamp, and a photosensitive meter; (3) measurement of the temperature change when a temperature-sensitive resistor (bolometer) absorbs energy. The corresponding change of resistance is measured by a bridge circuit; (4) measurement of part of the heat produced in a resistor using the bolometer method (calorimetric active power meters). These methods may be used to implement low-frequency active power meters. Nevertheless, the meters commercially available are almost exclusively designed for the radio-frequency domain. For that reason, those types of meters are not considered in this article. Interested readers are directed to Refs. 2 and 3.

Reactive and apparent powers are important in power systems and so the solutions considered in the following paragraphs are used in low-frequency power meters.

ANALOG MULTIPLICATION POWER METER

Electrodynamic Principle (Electrodynamic Volt-Ampere Meters)

Electrodynamic instruments are analog instruments that have two coils, one fixed (current coil or current circuit) and the other able to rotate around an axis inside the first coil (voltage coil). For frequencies higher than 1 Hz (4) the change of the angular position α between the two coils is proportional to the time average of the product of the currents in the two coils:

$$\alpha = k(i_1 i_2)_{\text{av}} = k \frac{1}{T} \int_T i_1(t) i_2(t) dt \quad (5)$$

To measure the active power in a load Z_L , the two coils are connected as shown in Fig. 1. The instrument indicates the active power in the load added to the active power in either the current circuit (connection 1–2) or in the voltage circuit

Figure 1. Connections of an electrodynamic wattmeter to a load Z_L . R_a is an additional resistance used in the voltage circuit.

(voltage coil in series with resistor R_a , connection 1–3). Thus, to obtain the correct value of the active power in the load, the indication has to be corrected. For details, see Refs. 4 and 5. Equation (5) reveals that as long as i_1 and i_2 represent the load current and load voltage, the electrodynamic wattmeter measures the active power. The shape of the waveform does not limit the validity of the measurement.

To measure reactive power, the voltage circuit of the wattmeter (fixed coil and resistance in series) must be slightly changed. In fact, taking into account that the measuring situation is relevant only when sinusoidal waveforms are present, for which Eqs. (3) and (4) are valid, and also that

$$\sin \varphi = \cos \left(\varphi - \frac{\pi}{2} \right) \quad (6)$$

the reactive power may be measured if the current in the moving coil is not proportional to the load voltage, but to a voltage lagging the load voltage by $\pi/2$. Figure 2 shows the voltage circuit of an electrodynamic reactive power meter (electrodynamic varmeter) and the vector diagram of the pertinent electrical quantities. The vector diagram presented is valid only for one frequency ω , which means that the electrodynamic varmeter is a single-frequency varmeter. The measurements are correct only when the load current and voltage are sinusoidal at the frequency considered in the design of the instrument. Commercial electrodynamic varmeters for measurements at the frequency of the main power supply are more common.

Figure 2. Voltage circuit of an electrodynamic varmeter and the corresponding vector diagram. The resistance r_0 is in parallel with the impedance of the voltage coil ($r_2 L_2$). i_2 lags i_0 and by an appropriate choice of r_0 , R_a and L_a , i_2 lags the load u by $\pi/2$.

The electrodynamic principle also allows constructing an instrument for measuring apparent power directly. For that purpose, the two coils of an electrodynamic instrument must be preceded by circuitry to output dc voltages or currents proportional to the rms values of the voltage and current involved in the circuit under test. This solution, however, is not used in the practice.

The series connection of the two coils of an electrodynamic instrument transforms it into a true rms current meter (electrodynamic ammeter) for frequencies ranging from dc to a few hundred hertz. A resistor in series with the two windings transforms the ammeter into a true rms voltmeter (electrodynamic voltmeter). The upper frequency limit of electrodynamic voltmeters is also a few hundred hertz but slightly lower than for electrodynamic ammeters.

Readers interested in typical values and specifications for electrodynamic instruments, are directed to Refs. 4 and 5.

Thermoelectric Conversion Principle (Thermal Volt-Ampere Meters)

Analog multiplication related to the thermoelectric effect is achieved by using two thermoelectric converters in the configuration depicted in Fig. 3. Currents i_1 and i_2 are proportional to the voltage and current involved in the power to be measured. The two thermoelectric converters are coupled, and their filaments (heaters) have resistances R_f . Because the circuit is symmetrical, the filament currents of the converters i_A and i_B are given by

$$i_A = \frac{1}{2}(i_1 + i_2) \quad (7)$$

$$i_B = \frac{1}{2}(i_1 - i_2) \quad (8)$$

These two currents produce two dc voltages U_A and U_B given by

$$U_A = k_C I_{A_{rms}}^2 = k_C (i_A^2)_{av} \quad (9)$$

$$U_B = k_C I_{B_{rms}}^2 = k_C (i_B^2)_{av} \quad (10)$$

where k_C is the constant of the converters.

Figure 3. Thermoelectric power meter using two identical thermoelectric converters that have resistance R_t . The currents i_1 and i_2 , whose average product is to be measured, enter the circuit at opposite corners of the bridge.

Replacing Eq. (7) in (9) and Eq. (8) in (10) yields

$$U_A = \frac{k_C}{4}[(i_1 + i_2)^2]_{av} = \frac{k_C}{4}(i_1^2)_{av} + \frac{k_C}{4}(i_2^2)_{av} + \frac{k_C}{2}(i_1 i_2)_{av} \quad (11)$$

$$U_B = \frac{k_C}{4}[(i_1 - i_2)^2]_{av} = \frac{k_C}{4}(i_1^2)_{av} + \frac{k_C}{4}(i_2^2)_{av} - \frac{k_C}{2}(i_1 i_2)_{av} \quad (12)$$

$$U_1 = U_A - U_B = k_C(i_1 i_2)_{av} \quad (13)$$

Equation (13) reveals that the dc voltage U_1 of Fig. 3 is proportional to the active power, provided that i_1 and i_2 themselves are proportional to the voltage and current in the circuit.

To assemble an active power meter, the circuit of Fig. 3 must be complemented with a dc voltmeter to measure U_1 and with a resistor to convert the voltage in the circuit into i_1 or i_2 .

To implement either an apparent power meter or an ammeter or a voltmeter, the considerations before about the corresponding electrodynamic meters are valid. Constructing a reactive power meter based on thermoconverters is also possible. All that is required is to include a circuit before that of Fig. 3 to produce a lag of $\pi/2$ in the current representing the voltage of the circuit. An active integrator can be used as the basic building block of that circuit.

The thermoelectric analog multiplication just presented permits assembling wideband multipower meters because thermoelectric converters can be used at frequencies up to a few hundred megahertz.

Hall Effect Principle (Hall Effect Volt-Ampere Meters)

The Hall effect is a phenomenon that occurs in conductors and semiconductors but is particularly important in the latter. It consists of the appearance of a voltage u_H between two parallel faces of a parallelepiped semiconductor chip when the semiconductor is subjected to a current i and to a magnetic induction field B acting in the two other orthogonal directions. The relationship among the three quantities is given by

$$u_H = \frac{R_H}{d} i B(t) \quad (14)$$

where R_H is the so-called Hall coefficient of the material and d is its thickness. Figure 4 represents the circuit configuration for the analog multiplication of a voltage and a current using the Hall effect principle. The magnetic field in the semiconductor is proportional to the current in the circuit and the current in the semiconductor is proportional to the voltage in the circuit. Thus, the time averaging of u_H , which can be done by mechanical or electrical means, is proportional to the active power. In the first case, a d'Arsonval meter is usually used. In the second, an electronic integrator (active low-pass filter) is the more common solution.

As in the case of thermoelectric conversion, the Hall effect principle can support the design of a multipower meter for measuring active, reactive, and apparent power. However, as far as we know, only active power meters have been assembled and used. The direct field sensor (DFS) from Landis & Gyr is an example of applying the Hall effect to measuring active power and also electrical energy. DFS incorporates a Hall sensor, a custom chip, and additional circuit elements. Its main positive characteristics are: (1) accuracy better than 1%; (2) good stability and the possibility of automatic calibration, which leads to highly reliable maintenance-free meters; (3) very good electromagnetic immunity, in part because of its inherent galvanic isolation; and (4) the possibility of integrating functions, such as radio telemetry.

Feedback Time-Division Multiplier Principle (FTDM Volt-Ampere Meters)

Time-division multiplication is a technique of analog multiplication based on the concept that the area of an electric pulse is equal to the product of the pulse width and pulse height. The circuit represented in Fig. 5(a) is a possible hardware solution

Figure 4. Hall effect analog power meter. The analog multiplication of the current and voltage comprised in the power is obtained by using the Hall effect principle. $B(t)$ is proportional to the current and i to the voltage in the circuit.

Figure 5. Time division multiplier: (a) amplitude modulator and low-pass filter. u' , the output voltage of the MSA converter, represented in (b), is multiplied by u_2 , and the average of this product is achieved by using a low-pass filter; (b) mark space amplitude converters. The duty cycle of a constant amplitude and period rectangular voltage, the output voltage u' , is modulated by a voltage u_1 .

to implement an analog multiplier according to this concept. Because of its positive characteristics, nowadays the FTDM principle first introduced by Yokogawa Electric Works (YEW) is extremely popular among manufacturers of electronic volt-ampere meters.

The basic component of the multiplier is the mark space amplitude (MSA) converter [Fig. 5(b)]. In this converter, the duty cycle of a constant amplitude and period rectangular voltage is modulated by a voltage u_1 . Thus, and referring to Fig. 5(b),

$$T = T_1 + T_2 = k_1 \quad (15)$$

$$T_1 - T_2 = k_2 u_1 \quad (16)$$

where k_1 and k_2 are two constants. By multiplying the MSA output voltage u' with the other voltage u_2 occurring in the product, one obtains a voltage u'_0 :

$$u'_0 = u_2(T_1 - T_2) = k_2 u_1 u_2 \quad (17)$$

This operation is performed by using an amplitude modulator and a low-pass filter [Fig. 5(a)].

The MSA Converter. The MSA converter represented in Fig. 5(b) was also introduced by YEW and is used, for instance, in its digital wattmeter model 2504.

The operation of the converter is as follows. A comparator compares a voltage u_c with a triangular waveform u_t (this voltage is internally generated in the model previously mentioned). When $u_c > u_t$, u' is positive ($u' > 0$) and S_1 switches so that u_0 becomes equal to $+U_{ref}$. When $u_c < u_t$, the comparator output voltage is negative, and S_1 changes to $-U_{ref}$.

If the frequency of the triangular waveform u_t is much higher than the frequency of u_1 and u_2 , then these voltages can be considered constant compared with u_t . Thus, in the steady state, u_c should be periodic and $(i_d)_{av} = 0$ because u_c is the integral of this current. Thus,

$$T_1 \left(\frac{u_1}{R} - \frac{U_{ref}}{R} \right) + T_2 \left(\frac{u_1}{R} + \frac{U_{ref}}{R} \right) = 0 \quad (18)$$

$$(T_1 + T_2) \frac{u_1}{R} = (T_1 - T_2) \frac{U_{\text{ref}}}{R} \quad (19)$$

$$(T_1 - T_2) = T \frac{u_1}{U_{\text{ref}}} = k_2 u_1 \quad (20)$$

$$T_1 = \frac{T}{2} \left(1 + \frac{u_1}{U_{\text{ref}}} \right) \quad (21)$$

This means that T_1 is continuously adjusted by comparing u_c and u_t . If the average value of i_d is not zero, then the voltage u_c is not periodic but increases or decreases, changing the relationship between T_1 and T_2 . The steady state occurs when $(i_d)_{\text{av}} = 0$. The action of the closed-loop set comparator switch is instrumental for that purpose.

The Amplitude Modulator and Low-Pass Filter. Referring to Fig. 5(a), and taking into consideration that the output voltage u' of the comparator of the MSA converter controls switch S_2 ,

$$u'_0 = \begin{cases} +u_2 & \text{if } u' < 0 \\ -u_2 & \text{if } u' > 0 \end{cases} \quad (22)$$

and thus,

$$\begin{aligned} u_0 &= (u'_0)_{\text{av}} = \frac{1}{T} \int_T u'_0(t) dt = \frac{1}{T} [u_2 T_1 - u_2 (T - T_1)] \\ &= \frac{1}{T} [2u_2 T_1 - u_2 T] = \frac{1}{T} \left[2u_2 \frac{T}{2} \left(1 + \frac{u_1}{U_{\text{ref}}} \right) - u_2 T \right] = \frac{u_1 u_2}{U_{\text{ref}}} \end{aligned} \quad (23)$$

The FTDM principle for analog multiplication can be used for active, reactive, or apparent power measurement. Naturally, the voltage and current of the circuit test must be conditioned before they are applied to the multiplier input. In the case of the current, the conditioner must include a current-to-voltage converter using, for instance, a shunt resistor and an operational amplifier.

For active power measurement, the output voltage u_0 of the circuit of Fig. 5(a), must be averaged by another low-pass filter, usually by electronic means.

For reactive power measurement, the voltage of the circuit test must be lagged by $\pi/2$ before it is input to the FTDM. That lag is easily obtained from electronic circuitry and, thus, it is performed after the voltage input conditioner. The output of the multiplier must also be low-pass filtered to yield the reactive power value.

For apparent power, the easiest solution involves two rms converters placed between the input conditioners and the multiplier. The product of the two dc voltages output by the rms converters indicates the value of the apparent power.

The measurement of voltage and current is also easily implemented by using the FTDM multiplier. For that purpose, it is sufficient to connect the output of the voltage conditioner or of the current conditioner to both inputs of the multiplier.

Several FTDM volt-ampere meter manufacturers, such as YEW, Dranetz, Landis & Gyr, and Schlumberger offer energy counters based on the FTDM multiplying principle. In fact, all that it is required is to add an integrator to the active power meter. In the YEW wattmeter model 2504, the integrator is a stand-alone instrument (YEW 2513).

Logarithmic Conversion Principle

One easy way of performing the analog multiplication of two electric quantities (voltages or currents) is with logarithmic amplifiers (6). In fact, because

$$\log(ab) = \log a + \log b \quad (24)$$

the logarithmic conversion of two quantities transforms its product into a sum, easily achieved by using operational amplifiers. Applying the inverse function to Eq. (24) the product of the two quantities a and b is given by

$$\log^{-1}[\log(ab)] = ab = \log^{-1}(\log a + \log b) \quad (25)$$

Figure 6 presents a circuit based on logarithmic and antilogarithmic converters which multiplies u_1 and u_2 . The first module uses two identical logarithmic converters, whose output voltages are related to the input voltages by

$$\begin{aligned} u_{01} &= -k_1 \log_{10} \frac{u_1}{RI_{\text{ref}}} \\ u_{02} &= -k_1 \log_{10} \frac{u_2}{RI_{\text{ref}}} \end{aligned} \quad (26)$$

where

$$k_1 = \frac{R_T + R_1}{R_T} \cdot \frac{kT}{q} \frac{1}{0.434} \quad (27)$$

In Eq. (27), k is the Boltzmann constant ($1.38 \times 10^{-23} \text{ J}\cdot\text{K}^{-1}$), T is the absolute temperature of the semiconductor junctions, and q is the charge of the electron ($1.6 \times 10^{-19} \text{ C}$).

The operational amplifier of the intermediate stage provides

$$u_{03} = -k_1 \log_{10} \frac{u_1 u_2}{R^2 I_{\text{ref}}^2} \quad (28)$$

The final module performs the antilogarithmic operation. The output voltage is proportional to the antilogarithmic of the input voltage

$$u_0 = RI_{\text{ref}} \log_{10}^{-1} \left[k_1 \times \frac{\log_{10} \left(\frac{u_1 u_2}{R^2 I_{\text{ref}}^2} \right)}{k_1} \right] = \frac{u_1 u_2}{RI_{\text{ref}}} \quad (29)$$

Implementing power meters using this principle is fairly easy but leads to instruments with moderate performance. In fact, the existence of logarithmic and antilogarithmic amplifiers and of log/antilog multipliers as integrated circuits (e.g., Burr-Brown 4127, Burr-Brown 4302) simplifies designing and constructing power meters. However, such components are either inexpensive and moderately accurate or they perform well, but then they are quite expensive. For that reason volt-ampere meters based on this type of component are not popular and are limited to applications demanding only low accuracy (not less than 1%).

As long as the multiplier block operates with positive and negative input voltages (four-quadrant multiplier), its functionality, from the viewpoint of the terminal voltages, is similar to that of the FTDM. This means that the considerations in the

Figure 6. Analog multiplication using logarithmic and anti-logarithmic amplifiers: $u_{01} \propto \log u_1$; $u_{02} \propto \log u_2$; $u_{03} \propto \log u_1 + \log u_2$; $u_0 \propto \log^{-1}(u_{03}) = \log^{-1}(\log u_1 + \log u_2) = u_1 u_2$.

previous section regarding circuitry for measuring the different types of power, voltage, current and even energy are still pertinent.

Other Solutions for Electric Analog Multiplication

Two other types of solutions for analog multiplication of two voltages (or currents) are worth a short discussion.

The first has its origin in the following relationship:

$$(a + b)^2 - (a - b)^2 = 4ab \quad (30)$$

The circuitry used to implement this idea also involves, in general, logarithmic amplifiers, and thus this type of multiplier is considered a variation of the log/antilog multiplier mentioned in the preceding paragraph.

In the second type we include several different multipliers that are based on different principles but have two aspects in common. They are electronic multipliers, and they are available as integrated circuits. The so-called transconductance principle (7,8) is an example of a principle used, for instance, in Burr-Brown MPY 100 and in Harris ICL8013.

DIGITAL POWER METER

The digitization of low-frequency electrical voltages and currents is presently achieved simply and at low cost. It originated from low cost, high-performance, and reliable analog and digital integrated circuits. The basic blocks of a digitizing system are naturally the sample-and-hold and the analog-to-digital converter. The performance of digitizing systems is highly dependent on the performance level of those compo-

nents. Notwithstanding, the advances in digital circuits for control, data processing, data storage, and data transmission led to the replacement, whenever possible, of analog measuring methods by digital measuring methods. This trend is also felt in the domain of low-frequency power and energy measurements. As already mentioned, active power, reactive power, and apparent power are measured digitally in two steps. First, the voltage and current are simultaneously converted to digital words, and then the resultant data is digitally processed by some processing unit. This means that two equally important components are involved in the operation of this type of power meter, the hardware and the software. The routines that constitute the software can be quite different from instrument to instrument. The hardware components of the instruments have, however, some similarities. Figure 7, which represents the implementation used by Yokogawa in models WT110/WT130, gives a good picture of the building blocks of a typical low-frequency multi-power meter.

This instrument consists of various sections: input circuits (voltage and current input circuits), a digital signal processor (DSP), a central processing unit (CPU), a display and interface circuits.

In the voltage input conditioner, the input voltage is attenuated and then sent to an analog-to-digital converter (ADC). In the current input conditioner, the current involved is converted into a voltage by using a shunt resistor. Then the voltage is amplified and formalized by an operational amplifier before entering another ADC converter. The outputs from both ADC converters are sent to the digital signal processor (DSP). The DSP reduces the data to produce the values of voltage, current, and active power for each sampled datum sent from the ADC converter. After processing a certain number of sets of data,

Figure 7. Digital power meter: after digitizing the voltage and current, the CPU reduces the data to compute the active, reactive, or apparent power.

computation of the apparent power, reactive power, power factor, and phase angle starts. Computational results are sent to the CPU where computations, such as range conversion and scaling, are carried out. Display and outputs are also controlled by the CPU. The output goes to a readout driver (display).

GENERAL CONSIDERATIONS

Although the measurement of active power is important in different frequency domains, reactive power and apparent power measurements are required basically in power systems. The measuring principles discussed take that into account.

In power systems, it is often necessary to measure the three-phase power and energy. It is worth mentioning that some measuring methods, such as the Aron method, avoid the use of three volt-ampere meters. Interested readers are directed to Chapter VI of Ref. 4 and Chapter 6 of Ref. 5.

Excluding electrodynamic volt-ampere meters, all of the analog multiplication power meters considered are built around a block that produces a voltage (or current) proportional to the product of the current and voltage of the circuit under test. The meter hardware must be complemented with a voltage (or current) measuring device and with input conditioning circuitry whose composition depends on the quantity to be measured by the power meter and on its accuracy. For measurements in the range 45 to 65 Hz with accuracy better than 0.5%, the input circuits include current and voltage transformers or, less often, voltage dividers and current shunts. These components, that reduce the amplitude of the input current and voltage to levels accepted by the electronic components, are the front end of the meters and much of the meters performance depends on the metrological characteristics of such passive components. The reader should take the solutions considered in the text as guidelines for understanding the internal composition of those types of volt-ampere meters.

The following values are typical for the accuracy of volt-ampere meters: analog type—0.1% to 2% full-scale value (FSV); digital type—0.2% to 2% FSV. Presently, the standards used for calibration are usually of the FTDM type (e.g., YEW 2855) whose accuracy is around 0.02% FSV.

In this article, we elected to separate volt-ampere meters into analog and digital types according to the principle of measurement they use, but this classification is not universal. In fact, most manufacturers use the term digital whenever the meter displays the measurement numerically. The reader must be aware of this fact when consulting different manufacturers' catalogs.

POWER FACTOR MEASUREMENT

A source of alternating current (ac) delivers electric energy to a receiver at an average rate, over the period of the current, called an active power. The mathematical product of the active power and the time of energy delivery provides the amount of energy delivered. Customers are billed for this energy.

Electric energy receivers operate at a voltage specified by its root mean square (*rms*) value and frequency. The supply source has to provide this voltage. Electrical power systems are built in such a way that this supply voltage has a near to sinusoidal waveform and is almost independent of receivers. While the supply source delivers energy to the receiver, a supply current flows through the source. Similar to the voltage, this current has an rms value.

The mathematical product of the voltage rms value and the supply current rms value is called the apparent power. This power has no physical meaning. The apparent power cannot be lower than the active power, and it is usually higher. When it is, the supply current rms value is greater than that needed for active power delivery.

The ratio of the active power to the apparent power is known as the power factor (PF). Since the active power cannot be higher than the apparent power, the PF cannot be higher than one. A power factor value lower than one indicates that the receiver is loading the supply source with a current of higher rms value than that needed for active power delivery.

The power factor value is a matter of concern for electric power utilities, which provide electric energy to customers. Power system equipment has to have the capability to handle the needed current rms value. At a low power factor, the supply current rms value is higher than that at high power factor. Thus, a low power factor when supplying receivers has several inconveniences for power utilities: (1) To handle currents with higher rms values, distribution system equipment has to be more expensive. (2) When energy is delivered to a customer, a part of it is lost in the distribution system equipment. This

loss increases with the square of the supply current rms value, that is, with the decline of the power factor. (3) The supply current causes a voltage drop at the impedance of the distribution system, which reduced the voltage provided to customers. In a case of inductive loads and a sinusoidal supply voltage, the lower the PF, the higher the voltage drop.

Consequently, a decline of the PF increases the investment and operating cost of electric power utilities. Therefore the power factor affects the financial accounts for energy between utilities and customers, especially the large ones. This is the reason for the measurement of power factor. Also, this is the reason for developing methods of power factor improvement.

The power factor is a feature of energy receivers. The PF of single-phase receivers that, when supplied with sinusoidal voltage, do not cause current distortion, depends on the phase-shift between the supply voltage and the supply current. Such receivers are referred to as linear. This phase-shift is the only cause of the power factor decline for linear receivers. The supply current, which is shifted with respect to the voltage, contains two components. One of them is in phase with the voltage. Another is shifted by a quarter of the current's period. Only the component in phase with the voltage contributes to the active power delivery. The remaining one only increases the rms value of the supply current and the apparent power. The PF of linear receivers is equal to the cosine value of the phase-shift angle between the supply voltage and current.

When supplied with nonsinusoidal voltage, linear receivers may cause supply current distortion. Also, nonlinear receivers cause current distortion. In both such situations the supply current cannot be referred to as shifted with respect to the voltage. The power factor of such receivers does not equal the cosine value of any angle. Harmonics of the supply current contribute to an increase of the current rms value and consequently to the decline of the power factor. Only the ratio of the active and apparent powers provides the value of the power factor, as defined by Eq. (1).

The power factor of linear three-phase receivers supplied with a sinusoidal voltage is specified similarly as for single-phase receivers only if the supply voltage is symmetrical and the receivers are balanced. In such a case, the PF is equal to the cosine value of the phase-shift angle between the line current and the line-to-ground voltage.

When impedances of particular phases of a 3-phase system are mutually different, the system is unbalanced. Line currents of a three-phase system with unbalanced receivers contain components that do not contribute to the active power of the load. These components contribute only to an increase of the supply current rms value. Therefore load imbalance reduces the power factor. In asymmetrical systems, only the ratio of the active and apparent powers provides the value of the power factor. Unfortunately, a few different quantities are considered to be the apparent power in three-phase systems. These apparent powers are mutually equivalent only when a three-phase system is symmetrical. When the system is asymmetrical, these apparent powers differ. Consequently, the PF depends on the chosen definition of the apparent power.

Measurements of the power factor in systems where it is equal to the cosine value of the voltage and current phase-shift angle are a relatively simple task. The first power factor meters for such systems were built in the last years of the nineteenth century. Construction of the power factor meters for systems where the power factor can be expressed only as the ratio of

the active and apparent powers had to wait, however, until sufficient progress in electronics was achieved.

A power factor meter is a direct-reading instrument for measuring power factor. It is provided with a scale graduated in PF or with a digital display. There are two different types of PF meters: (1) electrodynamic meters (iron-vane or crossed-coil), and (2) electronic (analog or digital) meters.

Single-phase, electrodynamic meters of the power factor, known as cross-coil meters, have two moving coils rigidly connected on a shaft located in the center of the third, a fixed coil carrying the load current. The current in one of the moving coils is proportional to the load voltage. The current in the second coil is shifted by 90° with respect to the current in the first moving coil. The currents flowing through the three coils produce magnetic fields, and consequently, torques are exerted on moving coils. One torque increases with the deflection angle of the coils: the remaining torque declines with that angle. They balance each other at the deflection angle equal to the phase-shift angle between the supply voltage and current. To have the scale of the meter graduated in power factor, the values of the cosine function are allocated to particular deflection angles.

Analog meters can measure the power factor when it is equal to the cosine value of the phase-shift angle as well as when it is only the ratio of the active and apparent powers. In the first case, the difference in the zero crossings of the supply voltage and the supply current provide the phase-shift angle as a fraction of the period, 2π . This fraction is next converted electronically to a cosine value. When the power factor is only the ratio of the active and apparent powers, these powers are converted to dc voltage with electronic multipliers, integrators and rms value to dc voltage converters. These two dc voltages proportional to the active and apparent powers are divided electronically. The output voltage of the divider is proportional to the power factor. It can be measured by a voltmeter with a scale graduated in power factor or with a digital display.

Digital meters calculate the PF based on sequences of digital samples of the supply voltage and current. When sufficiently dense sequences of digitized instantaneous values of the voltage and current are available, all powers, thus also the power factor, can be calculated. Sampling circuits and analog-to-digital (ADCs) converters are the main components of such meters. Also, digital hardware capable of performing calculating algorithms is needed. This can be done by a separate microcontroller or a microcomputer. Digital meters can measure PF if it is equal to the cosine value of the phase-shift angle, or if it is only the ratio of the active and reactive powers.

POWER FACTOR AND ITS MEANING

Power factor λ of a receiver of electric energy is the ratio of active power P of the receiver to its apparent power S , that is, the power factor is defined as

$$\lambda = \frac{P}{S} \quad (1)$$

Active power P is the average rate of energy flow from the supply source to the energy receiver, calculated or measured over one period T of the voltage. In single-phase circuits, the apparent power S is the product of rms values of voltage and

Figure 1. A single-phase load with a supply source and quantities that specify power factor at the supply terminals.

current, U and I , at the terminals of the supply source, as shown in Fig. 1. This is the maximum value of active power P that can be delivered at voltage and current rms values U and I . The PF has similar meaning in 3-phase balanced systems. However, various quantities are considered to be the apparent power in three-phase unbalanced systems, and consequently, there is a controversy regarding the meaning of the power factor.

Various features of energy receivers, such as current phase shift, generation of current harmonics, and current asymmetry of 3-phase equipment cause active power P to be lower than the apparent power S . Therefore, power factor can be interpreted as a measure of the supply source utilization.

POWER FACTOR IN SINGLE-PHASE, TWO-PHASE, AND THREE-PHASE BALANCED CIRCUITS WITH SINUSOIDAL VOLTAGE AND CURRENT

In single-phase circuits with sinusoidal voltage and sinusoidal current, that is, equal to

$$u = \sqrt{2}U \sin \omega t \quad i = \sqrt{2}I \sin(\omega t - \varphi) \quad (2)$$

where U and I denote the rms values of the voltage and current and φ denote their phase-shift angle, the power factor is equal to the cosine value of the voltage and current phase-shift angle φ , since

$$\lambda = \frac{P}{S} = \frac{UI \cos \varphi}{UI} = \cos \varphi \quad (3)$$

The phase-shift between supply voltage and current is the only cause for the power factor's decline in single-phase circuits with sinusoidal voltages and currents. The same is true with balanced 2-phase, 3-wire systems, where

$$\lambda = \frac{P}{S} = \frac{\sqrt{2}UI \cos \varphi}{\sqrt{2}UI} = \cos \varphi \quad (4)$$

where U denotes the rms value of the line-to-line voltage, I is the rms value of the line current, and φ is the phase-shift angle between line-to-ground voltage and the line current. Similarly, in balanced 3-phase systems

$$\lambda = \frac{P}{S} = \frac{\sqrt{3}UI \cos \varphi}{\sqrt{3}UI} = \cos \varphi \quad (5)$$

The power factor in single-phase circuits with sinusoidal voltages and currents can be expressed not only in terms of powers but also in terms of rms values of the active and reactive components of the supply current. These rms values, I_a and I_r , are equal to the real and imaginary parts of the complex rms (crms) value of the supply current $\mathbf{I}$ at the voltage crms value $\mathbf{U} = Ue^{j0}$. At such a voltage, the supply current crms value is

equal to

$$\mathbf{I} = Ie^{-j\varphi} = I \cos \varphi - jI \sin \varphi = I_a - jI_r \quad \text{with} \quad I = \sqrt{I_a^2 + I_r^2} \quad (6)$$

The PF can be expressed as

$$\lambda = \frac{P}{S} = \frac{UI \cos \varphi}{UI} = \frac{I_a}{\sqrt{I_a^2 + I_r^2}} = \frac{1}{\sqrt{1 + (I_r/I_a)^2}} \quad (7)$$

This result means that the presence of the reactive component in the supply current is the cause of the PF decline.

The power factor in single-phase circuits with sinusoidal voltages and currents can also be expressed in terms of the load parameters. If $\mathbf{Y} = Y e^{-j\varphi} = G + jB$ is the load admittance, then the rms values of the active and reactive components of the supply current are equal to $I_a = GU$ and $I_r = |B|U$, respectively, and consequently, power factor can be expressed as

$$\lambda = \frac{1}{\sqrt{1 + (B/G)^2}} \quad (8)$$

If $\mathbf{Z} = Ze^{j\varphi} = R + jX$ is the load impedance, then the load conductance G and susceptance B are equal to

$$G = \frac{R}{R^2 + X^2} \quad B = -\frac{X}{R^2 + X^2} \quad (9)$$

and the power factor can be expressed as

$$\lambda = \frac{1}{\sqrt{1 + (X/R)^2}} \quad (10)$$

Thus, a nonzero reactance (a nonzero susceptance) of the load is the cause of the power factor's decline. The Eqs. (6)–(9) are also valid for balanced 3-phase circuits with sinusoidal voltages and currents.

EFFECTS OF THE POWER FACTOR ON THE SUPPLY SOURCE

Differences in active power delivery at different power factors are illustrated with Fig. 2. Figure 2(a) shows the single-phase equivalent circuit of a supply source and an inductive load. Figures 2(b) and 2(c) show phasor diagrams of the voltage, current, and voltage drop on the inductance and resistance of the supply for two different PF, $\lambda = 0.95$ and $\lambda = 0.5$, but with the same load active power P . Active power P delivery at a low PF requires a higher rms value I of the supply current as compared with active power delivery at a higher PF. Consequently, the active power loss in the supply source, ΔP_s , equal to

$$\Delta P_s = R_s I^2 \quad (11)$$

increases as the PF declines. The same is true for the voltage drop on the internal impedance of the source, ΔU_s . Moreover, as can be seen in Fig. 2(c), the voltage drop on the reactance $\omega_1 L_s$ at a low PF contributes mainly to the magnitude of the difference between the load voltage u and internal voltage e of the supply. The voltage drop on the resistance R_s contributes to a phase-shift between these two voltages. It is almost opposite at a high PF, namely, as shown in Fig. 2(b), the voltage drop on the

Figure 2. (a) Equivalent circuits of the load and the source, (b) phasor diagram of the circuit with a high power factor, equal to $\lambda = 0.95$, (c) phasor diagram of the circuit with a low power factor, equal to $\lambda = 0.5$. Active power P in both situations is the same but the supply current rms value I and voltage drop ΔU in the supply source are higher at a low power factor.

resistance contributes mainly to the magnitude of the voltage difference, while the voltage drop on the reactance contributes to the phase shift. The reactance of distribution systems is usually a few times higher than the resistance, and therefore the load voltage declines more strongly when the PF is low than when it is high. Consequently, a low PF has a number of harmful effects on distribution systems:

1. It increases the needed power ratings of the distribution equipment, thus increasing the investment cost.
2. It increases the active power loss in the distribution system, thus increasing the fuel cost.
3. It generally reduces the load voltage. This may require the elevation of the distribution voltage, thus increasing the operational cost needed for voltage regulation. Also, at higher values of the distribution voltage e the active power loss in the distribution system is higher.

These detrimental effects of a low PF, λ , are the reason for which it is measured for energy accounts between power utilities and customers. It is important to observe that all extra costs caused by low power factors are on the power utilities' side. Therefore, PF may affect the energy tariff, or customers may be obliged to pay penalties if the power factor of their loads is too low. This is also the cause for developing various methods of power factor improvement.

POWER FACTOR IN THREE-PHASE UNBALANCED SYSTEMS WITH SINUSOIDAL VOLTAGES AND CURRENTS

Power factor is the ratio of active to apparent power. The apparent power in 3-phase systems can be defined, however, in

various ways. When the system is balanced, these definitions result in the same value; differences appear only when the system is unbalanced. Consequently, the power factor in unbalanced systems depends on the chosen definition of apparent power.

The apparent power in 3-phase systems is defined according to the conclusion (1) of the joint committee of AIEE and NELE (presently, Edison Institute) in 1920. Thus, the apparent power can be defined as

$$S_G = \sqrt{P^2 + Q^2} \quad (12)$$

where Q is the reactive power of the load. This quantity is known as geometric apparent power. It can also be defined as

$$S_A = U_R I_R + U_S I_S + U_T I_T \quad (13)$$

where U_R , U_S , and U_T are the rms values of the line-to-ground voltages, and I_R , I_S , and I_T are the rms values of the line currents. This quantity is known as arithmetical apparent power. The controversy and confusion caused by the presence of different definitions of apparent power with respect to PF measurement is discussed in Ref. 2 and remain unsolved. The latest edition of the *Standard Dictionary of Electrical and Electronic Terms* (3) provides both definitions.

The controversy regarding apparent power and power factor is illustrated here with a numerical example. Figure 3 shows a 3-phase symmetrical source that supplies two customers with the same active power, $P = 100$ kW. Thus they are billed for the

Figure 3. Two three-phase circuits with the same load active power $P = 100$ kW, but circuit (a) is balanced while circuit (b) is unbalanced. The load imbalance causes an increase of the active power loss. Arithmetic and geometric apparent powers and power factors in the balanced circuit are the same, but different in the unbalanced circuit.

same energy. However, one load is balanced, and the second is unbalanced. The unbalanced load requires higher current ratings of the supply source (142.7 A) than the source that supplies the balanced load (77.8 A). Moreover, the active power loss in the supply source is higher when supplying the unbalanced load (11.2 kW) than when supplying the balanced one (5.5 kW). The increase of the active power loss is comparable to the delivery of the same active power $P = 100$ kW in the balanced circuit with the power factor of the order of $\lambda = 0.7$. However, the geometric apparent power S_G is not affected by the load imbalance; $S_G = 100$ kVA and $\lambda_G = P/S_G = 1$. The arithmetic apparent power amounts to $S_A = 118.9$ kVA and $\lambda_A = P/S_A = 0.84$, that is, the arithmetic PF is higher than the PF of an RL load, which causes the same increase of the active power loss. Thus, geometric and arithmetic apparent powers do not have the same properties as the apparent power in single-phase circuits $S = UI$ which is the product of quantities that are responsible for the line and shunt active power loss, $R_s I^2$ and $G_s U^2$.

Three-phase distribution equipment is manufactured as symmetrical devices, thus the line resistance $R_R = R_S = R_T = R_s$. It was shown in Ref. 4 that the active power loss in such a device caused by line currents i_R, i_S , and i_T arranged in a vector

$$\mathbf{i} = \begin{bmatrix} i_R \\ i_S \\ i_T \end{bmatrix}$$

can be expressed as

$$\Delta P_s = R_s \frac{1}{T} \int_0^T (i_R^2 + i_S^2 + i_T^2) dt = R_s \frac{1}{T} \int_0^T \mathbf{i}^t \mathbf{i} dt = R_s \|\mathbf{i}\|^2 \quad (14)$$

where $\mathbf{i}^t$ denotes a transposed vector, and

$$\|\mathbf{i}\| = \sqrt{\frac{1}{T} \int_0^T \mathbf{i}^t \mathbf{i} dt} = \sqrt{\|i_R\|^2 + \|i_S\|^2 + \|i_T\|^2} \quad (15)$$

is the rms value of the 3-phase current vector. A symmetrical 3-phase resistive device with the line currents, i_R, i_S , and i_T , is shown in Fig. 4(a). It is equivalent, with respect to active power loss, to a single-phase device shown in Fig. 4(b) with the current rms value $\|\mathbf{i}\|$. Similarly, the active power loss caused by line-to-ground voltages, arranged in the vector

$$\mathbf{u} = \begin{bmatrix} u_R \\ u_S \\ u_T \end{bmatrix}$$

Figure 4. (a) A three-phase symmetrical device with asymmetrical currents i_R, i_S , and i_T and (b) a single-phase device equivalent with respect to the active power P at the current rms value $\|\mathbf{i}\|$.

can be expressed as

$$\Delta P_s = G_s \frac{1}{T} \int_0^T \mathbf{u}^t \mathbf{u} dt = G_s \|\mathbf{u}\|^2 \quad (16)$$

where

$$\|\mathbf{u}\| = \sqrt{\frac{1}{T} \int_0^T \mathbf{u}^t \mathbf{u} dt} = \sqrt{\|u_R\|^2 + \|u_S\|^2 + \|u_T\|^2} \quad (17)$$

is the rms value of a 3-phase voltage vector.

Since the rms values $\|\mathbf{i}\|$ and $\|\mathbf{u}\|$ are related to the active power loss in 3-phase supply sources similarly as the rms values U and I are related to active power loss in single-phase sources, then the apparent power in 3-phase systems with symmetrical distribution equipment should be defined as

$$S = \|\mathbf{u}\| \|\mathbf{i}\| \quad (18)$$

Such a definition was assumed in Ref. 4 for 3-phase systems with nonsinusoidal voltages and currents. For 3-phase systems with sinusoidal waveforms, such a definition was suggested by Buchholz (5) in 1922, but this definition is not referenced by the IEEE Standard (3).

The rms values $\|\mathbf{i}\|$ and $\|\mathbf{u}\|$ in the previous example are equal to $\|\mathbf{i}\| = 201.8$ A, and $\|\mathbf{u}\| = 741.2$ V; and apparent power $S = 149$ kVA. The active power loss in the supply source is equal to $\Delta P_s = R_s \|\mathbf{i}\|^2 = 0.275 \times (201.8)^2 = 11.2$ kW. The power factor using such a definition of apparent power is equal to $\lambda = 0.67$.

The increase of the supply current rms value and decline of the PF in 3-phase systems with sinusoidal voltages and currents is caused by the presence of the reactive current. The example considered above shows that PF may also decline in the absence of the reactive current only because of the load imbalance. This conclusion was reported by Lyon in 1920 (6). Reference 7 shows that this is because the current vector $\mathbf{i}$ contains not only the active and reactive currents, $\mathbf{i}_a$ and $\mathbf{i}_r$, but also an unbalanced current, $\mathbf{i}_u$. Therefore the supply current in three-phase systems can be decomposed into three currents, namely

$$\mathbf{i} = \mathbf{i}_a + \mathbf{i}_r + \mathbf{i}_u \quad (19)$$

Since the rms values of these currents fulfill the relationship

$$\|\mathbf{i}\| = \sqrt{\|\mathbf{i}_a\|^2 + \|\mathbf{i}_r\|^2 + \|\mathbf{i}_u\|^2} \quad (20)$$

then, the power factor can be expressed as

$$\lambda = \frac{P}{S} = \frac{\|\mathbf{u}\| \|\mathbf{i}_a\|}{\|\mathbf{u}\| \|\mathbf{i}\|} = \frac{\|\mathbf{i}_a\|}{\sqrt{\|\mathbf{i}_a\|^2 + \|\mathbf{i}_r\|^2 + \|\mathbf{i}_u\|^2}} \quad (21)$$

where the rms values of these currents depends on the load equivalent conductance G_e , equivalent susceptance B_e , and unbalanced admittance A ; expressed

$$\|\mathbf{i}_a\| = G_e \|\mathbf{u}\|, \quad \|\mathbf{i}_r\| = |B_e| \|\mathbf{u}\|, \quad \|\mathbf{i}_u\| = A \|\mathbf{u}\| \quad (22)$$

Equation (21) shows that the unbalanced current $\mathbf{i}_u$ contributes to the decline of the PF in a manner similar to the reactive current $\mathbf{i}_r$.

POWER FACTOR OF LINEAR LOADS WITH NONSINUSOIDAL VOLTAGE

An increase of the supply current rms value and decline of the PF in linear single-phase circuits with nonsinusoidal voltage is caused by (1) a phase shift of the voltage and current harmonics and (2) by a varying of the load conductance with harmonic frequency. The supply current i in such circuits may contain, according to Ref. 8, not only active and reactive currents i_a and i_r , but also a scattered current i_s , namely

$$i = i_a + i_s + i_r \quad (23)$$

The rms values of these currents fulfill the relationship

$$\|i\| = \sqrt{\|i_a\|^2 + \|i_s\|^2 + \|i_r\|^2} \quad (24)$$

Therefore, the power factor can be expressed as

$$\lambda = \frac{P}{S} = \frac{\|i_a\|}{\sqrt{\|i_a\|^2 + \|i_s\|^2 + \|i_r\|^2}} \quad (25)$$

The scattered current i_s contributes to a PF decline in a manner similar to the reactive current i_r . However, reactive shunt compensators are incapable of compensating scattered current.

POWER FACTOR OF NONLINEAR LOADS WITH SINUSOIDAL SUPPLY VOLTAGE

The conclusion that the PF can decline because of current distortion, without any phase shift, was drawn for the first time by Steinmetz (9) in 1892 and discussed in Ref. 10.

If the supply voltage is sinusoidal, then current distortion occurs when the load is nonlinear, and/or its parameters change periodically because of periodic switching. The supply current i of such a load may contain not only active and reactive currents i_a and i_r , but also a load generated harmonic current i_g , namely

$$i = i_a + i_r + i_g \quad (26)$$

Since the rms values of these currents fulfill the relationship

$$\|i\| = \sqrt{\|i_a\|^2 + \|i_r\|^2 + \|i_g\|^2} \quad (27)$$

the power factor can be expressed as

$$\lambda = \frac{P}{S} = \frac{\|i_a\|}{\sqrt{\|i_a\|^2 + \|i_r\|^2 + \|i_g\|^2}} \quad (28)$$

The load generated harmonic current i_g contributes to the decline of the PF in a manner similar to the reactive current i_r .

Active and reactive currents i_a and i_r are sinusoidal currents of the fundamental frequency, that is, $i_a + i_r = i_1$. Their rms values are commonly denoted by I_a , I_r , and I_1 . Hence, the PF can be expressed as

$$\lambda = \frac{\|i_a\|}{\sqrt{\|i_a\|^2 + \|i_r\|^2}} \frac{1}{\sqrt{1 + \frac{\|i_g\|^2}{\|i_a\|^2 + \|i_r\|^2}}} = \frac{\lambda_1}{\sqrt{1 + \delta_i^2}} \quad (29)$$

where

$$\lambda_1 = \frac{\|i_a\|}{\sqrt{\|i_a\|^2 + \|i_r\|^2}} = \frac{I_a}{\sqrt{I_a^2 + I_r^2}} = \cos \phi_1 \quad (30)$$

is known as a *displacement power factor*. The angle ϕ_1 is the phase-shift angle between the supply voltage and the current fundamental harmonic i_1 . The coefficient

$$\delta_i = \sqrt{\frac{\|i_g\|^2}{\|i_a\|^2 + \|i_r\|^2}} = \sqrt{\sum_{n=2}^{\infty} \left(\frac{I_n}{I_1}\right)^2} \quad (31)$$

where I_n denotes the rms value of the n -th order harmonic, specifies the supply current harmonic distortion.

The power factor is affected, according to Eqs. (29) and , by the phase shift ϕ_1 of the voltage and current fundamental harmonics and the current harmonic distortion δ_i . Therefore, the power factor λ alone does not provide (26) sufficient information relative to the loading conditions and the possibility of the power factor improvement. The displacement power factor λ_1 and the current harmonic distortion δ_i have to be known for this. Methods of improvement of the power factor have to take into account their effect both on the displacement power factor λ_1 and on the current distortion δ_i . In particular, capacitive compensation may be ineffective, since an improvement in the displacement power factor is accompanied usually with an increase in the current distortion.

POWER FACTOR MEASUREMENT

To measure the power factor, occasionally it is enough to measure the active power P , the supply voltage and current rms values U and I , and then calculate the apparent power S . The ratio of powers P and S provides the power factor. Such a measurement in single-phase circuits, shown in Fig. 5, provides the power factor whether or not the voltage and current waveforms are sinusoidal. However, such a measurement may provide an incorrect value of the power factor in 2-phase, 3-wire circuits and in 3-phase circuits when the voltages and currents are non-sinusoidal. When waveforms are sinusoidal and the load is balanced, then the meters connected as shown in Fig. 6 and Fig. 7 provide data needed for calculating the power factor in 2-phase and in 3-phase, 3-wire circuits. The PF in a balanced 2-phase circuit with meters connected as shown in Fig. 6 can be calculated as in a single-phase circuit, that is,

$$\lambda = \frac{P}{UI} \quad (32)$$

In the case of a three-phase balanced circuit with meters

Figure 5. Meter arrangement for power factor calculation in single-phase circuits.

Figure 6. Meter arrangement for power factor calculation in balanced two-phase, three-wire circuits.

connected as shown in Fig. 7, the power factor is equal to

$$\lambda = \frac{W_1 + W_2}{\sqrt{3}UI} \quad (33)$$

where W_1 and W_2 are the values measured by wattmeters. In two-phase, three-wire balanced circuits, the power factor can also be calculated from data provided by two wattmeters connected as shown in Fig. 8. Since the voltage coil of the wattmeter W_2 is supplied with a voltage shifted by $\pi/2$, this wattmeter measures the value

$$W_2 = -UI \cos(\varphi + \pi/2) = UI \sin \varphi \quad (34)$$

the ratio

$$\frac{W_2}{W_1} = \frac{UI \sin \varphi}{UI \cos \varphi} = \tan \varphi \quad (35)$$

Hence

$$\lambda = \cos \left(\text{atan} \left\{ \frac{W_2}{W_1} \right\} \right) \quad (36)$$

Similarly, the power factor can be measured with only two wattmeters in 3-phase balanced systems. As shown in Ref. 11, wattmeters connected for active power measurement also provide data sufficient for the PF calculation. Wattmeters connected as shown in Fig. 9 measure the values

$$W_1 = UI \cos(\varphi - 30^\circ) \text{ and } W_2 = UI \cos(\varphi + 30^\circ) \quad (37)$$

respectively, where U is the rms value of the line-to-line voltage. Hence, the power factor is equal to

$$\lambda = \cos \left(\text{atan} \left\{ \sqrt{3} \frac{W_1 - W_2}{W_1 + W_2} \right\} \right) \quad (38)$$

Figure 7. Meter arrangement for power factor calculation in balanced three-phase, three-wire circuits.

POWER FACTOR METERS

Until a sufficient progress in electronics was made so that the measurement of the power factor according to definition (1) was possible, all PF meters were built only as meters of the phase-shift angle ϕ between voltage and current. Such meters are scaled in the cosine of this angle, that is, in power factor, or this angle is electronically converted to the power factor.

There are two main types of such power factor meters:

1. Electrodynamic PF meters (iron-vane or crossed-coil PF meters),
2. Electronic PF meters, built as analog or digital instruments.

IRON-VANE PF METERS

An iron-vane PF meter was the first PF meter built in the USA, patented in 1899 (12). There are a number of varieties of construction of iron-vane PF meters. Essentially, such meters are 3-phase instruments; one of them is shown in Fig. 10. It is built of three stationary coils supplied with 3-phase voltage, a stationary coil with the line current, and a movable soft-iron vane with a pointer to a PF-scale. The resistors connected in series with the 3-phase coils are sufficiently large so that the coil currents are approximately in phase with the line-to-ground voltages. The conductors in the coil are distributed such that the radial component of the magnetic field intensity in Θ direction changes as the sine of direction angle Θ , that is, for the coil supplied with the voltage $u_R = U_m \cos(\omega t + \alpha)$, the radial component of the magnetic field intensity is equal to

$$H_R(t, \Theta) = k u_R \sin \Theta = H_{vm} \cos(\omega t + \alpha) \sin \Theta \quad (39)$$

where k is a dimensional coefficient. The voltage coils are distributed around axes rotated by 120° and are supplied with the

Figure 9. Wattmeter connection that enables PF calculation without measuring voltage and current rms values in three-phase, three-wire balanced circuits.

Figure 10. Iron-vane PF meter and its connection to a three-phase system. Coils C_R , C_S , and C_T create a rotating magnetic field H_u , which deflects the iron vane V with magnetic field H_i , which is created by stationary coil by the angle Θ equal to the phase-shift angle ϕ .

voltage shifted by 120° . Hence

$$H_S(t, \Theta) = H_m \cos(\omega t + \alpha - 120^\circ) \sin(\Theta + 120^\circ) \quad (40)$$

$$H_T(t, \Theta) = H_m \cos(\omega t + \alpha - 120^\circ) \sin(\Theta + 120^\circ) \quad (41)$$

The resultant radial component in Θ direction, $H_v(t, \Theta)$, of the magnetic field intensity created by the voltage coils is equal to

$$\begin{aligned} H_v(t, \Theta) &= H_R(t, \Theta) + H_S(t, \Theta) + H_T(t, \Theta) \\ &= \frac{3}{2} H_{vm} \sin(\omega t + \alpha + \Theta) \end{aligned} \quad (42)$$

The maximum of this radial component of the magnetic field intensity occurs at direction

$$\Theta = \pi/2 - \alpha - \omega t \quad (43)$$

that is, it rotates with the radial frequency ω . Because of this, these meters are often referred to as PF meters with a rotating field. This term does not distinguish them from crossed-coil PF meters, however, since the crossed coils in those meters also induce a rotating magnetic field.

The current coil induces a magnetic field in the soft-iron vane. Since the vane forms an asymmetrical magnetic path, the maximum field intensity is along the vane. If the current in line R is equal to $i_R = I_m \cos(\omega t + \alpha - \phi)$, the magnetic field intensity along the vane changes as

$$H_c(t) = H_{cm} \cos(\omega t + \alpha - \phi) \quad (44)$$

The vane positions in the rotating field in such a direction Θ that the maximum of its magnetic field H_c , which occurs at

$\omega t = -\alpha + \phi$, coincides with the maximum of the rotating field H_v , in that direction, hence,

$$\Theta = \pi/2 - \alpha - (-\alpha + \phi) = \pi/2 - \phi \quad (45)$$

Thus, the pointer deflects from the $\pi/2$ angle by the phase-shift angle ϕ . Cosine values are allocated on the scale to the phase-shift angles ϕ , so that the device measures the power factor of the load, both for lagging and leading current. Due to properties of the cosine function, the scale of such meters cannot be uniform. It is denser for lower power factors than for higher ones.

Iron-vane PF meters are essentially 3-phase devices, though they also can be built for 2-phase systems, and, equipped with additional phase-shift circuits, even for single-phase systems.

However, accuracy of iron-vane PF meters is low because the space distribution of magnetic fields created by voltage coils may differ substantially from the required sinusoidal distribution. Also, the sine function varies slowly around its maximum. Consequently, because of the friction of the movable vanes, fields H_v and H_c may not align accurately. Iron-vane PF meters for 2-phase and for single-phase systems are even less accurate than 3-phase PF meters, since the magnitude of the magnetic field intensity H_v cannot be kept constant during the field rotation (because it is induced with only two coils). In the case of PF meters for single-phase circuits, a capacitor or an inductor is connected instead of the series resistor to obtain a phase-shift between the magnetic fields produced by these two coils.

CROSSED-COIL PF METERS

Crossed-coil power factor meters are developments from the phase-shift meter developed by Tuma (13) in 1897. Detailed analyses can be found in Refs. 14 and 15.

A single-phase crossed-coil PF meter is shown in Fig. 11. It is built of two movable coils, C_a and C_b , pivoted to rotate freely with a pointer inside of a stationary coil, C_c . Movable coil planes are deflected by a fixed angle Δ , hence these devices are known as *crossed-coil* meters. Movable coils are supplied with the load voltage in such a way that no mechanical torque is exerted on the movable part. Their currents i_a and i_b are mutually shifted, since one coil is supplied through a series resistor R and the other through a series inductor L . The stationary coil induces a magnetic field proportional to the load current. The stationary coil is constructed in such a way that the magnetic field around the movable coils is uniform.

At the supply voltage $u = U_m \sin \omega t$, the currents in coils C_a and C_b are equal to

$$i_a = I_{am} \sin(\omega t - \alpha) \quad (46)$$

$$i_b = I_{bm} \sin(\omega t - \beta) \quad (47)$$

The instantaneous torque exerted on the coil C_a , deflected from the coil C_c plane by angle Θ , at the load current $i = I_m \sin(\omega t - \phi)$, is equal to

$$\tau_a = k_a i_a i \sin \Theta = k_a I_{am} I_m \sin(\omega t - \alpha) \sin(\omega t - \phi) \sin \Theta \quad (48)$$

where k_a is a coefficient dependent on the windings and geometry of coils C_a and C_c . The average torque in one cycle T of the

Figure 11. Crossed-coil PF meter and its connection to a single-phase circuit. Movable coils with currents i_a and i_b are deflected in the magnetic field of the stationary coil. Torques T_a and T_b are in equilibrium at deflection angle Θ equal to the phase-shift angle ϕ .

supply voltage is equal to

$$T_a = \frac{1}{T} \int_0^T \tau_a dt = T_{am} \sin \Theta \cos(\varphi - \alpha), \quad T_{am} = \frac{1}{2} k_a I_{am} I_m \quad (49)$$

Similarly, the average torque exerted on the coil C_b deflected with respect to coil C_a by angle Δ is equal to

$$T_b = T_{bm} \sin(\Delta + \Theta) \cos(\varphi - \beta), \quad T_{bm} = \frac{1}{2} k_b I_{bm} I_m \quad (50)$$

If the currents in coils C_a and C_b are such that maximum torques T_{am} and T_{bm} are mutually equal, which requires that $k_a I_{am} = k_b I_{bm}$, then the movable part with the pointer is in equilibrium when

$$T_a = T_b \quad (51)$$

at such a deflection angle Θ that

$$\sin \Theta \cos(\varphi - \alpha) - \sin(\Delta + \Theta) \cos(\varphi - \beta) = 0 \quad (52)$$

In an ideal case, when $\alpha = 0$ and $\beta = 90^\circ$, coil C_b should be deflected with respect to coil C_a by the angle $\Delta = 90^\circ$. Then, Eq. (52) simplifies to the form

$$\sin \Theta \cos \varphi - \cos \Theta \sin \varphi = 0 \quad (53)$$

and results in the deflection angle

$$\Theta = \varphi \quad (54)$$

equal to the phase-shift angle between the supply voltage and current.

Because of some inductance in the coil C_a circuit there is, however, a phase shift between the supply voltage and the coil

current i_a , thus $\alpha > 0$. Also, because of a resistance in the coil C_b circuit, the phase-shift angle β between the coil current i_b and the supply voltage is lower than 90° . In such a case, even at $\phi = 0$, the movable part deflects by an angle Θ_0 which satisfies the equation

$$\sin \Theta_0 \cos \alpha - \sin(\Delta + \Theta_0) \cos \beta = 0 \quad (55)$$

Hence, it is equal to

$$\Theta_0 = \tan^{-1} \left(\frac{\sin \Delta \cos \beta}{\cos \alpha - \cos \Delta \cos \beta} \right) \quad (56)$$

When the angle between coils C_a and C_b is chosen such that

$$\Delta = \beta - \alpha \quad (57)$$

thus the initial deflection Θ_0 becomes independent of Δ and it is equal to

$$\Theta_0 = 90^\circ - \beta \quad (58)$$

If condition (57) is fulfilled, the equilibrium Eq. (53) has the solution

$$\Theta = \Theta_0 + \varphi \quad (59)$$

The meter can be scaled in power factor with respect to the initial deflection angle Θ_0 , which can be used for calibrating the meter rotating the stationary coil by that angle, that is, to $\lambda = 1$ at a resistive load.

Figure 12 shows the structure of a three-phase crossed-coil PF meter. Since there are voltages shifted mutually in three-phase circuits, the inductor is not needed for shifting the current in the coil C_b . Such a device measures the power factor in balanced circuits with sinusoidal and symmetrical supply

Figure 12. Three-phase crossed-coil PF meter and its connection to the circuit. The pointer is permanently deflected from the coil C_a plane by 60° .

voltage. In such a case, the phase-shift angles of the coil currents are $\alpha = -30^\circ$, $\beta = 30^\circ$, respectively. Consequently, coil C_b should be deflected with respect to coil C_a by the angle $\Delta = \beta - \alpha = 60^\circ$. The initial deflection angle, Θ_0 , according to Eq. (58), amounts to $\Theta_0 = 60^\circ$. To simplify the scale and the meter design, the pointer is deflected by this angle from the coil C_a plane, as shown in Fig. 12.

ELECTRONIC POWER FACTOR METERS BASED ON PHASE-SHIFT ANGLE MEASUREMENT

Electronic PF meters are built as analog, digital, or hybrid devices. Analog devices measure the phase-shift angle as an interval of time by detecting the zero crossings of the supply voltage and current. This interval of time, referenced to the voltage period T , is converted next to the cosine value, hence, to the power factor. It can be done with continuous or with digital signals, consequently, the PF meter is referred to as an analog or as a hybrid device. Digital PF meters provide the power factor as a result of a digital algorithm on sequences of digital samples of the supply voltage and current.

The structure of one of the first analog electronic PF meter, described in Ref. 16, is shown in Fig. 13. A synchronous switch, built of four diodes and resistors, is the main component of the device. When current i_b is positive, diodes D1 and D2 are conducting and the voltage $u_x = 0$. The voltage at the voltmeter is equal to

$$u_v = u_x + u_a = u_a \quad (60)$$

When current i_b is positive, diodes D3 and D4 are conducting and the voltage $u_y = 0$. The voltage at the voltmeter is equal to

$$u_v = u_y - u_a = -u_a \quad (61)$$

and has the waveform shown in Fig. 14. The voltmeter measures the average value of this voltage. It is equal to

$$\begin{aligned} \bar{u}_v &= \frac{1}{\pi} \int_{\varphi}^{\pi+\varphi} u_a d(\omega t) = \frac{1}{\pi} \int_{\varphi}^{\pi+\varphi} U_{am} \sin \omega t d(\omega t) \\ &= \frac{2U_{am}}{\pi} \cos \varphi = k\lambda \end{aligned} \quad (62)$$

Figure 13. Electronic PF meter with synchronous switch. Diodes D1 and D2 are conducting at positive current i_b . Diodes D3 and D4 are conducting at negative current i_b .

Figure 14. Voltage at the voltmeter provided by the synchronous switch, (shown in Fig. 13) that is controlled by the load current. The average value of voltage u_a is proportional to the power factor of the load.

Thus, the voltmeter can be calibrated directly in power factor. It has a linear scale. Unfortunately, changes in the voltage amplitude, U_{am} , affect the measurement result. Also, lagging and leading PF cannot be distinguished. Frequency division is suggested in (Refs. 17–19) to eliminate the dependence of the measurement result on the voltage. A voltage to frequency converter (VFC) converts the mean value of the voltage u_v into sequence of binary pulses of frequency

$$f_1 = k_1 U_{am} \cos \varphi \quad (63)$$

At the same time, voltage u_a is rectified and its mean value converted to binary pulses of frequency

$$f_2 = k_2 U_{am} \quad (64)$$

by another VFC. The device has two binary counters, C1 and C2. Counter C2 specifies the time interval T_2 needed for counting N_2 pulses of frequency f_2 , which is expressed

$$T_2 = \frac{N_2}{f_2} \quad (65)$$

The number of pulses of frequency f_1 counted in the interval T_2 is equal to

$$N_1 = T_2 f_1 = N_2 \frac{f_1}{f_2} = \frac{k_1}{k_2} \cos \varphi = k\lambda \quad (66)$$

Such a device can be directly equipped with a digital display for reading the PF value.

Figure 15 shows the structure of another analog PF meter, described in Ref. 20 with the measuring results independent of the supply voltage. A reference dc voltage U_{ref} is applied to a voltmeter through two electronically controlled switches. The switch S_A turns dc voltage U_{ref} ON when the supply voltage u changes to a positive value, and turns it OFF when the supply current i changes to a negative value, as shown in Fig. 16. The switch S_B turns the voltage U_{ref} ON when the supply current i changes to a positive value, and turns it OFF when the supply voltage u changes to a negative value. The average value of the voltmeter voltage, $u_v = u_A - u_B$, is equal to

$$\bar{u}_v = U_{ref} \frac{\varphi}{90} = k\varphi; -90 \text{ deg} < \varphi < 90 \text{ deg} \quad (67)$$

Figure 15. Electronic PF meter with sign and zero detectors of the supply voltage and current. A dc voltmeter measures the value proportional to the phase-shift angle ϕ both for lagging and leading power factor.

and a voltmeter, scaled in cosine value of the angle ϕ , with zero in the middle, provides both the lagging and leading power factor. However, its scale is not uniform. It becomes denser as the phase-shift angle approaches $\pm 90^\circ$. It is inconvenient in the case of an analog meter, that is, with a voltmeter scaled in PF. However, the power factor cannot be displayed digitally. A non-linear converter of the voltage to its cosine value is needed in such a case. Reference 21 describes such a converter for power factor measurement applications.

ELECTRONIC POWER FACTOR METERS BASED ON THE MEASUREMENT OF THE RATIO OF ACTIVE TO APPARENT POWER

When the voltage and current waveforms are nonsinusoidal and/or the 2-phase or 3-phase system is asymmetrical, then data provided by PF meters, that are based on phase-shift angle measurement are meaningless. The PF meter has to operate

Figure 16. Generating switching pulses by the sign and zero detectors and logic circuits in the PF meter shown in Fig. 15.

Figure 17. Structure of PF meter built of rms/dc converters, analog multipliers, divider, and a low-pass filter.

in such a case according to power factor definition (1). It has to measure the ratio of the active and apparent power. Analog, binary, and digital signal technology can be employed for this. There is, however, the problem of selection of the apparent power definition in asymmetrical 3-phase systems. When the system is symmetrical, PF can be measured with a single-phase power factor meter.

Single-phase analog PF meters can be built of two integrated analog multipliers, a divider, two rms-to-dc converters, and a low-pass filter. The supply voltage and current have to be conditioned to voltage signals, usually bounded by ± 10 V with voltage and current converters. Figure 17 shows the basic structure of an analog PF meter. Conditioning and supply circuits are not shown. Arrows denote voltage signals proportional to various quantities in the device. Dimensional coefficients are omitted. The output voltage can be used for PF control or measured by a voltmeter scaled in PF. Such a meter cannot have PF value $\lambda = 1$ in the middle of the scale, since definition (1) does not specify whether the PF is lagging or leading. Also, in circuits with nonsinusoidal waveforms these terms are meaningless. Analog PF meters can also be built with a digital display, as discussed in Refs. (22,23).

An operation principle of a hybrid, that is, an analog and digital PF meter, is presented in Ref. 24. Two converters of the supply voltage and current provide voltages $k_u u$ and $k_i i$, where k_u and k_i are conversion coefficients, to a rms value meter. It measures the rms values $k_u |u|$ and $k_i |i|$, as well as, the rms value of the sum $u_s = k_u u + k_i i$ and the difference $u_d = k_u u - k_i i$. These four rms values are transferred to a computer. The difference of the squares of the rms values of voltages u_s and u_d , calculated by the computer gives

$$\|u_s\|^2 - \|u_d\|^2 = 4k_u k_i P \quad (68)$$

This value divided by $4k_u |u| k_i |i|$ is the PF of the load.

Figures 18 and 19 show structures of an analog-to-binary (A/B) signal converter and a PF meter based on binary signal technology, described in Ref. 25. A binary voltage signal x_B is a signal that has only two values, U and $-U$. Information on the magnitude of the analog input quantity $x(t)$ is coded in the duty factor $d(t)$, actually the ratio of time interval τ_+ (when $x_B = U$) to the switching cycle time $\tau = \tau_+ + \tau_-$, where τ_- is the

Figure 18. Converter of analog signal $x(t)$ to its binary representation x_B . Information on the analog signal's instantaneous value is coded in the duty factor of the binary signal.

time interval when $x_B = -U$, namely

$$d(t) = \frac{\tau_+}{\tau_+ + \tau_-} \quad (69)$$

Electronically controlled switches S_A and S_B are turned ON when $x_B = U$ and turned OFF when $x_B = -U$, consequently, capacitors C_1 and C_2 are charged with positive or negative voltages x and z . The charges on these capacitors must remain unchanged during each operation cycle, that is, time interval τ . The charging and discharging equilibrium occurs at the duty factor

$$d(t) = \frac{1}{2} - \frac{1}{2}k \frac{x(t)}{\|x\|} \quad k = \sqrt{\frac{R_2 R_3}{R_1 R_4}} \quad (70)$$

and is dependent on the instantaneous value $x(t)$ of analog signal normalized with respect to its rms value $|x|$.

Binary representations u_B and i_B of the supply voltage and current are applied to a logical EXCLUSIVE OR gate as shown in Fig. 19. The duty factor $d_E(t)$ of the output signal of this gate is equal to

$$d_E(t) = d_u(t)\bar{d}_i(t) + d_i(t)\bar{d}_u(t) \quad (71)$$

where $\bar{d}$ denotes the duty factor of the negative binary signal x_B . Since $d(t) + \bar{d}(t) = 1$, then

$$\bar{d}(t) = \frac{1}{2} + \frac{1}{2}k \frac{x(t)}{\|x\|} \quad (72)$$

Figure 19. Electronic PF meter built of two analog-to-binary (A/B) converters, an EXCLUSIVE OR gate with an electronically controlled switch, and a dc voltmeter supplied from a source of reference voltage U_{ref} .

When the duty factors $d_u(t)$ and $d_i(t)$ of binary representations of the supply voltage and current are expressed in the form of Eq. (69), then Eq. (70) results in

$$d_E(t) = 1 - k_u k_i \frac{u(t)i(t)}{\|u\| \|i\|} = 1 - \frac{p(t)}{S} \quad (73)$$

since the coefficients k_u and k_i should be chosen such that $k_u k_i = 1$. Thus, a dc voltmeter supplied from a reference voltage U_{ref} through a switch S can be scaled in power factor. If the EXCLUSIVE OR gate ON signal opens the switch, the value $\lambda = 1$ is at the right end of the scale; if the gate ON signal closes the switch, the value $\lambda = 1$ is at the left end.

A single-phase, digital PF meter provides the power factor calculated from sequences of uniformly distributed digital samples u_n and i_n of the supply voltage and current. The meter is built of voltage and current converters that provide conditioned voltages in the range of, usually, ± 10 V; sample and hold (S&H) circuits, analog to digital converter (ADC), and an arithmetic unit, usually in the form of a microcontroller or microcomputer with a digital display or a printer.

The sampling frequency should be more than twice the frequency of the highest harmonic order of the supply voltage and current. If N denotes the number of samples in one cycle of the voltage, then the power factor in a single-phase or symmetrical 3-phase circuit is calculated from the formula

$$\lambda = \frac{P}{S} = \frac{\frac{1}{N} \sum_{n=0}^{N-1} u_n i_n}{\sqrt{\frac{1}{N} \sum_{n=0}^{N-1} u_n^2} \sqrt{\frac{1}{N} \sum_{n=0}^{N-1} i_n^2}} = \frac{\sum_{n=0}^{N-1} u_n i_n}{\sqrt{\sum_{n=0}^{N-1} u_n^2} \sqrt{\sum_{n=0}^{N-1} i_n^2}} \quad (74)$$

Such a digital PF meter can be very accurate but expensive. Such a measurement is inexpensive, however, taking into account that the PF measurement is usually accompanied by a variety of other measurements, recordings, and analysis.

ELECTRICAL ENERGY MEASUREMENT

Energy can be defined as the capacity to do work, while power can be defined as the rate of doing work. There are different types of energy, including electrical energy, heat energy, nuclear energy, and solar energy. Energy may be converted from one form to another; for instance, electricity is often generated in power plants by converting hydraulic or fuel energy into electrical energy. Most vehicles are driven using energy derived from hydrocarbon fuels, and cooking is often done using electrical energy. Figure 1 shows the rapid increase of energy consumption in recent decades which helps us to get an idea of our ever increasing dependence on energy. Therefore, energy measurement becomes an extremely important topic for scientists and engineers. In this article, we will deal with different aspects of electrical energy measurement. Generally

Figure 1. Graph depicting our increasing dependence on energy.

speaking, the measurement of energy is essentially the same as the measurement of power, except that the instrument must not merely indicate the power, but must take into account the length of time for which this power supply is maintained (1). Energy meters can be broadly classified into (1) electrolytic meters, (2) clock meters, (3) motor meters, and (4) electronic or microprocessor-based meters.

THEORY

Before discussing energy measurement itself, let us mathematically define electrical energy with respect to power. This will help us to understand energy measurement in greater detail. In this context it is desirable to consider alternating current (ac) and direct current (dc). Alternating current varies in magnitude and direction with time. However, dc current remains constant with time. Now, dc power (P) is defined as the product of voltage and current, that is,

$$P = VI \quad (1)$$

where V is the dc voltage in volts and I is the dc current in amperes. The direction of positive current flow is defined to be the direction a positive charge flows (or would flow if possible), and positive power is delivered when positive current flows from a

point of higher voltage or potential to a point of lower voltage. Since V or I may be either positive or negative, power may itself be positive or negative. Positive power implies power delivered to a device or load, while negative power implies that power has been generated, that is, converted from some other form to electrical. Electrical power is typically expressed in watts.

In many systems the voltage and current are proportional, and are related by Ohm's law, $V = IR$, where R is the load resistance in ohms. Using Ohm's law, Eq. (1) may be rewritten as

$$P = I^2 R \quad (2)$$

If the voltage and current vary with time, the instantaneous power (p) is defined as

$$p = vi \quad (3)$$

where v is the instantaneous voltage and i is the instantaneous current. Typically power is distributed to consumers in sinusoidal form, so that both the voltage and current are assumed to be sinusoidal and have the same frequency. An important measure of power, especially for periodic voltages and currents, is called average power. The average power is equal to the average rate at which energy is absorbed by an element, and it is independent of time (2). This is the power monitored by the electric utility company in determining monthly electricity bills. The average power (P_a) associated with a periodic instantaneous power signal is given by

$$P_a = \frac{1}{T_p} \int_{t_0}^{t_0+T_p} p \, dt = \frac{1}{T_p} \int_{t_0}^{t_0+T_p} vi \, dt \quad (4)$$

where T_p is the period of both v and i , and t_0 is arbitrary. If the effective or root mean square (rms) values of the instantaneous voltage v and instantaneous current i are denoted by $|V|$ and $|I|$, and the phase angles of the voltage and current are θ_v and θ_i , then the average power delivered to the load is

$$P_a = |V| |I| \cos \theta \quad (5)$$

where $\theta = \theta_v - \theta_i$ is the phase difference between v and i . The factor $\cos \theta$ is called the power factor, and θ is the power factor angle. P_a is called real power, which implies that the power has transformed from electrical to nonelectrical form such as radiant, chemical, or mechanical. If the load is purely resistive, the voltage and current signals are in phase, and the average power becomes $P_a = |V| |I|$. The average power associated with purely inductive or capacitive circuits is zero, since power delivered to the inductor or capacitor during part of the cycle is returned during another part of the cycle. The power factor is zero, since the phase angle is 90° . In this case, the power is purely reactive. The reactive power (Q) is defined as

$$Q = |V| |I| \sin \theta \quad (6)$$

where the factor $\sin \theta$ is called the reactive factor. Reactive power is expressed in vars (volt-amperes reactive).

Energy is defined as the total work done over an interval of time (T), and the basic unit of energy is called the joule or watt-second. In many instances, this unit is inconvenient to use and

larger units such as kilowatt-hour are used. Using Eq. (2), the dc energy can be expressed as

$$E_d = I^2 RT \quad (7)$$

Using Eq. (5), the total energy delivered during time interval T can be expressed as

$$E_a = |V| |I| T \cos \theta \quad (8)$$

Similarly, using Eq. (6), the reactive energy can be expressed as

$$E_r = |V| |I| T \sin \theta \quad (9)$$

The generation, transmission, distribution, and utilization of large amount of electric energy are accomplished by means of three-phase circuits. A comprehensive analysis of three-phase circuits is beyond the scope of this article; a general understanding of balanced three-phase circuits is sufficient for our purpose. The basic structure of a three-phase system consists of voltage sources connected to the loads by means of transformers and transmission lines. Figure 2 shows the simplified block diagram of a basic three-phase circuit. A set of balanced three-phase voltages consists of three sinusoidal voltages that have identical amplitudes and frequency but are out of phase with each other by exactly 120° . In three-phase circuits the standard practice is to refer to the three phases as A, B, and C. Furthermore, phase A is almost always used as the reference phase. Because the phase voltages are out of phase by 120° the following two possible relationships can exist between the voltages:

First Possibility. $V_A = V_m \angle 0^\circ$, $V_B = V_m \angle -120^\circ$, $V_C = V_m \angle +120^\circ$

Second Possibility. $V_A = V_m \angle 0^\circ$, $V_B = V_m \angle +120^\circ$, $V_C = V_m \angle -120^\circ$

Here V_m represents the peak amplitude of the sinusoidal voltage. The energy delivered by a three-phase source and consumed by a three-phase load is found simply by adding the energies in the three phases. In a balanced three-phase circuit, however, this is the same as multiplying the average energy in any one phase by 3, since the average energy is same in all phases. Thus for a balanced three-phase circuit the active energy or energy may be expressed as

$$E_a = 3V_p I_p T \cos \theta_p \quad (10)$$

where V_p represents the magnitude of the phase voltage, I_p represents the magnitude of the phase current, and θ_p represents

Figure 2. A basic three-phase circuit.

the phase difference between V_p and I_p . Similarly, the total reactive energy can be expressed as

$$E_r = 3V_p I_p T \sin \theta_p \quad (11)$$

In the case of energy the measuring instrument is called a watt-hour meter, while in the case of reactive energy the measuring instrument is called a reactive volt-ampere-hour meter.

WATT-HOUR METERS

A meter that records energy in watt-hours or kilowatt-hours is called a watt-hour meter. An important requirement of an energy meter is that it should indicate a given amount of energy proportional to power and time. For example, it should

Figure 3. Electrolytic watt-hour meter. A, anode mercury; B, glass fence; C, cathode; D, negative terminal; E, positive terminal; K, shunt; H, compensating resistance in series with tube.

record 1 kW · h, whether this consists of 1 W flowing for 1000 h or 1000 W flowing for 1 h. Different types of watt-hour meters have been developed in the last few decades for the measurement of energy. We shall briefly discuss only those that are relevant today.

Electrolytic Watt-Hour Meters

Figure 3 shows an electrolytic watt-hour meter. This type of meter is mainly used for dc energy measurement, although it can be adapted, by using a metal rectifier circuit and a current transformer, to function as an ac circuit for measuring kilovolt-ampere-hours. The operating current is passed through a solution, causing electrolytic action. Depending on the meter type, this gives a deposit of mercury or liberates gas proportional to the number of coulombs or ampere-hours passed through the meter. Assuming the voltage supply to the meter remains constant, the meter can be calibrated in kilowatt-hours; otherwise it is calibrated in ampere-hours. These meters are inexpensive to manufacture, but tend to require fairly frequent inspection, as they include a large amount of glass in their construction.

Clock Watt-Hour Meters

Figure 4 shows a clock watt-hour meter. There are two identical circular coils (C1 and C2), placed at the bottom ends of two pendulums, which are continuously driven by clockwork. These coils are connected in series with one another and with a high resistance, and they carry a current proportional to the line voltage. There are two current coils (C3 and C4), placed beneath the pendulums, which are connected in series with the line and are wound in such a way that their magnetic fields are in the opposite directions. When no current is flowing, the pendulums swing at the same rate. However, when current flows through C3 and C4, one of these coils exerts an accelerating force on one pendulum and the other coil exerts a retarding force on the other pendulum. The resulting difference in the time period of oscillation of two pendulums is arranged to give an indication on the dial register proportional to the energy passing through the meter. This meter is comparatively free from temperature errors and stray fields and is suitable for both ac and dc energy measurements.

Motor Watt-Hour Meters

Motor watt-hour meters can be broadly divided into two categories: those for dc and for ac energy measurement. The latter—

Figure 4. Clock watt-hour meter.

Figure 5. Motor watt-hour meter for dc energy measurement.

also called induction watt-hour meters—can be further classified into single-phase and polyphase watt-hour meters.

Motor Watt-Hour Meter for dc Energy Measurement. A motor meter for dc energy measurement essentially consists of a small motor that is provided with a magnetic braking mechanism as shown in Fig. 5. The field coils of this meter consist of a few turns of heavy copper wire carrying the current under measurement, so that the field strength is directly proportional to the load current. Motor meters for dc energy measurement consist of three main parts—a rotating element, a braking system, and a clock or dial register. The rotating element is driven at a speed proportional to the energy or in some cases the quantity of electricity passing through the driving system. Proportionality between the energy and speed is ensured by the braking system, which supplies a controlling action proportional to the speed of the rotor element.

Single-Phase Induction Watt-Hour Meter. Induction meters are almost universally used for ac energy measurement, since they are simple in construction, provide high torque-to-weight ratio, and are relatively inexpensive. An induction watt-hour meter consists of an induction motor whose output is largely absorbed by the braking disk and dissipated as heat as shown in Fig. 6. In this watt-hour meter there are two current poles (2 and 4), which are displaced from the voltage pole (3) as shown in Fig. 6(a). At unity power factor, the flux ϕ_i from the current coils is in phase both with the voltage v and current i . The flux from the voltage coil, ϕ_v , is in quadrature (90° phase

displacement) with respect to ϕ_i , as shown in Fig. 6(b). At time instant a , both the current i and current flux ϕ_i are maximum, the voltage v is maximum, and the voltage flux ϕ_v is minimum. The flux paths through the disk are from 2 to 1, from 2 to 3, from 3 to 4, and from 5 to 4. At time instant b , both the current i and current flux ϕ_i are minimum, but the voltage v is minimum and the voltage flux ϕ_v is maximum. At time instant c , both the current i and current flux ϕ_i are maximum, but the voltage v is maximum and the voltage flux ϕ_v is minimum. The flux paths through the disk are from 1 to 2, from 3 to 2, from 4 to 3, and from 4 to 5. Thus the flux has effectively moved across the disk from left to right. This change causes eddy currents to be set up in the disk. The reaction between the eddy currents and the field tends to move the disk in the direction of the field.

Since the disk revolves continuously when on load, electromagnetic forces (emfs) will be induced in it dynamically, as it cuts through the flux between the poles, in addition to the statically induced emfs due to the alternating flux in these poles. The torque due to the dynamically induced eddy currents in the disk will be negligible compared to the operating torque produced by the statically induced currents. Neglecting the effect of friction in the meter, and assuming that the active flux from the voltage pole lags 90° behind the impressed voltage, the operating or driving torque T_d becomes proportional to the power in the circuit, i.e.,

$$T_d \propto |V| |I| \cos \theta \quad (12)$$

Now the retarding torque T_r due to eddy currents is proportional to the speed of revolution, N , of the disk, i.e., $T_r \propto N$. Since for a steady speed of the disk, T_d must be equal to T_r , we can write

$$N \propto |V| |I| \cos \theta \quad (13)$$

i.e., the speed of revolution of the disk is proportional to the power. The total number of revolutions, N_T , over a time interval T may be expressed as

$$N_T = NT = |V| |I| T \cos \theta \quad (14)$$

From Eq. (14), it is evident that the total number of revolutions is proportional to the total energy supplied.

Polyphase Induction Watt-Hour Meter. Polyphase energy can be measured by several single-phase instruments, since the

Figure 6. Induction watt-hour meter for ac energy measurement.

Figure 7. Connection diagram for polyphase watt-hour meter method of energy measurement.

total power or energy is the sum of the readings of all the instruments. The connections to the polyphase meters are the same as those employed in the two wattmeter method of measuring three-phase power, as shown in Fig. 7. Most polyphase instruments, however, utilize two or more single-phase elements mounted in a single shaft, which drives the dial. These elements must be shielded from each other to avoid interaction between the fluxes produced by individual elements. For instance, three-phase energy can be measured by having three watt-hour meters with current coils in each line and potential coils connected across the given line and any common junction. Since the common junction is completely arbitrary, it may be placed in any of the three lines. When this is done, the watt-hour meter connected in that line will indicate zero energy, because its potential coil has no voltage across it. Therefore, the third watt-hour meter can be dispensed with, and the three-phase energy can be measured with only two watt-hour meters. In general, m -phase energy can be measured by $m - 1$ watt-hour meters.

Polyphase Watt-Hour Meter Connections. It is crucial to ensure appropriate connection of the various components of a polyphase watt-hour meter for registering accurate results. In a three-phase circuit, when the power factor is 1 corresponding to resistive loads, both watt-hour meters as shown in Fig. 7 will indicate the same reading; that is, the disk rotation will be

in the forward direction at the same speed. If the power factor is above 0.5, the disk rotation will always be forward whenever the current or the potential coil of either of the two watt-hour meters is disconnected. On the other hand, if the power factor is less than 0.5, the disk rotation of the two watt-hour meters will be in the opposite directions. It should be mentioned that if the current coils of the two watt-hour meters of Fig. 7 are interchanged and the power factor is 0.5, the meter reading will be 100% wrong although it will run at normal speed.

Induction Watt-Hour Meter Adjustments. All adjustments of induction watt-hour meter are usually made either at full load or at light load. To adjust the speed at full load, the drag magnet is usually shifted relative to the disk axis. Alternatively, speed adjustments can be made by using a movable soft iron bar for shunting the flux. To compensate for variations in ambient temperature, a small piece of temperature-sensitive iron-nickel alloy is generally used as a shunt in the air gap of the drag magnets.

MICROPROCESSOR-BASED ENERGY METERS

Microprocessor-based systems are increasingly being used in energy measurement. Figure 8 shows the simplified block diagram of a microprocessor-based energy measurement system employing synchronous counting (3). The system consists of an analog unit and a digital unit. The input signals v and i are multiplied in an analog multiplier. An analog integrator, such as a dual slope converter, performs integration on the multiplier output signal over a time interval T_i . The microprocessor sends a start pulse of suitable duration to activate the synchronization circuit. The synchronization circuit, after synchronization with the input signal v , generates a signal of duration T_i , which controls the time counter gating logic. Notice that T_i is the period of integration for the multiplier output signal and is always equal to an integer multiple of the input signal period. Subsequently, the analog integrator integrates a reference signal over a period T_j , which is measured by the time counter. The microprocessor keeps track of the entire duration (T) of measurement using an internal counter. The outputs of the event and time counters are fed into the microprocessor system, which internally calculates the total energy and outputs the calculated or measured energy on the display. With microprocessor-based energy meters, an accuracy of the order of 0.1% can be achieved.

Figure 8. Simplified block diagram of a microprocessor-based energy meter.

Figure 9. Simplified block diagram of an electronic reactive energy measurement system.

REACTIVE VOLT-AMPERE-HOUR METERS

Reactive energy is defined as the quantity measured by a perfect watt-hour meter that carries the current of a single-phase circuit and a voltage equal in magnitude to the voltage across the single phase circuit but in quadrature therewith (4). Reactive energy is often measured at single-phase and three-phase services. Reactive energy measurement is generally more complex than active energy measurement because additional processing of input signals is necessary. The most common reactive energy meters are watt-hour meters with the currents through the voltage coils displaced by 90° . To provide this 90° phase shift various methods such as potential cross phasing, *RC* and *RLC* circuits, varformers, digital phase shifting in sampling meters, and electronic integrators in time-division multiplier meters are used (5). If the voltage across the single-phase circuit is given by

$$v = |V| \sin \theta_v \quad (15)$$

then the voltage in quadrature is given by

$$v = |V| \sin(\theta_v - 90 \text{ deg}) \quad (16)$$

From the point of view of measuring system design, it is irrelevant whether the phase shift is performed on the voltage or on the current signal. Only the phase displacement between the input signals is of importance. Figure 9 shows the simplified block diagram of a reactive power and energy measurement system. At first, the voltage signal is given a 90° phase shift in the phase shifter; it is then multiplied with the current signal in the analog multiplier. The output signal from the multiplier unit, that is, the reactive power signal, is introduced into an analog-to-digital converter (ADC). The integrating unit inherent in any ADC provides the power integration step to generate the reactive energy, which after some intermediate processing is shown on the display unit. It should be mentioned that, for nonsinusoidal signals, the reactive energy of the fundamental frequency is usually the dominant reactive energy component. Therefore, the measurement of that component is most important. For better accuracy, additional higher harmonic terms may be incorporated.

METER RATINGS

The rise in temperature resulting from the losses in a meter must be accounted for when rating a meter because meter life span should not be unduly shortened by overheating and consequent deterioration of insulating materials surrounding the current carrying conductors. In general, a general purpose meter should have a lower permissible temperature than a special

purpose meter to accommodate a greater factor of safety. In the past, watt-hour meters were rated only at the full load which is currently referred to as the test ampere (TA) rating or test current rating. The TA rating is indicated on the nameplate by the manufacturer and is mainly used for test constant calculation as well as for determining and adjusting the percent registration of a meter at light and heavy loads. The percent registration of a watt-hour meter is defined as the ratio of the actual registration to the value of the quantity measured during a given time interval. Currently watt-hour meters are rated into a number of classes based on their maximum capacities. A class such as 10, 20, 100, or 200 usually indicates the peak of the load range in amperes.

RECENT TRENDS

Power and energy measurement using electronic systems, microprocessors, and digital techniques is becoming increasingly popular. Such systems can provide greater versatility and accuracy, and afford the potential to transmit data without the need for a meter reader. Since electronic systems are often smaller and lighter than electromechanical systems, these systems may be more portable as well as less expensive.

Switching devices, such as silicon-controlled rectifiers (SCRs), that draw current from the line during only a portion of the cycle are becoming commonplace. This trend has added to the problems of power companies, since the switching process generates harmonics of the line frequency, which have repercussion upon both customer and the supplier of electrical power.

As mentioned earlier, electronic equipment can be used in versatile ways to aid in measuring energy. The portable tester is one of the latest electronic gadgets to help us with energy measurement. Until recently a meter could only be tested by pulling it and taking it back to the shop. However, portable testers effectively alleviated that problem. They are especially helpful when customers live in remote areas.

ACCURACY

Electric utilities all over the world use single-phase watt-hour meters to measure residential energy consumption. Since the watt-hour meter serves as the cash register for the utility, both the utility and the regulatory body have a high interest in its accuracy. In order to ensure that the customers are not charged for more energy than they consume and the utility collects the revenue to which it is entitled, watt-hour meters are sampled on an annual basis, ensuring accurate registration of energy. Typically the sampled meters are sent to a central testing facility and tests are performed to indicate how accurately the meters are performing in service. The results of these sampled tests are reported to the regulatory body to satisfy its rules and

regulations. The utility also uses statistical tools for determining the performance of the meter population.

Single-phase watt-hour meters typically used in residential service are three-wire, 240 V, and class 200 (6). These meters are generally tested at two test load points: full load (FL), which is defined as 30 A, and light load (LL), which is defined as 3 A. In order to get an indication of how a meter performs over a load range of 0 to 200 A, the test results at full load and light load are weighted to yield an overall accuracy. The overall accuracy (OA) equation is written as

$$OA = \frac{4 \times FL + LL}{5} \quad (17)$$

For example, if the full-load accuracy is 100.2% and the light-load accuracy is 95%, then the overall accuracy is 99.16%. This method is one of the two methods recognized by the utilities. The second is the true average method. In this case the overall accuracy equation is defined as

$$OA = \frac{FL + LL}{2} \quad (18)$$

The second method is not in widespread use.

Energy meters are also classified as *precision grade* or *commercial grade*, depending on the degree of accuracy with which they make measurements. Commercial grade meters are those generally met with in ordinary factory and home service installations. Precision grade meters are designed to have negligible error and are retained exclusively for test-room measurements thus making them expensive.

Because of its low cost, the inductive watt-hour meter is still the most widely used energy meter. It is practically the only meter used in the residential sector. The accuracy of most inductive watt-hour meters is typically 1% for sinusoidal operation at a fixed frequency. Recently, energy meters based either on digital sampling or on time-division multiplier became available, which are very accurate ($\sim 0.1\%$) compared to the inductive watt-hour meters.

CALIBRATION

Phantom loading of watt-hour meters is a common method for their calibration. This mainly consists in supplying sources of calibration voltage that are independent of each other at one point and are adjustable. This practice has several advantages over the use of resistive and reactive loads, such as (1) better adjustment of voltage, current, and power factor in the laboratory, (2) reduced need for large current supplies, and (3) elimination of errors that might result from failure to take into account losses or loading effects in the test and reference instruments. Figure 10 shows two circuits commonly used in the calibration of watt-hour meters. In Fig. 10(a), the current circuits are connected in series and supplied with a stepdown transformer for the test and reference instruments. This isolates the current circuit from the voltage circuit. A smaller series adjusting resistor may also be used for adjusting the load current. This method is used when it is desired to simulate a unity-power-factor load. The voltage of the current supply transformer must be high enough so that it swamps the reactance of the current circuits of the meters. The circuit in Fig. 10(b) is used when low-power-factor loads of the order of 50 are desired. By using

Figure 10. (a) A basic calibration circuit for a watt-hour meter, and (b) a more sophisticated version of the calibration circuit.

a three-phase supply and taking the current supply from one phase and the voltage supply from another, it is possible to simulate low-power-factor loads if the phase angle is known. The phase for the voltage supply can be selected to lead or lag the current of the secondary of the supply transformer by 60° .

PORTABLE METER READING AND STANDARDS

Presently utilities all over the world are debating whether to incorporate *automated meter reading* (AMR) in their systems. AMR offers many other advantages than just remote meter reading. An AMR system can signal outages, perform remote connect and disconnect, deter meter tampering, prevent lockouts, and facilitate time-of-use metering. In addition, utilities can offer value-added services such as forced-entry alarms and low- or high-temperature alerts. Any of these can generate revenue. Over 30 vendors are in the AMR market, offering systems of every size and kind (7). The systems vary according to the communication media used, whether they are one-way or two-way, whether they read meters at high or low speed, and whether they are fixed or mobile. Utilities have been slow to adopt automated meter reading systems because the investment is high and the payback is slow. Other reasons

include reluctance to change, discomfort with new technology, and long-term satisfaction with walkaround readers. Furthermore, AMR system requires a coordinated, horizontal effort across the utility, involving metering, billing, customer service, and information systems.

The most widely used technique for watt-hour meter testing is called portable standard or rotating standard. Portable standards are transportable watt-hour meters with multiple current and voltage range and allows both whole and fractional reading. Initially, energy is measured by using the watt-hour under test. Then the portable standard meter is used to measure the same energy. The accuracy is determined by comparing the readings of the two meters.

REFERENCE STANDARDS

For ac watt-hour meter testing, a time reference standard such as a clock or a stop watch and a wattmeter may be used. Alternatively, a watt-hour meter is used as the reference standard which is started and stopped automatically by a signal (e.g., light) generated from the meter to be tested. For dc watt-hour meter testing, the reference standard may be ammeters and voltmeters or potentiometers.

Standards and technical practices are an essential tool in any field, and energy measurement is no exception. In the USA, approximately half of all standards are generated through a voluntary consensus process (8). Most engineering standards are developed by technical societies and trade associations. The private sector rather than the government generates the standards. The American National Standards Institute (ANSI) coordinates the voluntary development of standards in the USA. ANSI is a nonprofit organization composed of corporate members, trade associations, and technical societies. It is self-designated in its role in standard coordination and does not develop any standards. ANSI reviews the documents produced by others and certifies them as American National Standards. The Institute of Electrical and Electronic Engineers (IEEE) is the primary producer of electrical documents for ANSI. Other major nongovernment standard organizations producing electrical standards are the American Petroleum Institute (API), Associated Edison Illuminating Companies (AEIC), the National Electrical Manufacturers Association (NEMA), and the National Fire Protection Association (NFPA).

CONCLUSION

In this article we started off by defining some basic terms that would allow us to understand different aspects of energy measurement. We then described different types of energy-measuring instruments in detail, and briefly discussed some of the latest trends in energy measurement. All these topics were chosen by keeping in mind the diverse readership of this encyclopedia. With our present dependence on energy it is necessary that a wide section of the population become aware of different aspects of energy measurement.

WATTHOUR METERS

A watthour meter measures electric energy consumed by a utility customer in units of kilowatthours (kWh). The meter does this by measuring the integral of the active power with respect to time. This integral represents the energy delivered to the load (electric utility customer) in the interval over which the integration is done, and the units for convenience are in blocks of $1000 \times W$. The watthour is the electric energy used in 1 h when the average power during the hour is 1 W. The watt is the unit of active power and is defined as the rate of change of energy delivery to a load. The watt is the power used when a current of 1 A flows through a 1Ω resistance.

The watthour meter has been called the cash register of the utility industry and certainly from the viewpoint of the customer it has served this one purpose very well for over 100 years (1). In essence, the watthour meter transforms customer dollars to utility dollars and thus has enabled electric

utilities to bill relatively accurately for electric energy use and create (using revenue dollars earned) a multitrillion dollar transmission, distribution, and generation infrastructure worldwide.

The watthour meter measures active power, which represents the real power used by customers in end-use applications, such as heating, cooling, lighting, process control, electric machines, and running computers. Other components of energy at the power frequency level (fundamental 60 Hz to 50 Hz) include apparent and reactive powers. The measurement of these two quantities will not be addressed herein in detail, but certainly all three quantities form the basis of power network flow and define the electric product/service. For example, the reactive power, measured in kilovolt-amperes reactive (kVAR), controls primarily the voltage profile in power systems but does not contribute directly to end use. The apparent power S measured in kilovolt-amperes is all the power available to a customer, and from the ratio of active to apparent power, we may determine the power factor, which is an important factor in adjusting the reactive power. Certain types of watthour meters may measure all three quantities (active, reactive, and apparent) of power and many others such as harmonics.

Another purpose that the watthour meter is increasingly being used for is to provide both the utility and customer with information. The meter may provide not only revenue information, but also real-time demand, energy use patterns, profiling of loads and potential equipment failure information, and further control of equipment and other information technologies (Internet, cable) may be routed through the meter. The next generation of meters may well serve as the utility's information gateway to the customer.

THE DEVELOPMENT OF REVENUE METERING

With the invention of the electric light in 1879, Thomas Edison made the first electric equipment, the incandescent lamp. He knew that there was not only commercial value in lighting but also in heating homes and in transportation. Difficulties had to be overcome, especially because most people were unfamiliar with electrical technology and electricity, as well as its value compared to gas. Certainly to be of commercial value, electricity had to be measured. Edison was well aware that, in order to enjoy commercial success, he had to be able to deliver accurate measurements of electric use. The Mazda Light Company was first formed with Edison to solve the problem of accurate measurements in 1881 with the development of the chemical meter. With respect to a present-day meter, this was a primitive device. Basically, its operation hinged on the use of two electrodes. After a period of time, the electrodes in the chemical bath would interchange mass. Then the electrode would be weighed at the start and end of the billing period. This was also an attempt to make electricity more palatable to users in that the product (electricity) could be weighed much as one would weigh produce in the food market. This meter was used for a few years but became obsolete prior to the introduction of alternating current.

During and well after the time of the chemical meter, several leading people focused on satisfying customers by developing accurate metering. Among these people were Thompson, Shallenberger, Lamphier, and Duncan. The companies that these people worked for are still manufacturing watthour and

other meters. Thompson was the founder of the Fort Wayne Meter Company that eventually became part of General Electric. The work of Lamphier became the genesis of Sangamo Electric Company (today known as Schlumberger). Shallenberger was associated with Westinghouse (now ABB). Lastly, Duncan was the founder of the Duncan Meter Company (now Landis & Gyr).

The first practical wattmeter was developed by Professor Elihu Thompson in 1889. It was the first practical meter to measure true watthours and was awarded the 1889 Grand Prize at the Paris Exhibition. It could be used for alternating current (ac) or direct current (dc) electric power systems and became the industry standard. This was a significant advance over Edison's chemical meter, but it was not up to present-day standards. It is still remarkable for its innovation considering it was developed over 100 years ago. Also, in the same time period, Oliver Shallenberger developed an ampere-hour meter that was used exclusively in ac systems. This meter was adopted by many utilities because of low cost. However, with the increased use of ac, Thompson's meter was the desired choice because it measured watt-hours, which is the appropriate measure of electric energy.

The requirements of electric companies in the early days exceeded the availability of meters. Consequently, much electric energy was sold on a per-lamp cost basis. By 1890, it was recommended that this practice be halted and that in large metropolitan areas meters be used. This development in replacing the flat rate with a metered rate was made possible by the meters developed by Thompson and Shallenberger. The next several years witnessed the introduction of new meters by Duncan and Lamphier, which were primarily based on the pioneering work of Thompson and Shallenberger. In 1894, Shallenberger achieved one of the most important discoveries made in the metering field. He applied the induction meter, which would only previously measure ampere-hours, to measure watt-hours. He accomplished this via the method known as the lagging process, which continues to be at the crux of the metering field.

The first modern meter was introduced in early 1903 and is known as the Type 1 induction watthour meter. It was characterized by its compactness, high torque, ease of adjustment, large four-dial register, and long life. In 1913, the combination lag and light load plate was introduced. By 1925, F. Kinnard developed temperature-compensated magnets. Also, at this time, it was deemed necessary to respond to the rapidly increased use of electricity to form a mechanism for educating people in the utility industry on the proper maintenance and techniques associated with watthour meters. This organization was chartered with the University of Florida as the Southeastern Metermen's Association. This organization is still going strong and is now known as the Southeastern Electricity Metering Association (1). The middle 1920s saw a boom in the use of electricity and, as a result, saw the introduction of longer-range accuracy and increased current-carrying capacity in meters. Standardization of mounting dimensions was formed in 1934. In particular, the standardization of the "S" type meter and an agreement that manufacturers would produce two standard types of single-phase meters. One was the type "A," and the other was known as the type "S" meter. By 1938, the change to installing meters outdoors was the result of better materials being used in construction resulted in new problems. The main problem was in decalibration of the retarding magnets caused by current surges (due to switching and lightning) causing the meter

to speed up. This problem was rectified by the introduction of harder magnets, which were able to better resist knockdown under surge conditions, such as Alnico II. By 1948, the General Electric Company introduced the I-50 meter, which had magnetic suspension. This eliminated the need for replacement of the expensive jewel bearings in meters and increased calibration stability. The continued growth of residential loads resulted in two further improvements, one in 1955 extended the meters range from 60 A to 100 A, and the other improvement in 1957 increased the range to 200 A. Today we see up to class 320 meters used for 400 A service and class 600 meters (bolt-in type) are available.

Up to the 1970s, the many improvements in metering were primarily the result of the dominant manufacturers. After this time, innovative new firms, such as Scientific Columbus, Trans-Data, and Process Systems, among others, have produced novel breakthroughs in metering. The use of electronic and solid-state technologies has been on a steady increase. 1975 witnessed a major event in the introduction of the JEM-1 and solid-state watthour standard (SC-10) from Scientific Columbus. By 1982, the first commercially available solid-state register was produced. Today we see a revolution in the way meters may be applied to not only provide billing data but also to serve customers as an information gateway in energy use and communications.

MATHEMATICAL DEFINITIONS USED FOR THE MEASUREMENT OF POWER

The basic mathematical expressions recommended to be used in metering under single-phase sinusoidal conditions are given herein and are based on Ref. 2. In particular, it should be noted that Budeanu's theory is the approach most familiar to those in industry and the one taught in universities, and it is certainly the method most commonly used in instrumentation. Unfortunately, Budeanu's theory is not adequate for nonsinusoidal situations (3,4). Instead, the recommendations of IEEE Working Group on Nonsinusoidal Situations, chaired by A. E. Emanuel, should be used (2). Power theory under nonsinusoidal situations will not be developed herein; rather the sinusoidally valid approach used historically will be developed. Let us consider the single-phase case assuming a sinusoidal voltage and current.

For voltage, we have

$$v = \sqrt{2} V \sin(\omega t)$$

which, if applied to a linear load, will result in a current of the form

$$i = \sqrt{2} I \sin(\omega t - \theta)$$

where

I = root-mean-square (rms) value of current

V = rms value of voltage

$\omega = 2\pi f$

f = frequency in hertz

θ = phase angle

The instantaneous power in watts is

$$p = vi$$

p is composed of two components, an active and reactive component.

$$p = p_a + p_q$$

where

$$p_a = VI \cos \theta [1 - \cos(2\omega t)] = P[1 - \cos(2\omega t)]$$

and

$$p_q = VI \sin \theta \sin(2\omega t) = Q \sin(2\omega t)$$

The power p_a , which is an instantaneous quantity, is a result of the active current component, and represents the rate of change of energy

$$w_a = \int p_a dt = Pt - (p/2\omega) \sin(2\omega t)$$

w_a flows in one direction from the source to the load, and its rate of change is positive. On the other hand, the power p_q is a result of the reactive part of the current, and is the rate of change of energy

$$w_q = \int p_q dt = (Q/2\omega)[1 - \cos(2\omega t)]$$

w_q is an oscillatory quantity between the source and load and contributes no net energy to the load.

The active power in units of watts is

$$P = (1/kT) \int_{\tau} p dt = VI \cos \theta$$

where

$T = 1/f$, the cycle in seconds

k = an integer number

τ = the time when the measurement begins

The reactive power in units of vars is

$$Q = (\omega/kT) \int_{\tau} i \left[\int v dt \right] dt = VI \sin \theta$$

The quantity Q is the magnitude of the oscillating power p_q . With an inductive load, Q is positive, and with a capacitive load, Q is negative.

The apparent power in units of volt-amperes is

$$S = VI = \sqrt{P^2 + Q^2}$$

In addition, the power factor, which is a unitless quantity, is

$$\text{pf} = P/S$$

COMPONENT FEATURES AND OPERATING PRINCIPLES

Types of Meters

Watthour meters record energy and measure it in kilowatt-hours. The meters come in many types.

1. *Demand meters* record the demand and/or maximum demand and are used to ensure equitable charges to customers. Demand is the rate at which energy is consumed and is measured in kilowatts. The maximum demand is the greatest demand seen during a period of monthly billing. The demand interval is the period of time upon which the maximum demand is determined in the register and is usually taken over 1 min to 60 min intervals. Demand meters usually are three-phase and transformer rated for commercial loads, but they may also be self-contained. Two types of demand meters are (a) integrating demand meters and (b) thermal demand or lagged meters. The integrating demand meters record an average power during consecutive demand intervals. The watt-hour meter is the driver behind the register, which in turn rotates proportionally to the amount of watt-hours in the interval. This meter would show the maximum demand during a certain time period. On the other hand, the thermal demand meter has a pointer that changes in accordance with the temperature variation in its elements due to the current flow. Because the meter responds to temperature changes caused by current flow, it responds more slowly than a normal meter. The main difference between these two meters is with respect to the demand interval. One follows a heating response curve, and the other follows regular intervals. Both types of meters give comparable results with the exception of certain loads, which have large peaks during a short time period (in this case, the thermal meter would be slow to respond). On the other hand, thermal meters operate on a heating curve similar to equipment on the line and thus are preferred by some utilities. Many utilities also use fully solid-state meters with digital displays to measure demand.
2. *Electronic meters* are solid-state devices and have no moving parts. In these meters, the voltage and current waveforms are sampled at specified intervals and digitized. The signals are then processed using appropriate power definitions.
3. *Hybrid mechanical or hybrid electronic meters* may have a memory function and use electronic displays and have a mechanical rotor.
4. *Load profile meters* are an electronic or hybrid meter with an on-board memory so that the energy used for a certain time interval may be calculated and then downloaded to a computer for further analysis.
5. *Mechanical meters* are in large part used in residential applications and are primarily single-phase and self-contained.
6. *Primary meters* are put in service on the primary side of distribution transformers, usually 12 kV. In this case, the customer would own the transformer and its associated losses. Also, primary meters are used when a customer

has multiple points of service and it may be best to use a single meter rather than several.

7. *Pulse meters* are either mechanical or electronic and are used mostly by customers with energy management systems. In this type of meter, a pulse is set to be equivalent to a certain number of watt-hours, and the number of pulses in an interval will be the same as the average demand in the interval. A solid-state data recorder may be used to store and collect the pulses and has the ability of storing data to be read by computer via phone lines or handheld devices.
8. *Secondary meters* are located on the customers or secondary side of distribution transformers. In this case, the utility owns the transformer.
9. *Self-contained meters* are designed so that all the loads current flows through the meter. Depending on the size of the load, a self-contained meter may either be (a) plain meter or (b) demand meter.
10. *Time-of-use meters* record and store energy and demands during on-peak, off-peak, and other times as needed.
11. *Transformer-rated meters* record a fraction of the energy going to the load. Meters are not capable of directly being used on voltages above 480 V and currents greater than 400 A. Potential transformers (PT) and Current transformers (CT) are used in conjunction with the meter so that the meter is capable of measuring large loads (5).

Meter Form Types

The classification of meters into basic form types is necessary for meter selection and to use it in the correct manner with respect of current circuits and external wires. Table 1 (see also ANSI C12.10) illustrates many of the form types.

Andre E. Blondel's theorem says that "If energy is supplied to any system of conductors through N wires, the total power (energy) in the system is given by the algebraic sum of readings of N wattmeters (watthour meters), so arranged that each of the N wires contains one current coil, the corresponding potential coil being connected between that wire and some common point. If the common point is on one of the N wires (ground may also be included in N), the measurement may be made using $N - 1$ wattmeters (watthour meters)" (1). What this means is that energy may be metered using one less current and potential element than the wires in the system. Hence, we would use three stator meters for a three-phase four-wire system. Four kinds of watt-hour meters used in the United States typically apply to Blondel's theorem; these are forms 5, 9, 12, and 16. However, design modifications resulting from economics are also typically used by utilities. These include, for example, the $2\frac{1}{2}$ stator forms 6, 8, 14, and 15. The accuracy of these compromised design forms is contingent upon keeping the phase displacement between line voltages fixed. Figure 1 shows a simplified example of using a form 16s meter in a three-phase four-wire application.

Meter Components and Operation

A single-phase mechanical (induction) watt-hour meter is in essence a small induction motor that is used to measure kilowatt-hours. Figure 2 illustrates a three-wire single-phase induction watthour meter. The induction disk rotates because

Table 1. American National Standard for Watthour Meters: Basic Meter Form Types

Form	SC/TR	No. Stators	No. Current Circuits	No. External Wires
1s	sc	1	1	2
2s	sc	1	2	3
3s	tr	1	1	2
4s	tr	1	2	3

Note: tr = transformer rated, sc = self-contained, s = socket base, a = bottom connected.

of the torque developed by the magnetic field generated by currents flowing through the meter elements. The stator (stationary frame), which becomes an electromagnet when energized, has two coils. The coil in series with the line produces a magnetic field in proportion to the line current. The other coil, which is connected across the line, produces a magnetic field proportional to the voltage. Because the two coils are on the same stator frame, they develop a magnetic field that produces a torque on the disk which is proportional to the load power. Further, there exists a permanent magnetic field developed by the braking magnets; it creates a damping torque in proportion to the disk speed. The rate the disk turns now becomes proportional

**Figure 2.** Main Components of a single-phase, three-wire, mechanical induction watt-hour meter. (a) Rotating disk; (b) braking magnets; (c) stator frame; (d) voltage coil; (e) current coils; (f) shaft.

to the measured power. The number of revolutions during a specified time period is indicative of the power, and the power may now be displayed on the register through appropriate gearing between the register and the disk. A revolution made by the disk represents the watthours and is specified by the meters Kh factor, where $Kh = (\text{rated current} \times \text{rated voltage}) / (\text{rotations per minute} / 60)$.

The main components of the induction watt-hour meter consist of (a) base/cover, (b) disk and spindle, (c) damping magnet, (d) electromagnet or stator, and (e) register. The cover is usually constructed of glass or plastic and is sealed to protect the meter from the elements and tampering. The disk is constructed of aluminum, fitting between the magnetic poles of the current and potential coils, and is mounted on a shaft. Eddy currents on the disk, induced by the potential and current coils magnetic fields, in turn produce a flux that interacts with the two coils that then cause the disk to rotate. The disk drives two elements: (a) the gears and dial pointers by which the revolutions are added to kilowatts of energy used and (b) the shafting and gears in combination with a timing motor that add the revolutions in each demand interval to determine the kilowatt demand. The damping magnet produces a braking force on the disk, which is placed between the poles of the magnet, so that the speed of the disk becomes proportional to the power used by the load. The stator serves to direct the magnetic fields developed by the current and potential coils. The register is constructed of dials

**Figure 1.** Connection of a form 16s polyphase watthour meter in a three-phase four-wire power distribution system. (Courtesy of RJC Associates/CTGI, Southeastern Electricity Metering Association Course 140 Class Notes, 1996)

Figure 3. State-of-the-art solid-state polyphase revenue meter—the ABB Alpha meter. (ABB Power T&D Company, Electric Metering Systems, Raleigh, NC)

that record the amount of energy. The dials are driven by the rotation of the disk through a set of gears.

Metering is made more attractive if the register is electronic. Electronic demand registers were made possible with the introduction of nonvolatile memory. Mechanical registers use an externally operated recorder and translator to do rolling demand calculations. Electronic registers can determine rolling demand internally. The main part of an electronic register is a microprocessor. If an electronic register is used with a mechanical meter, the disk rotation is typically sensed by optical devices. These optical sensors create pulses for each rotation of the disk or by detection of disk shaft motion. Hence, a pulse represents some energy used. The electronic register may perform tasks to establish time intervals, count and sum pulses for display information, and count and sum pulses for demand intervals.

A state-of-the-art solid-state meter, typical of those produced by leading manufacturers, is shown in Fig. 3. In general, solid-state meters give tremendous flexibility by providing sound economic benefits and useful diagnostic information. The ABB Alpha meter is an integral meter and register. With this meter, it is possible to gather, process, and store energy use and demand information on a four rate time-of-use (TOU) or demand basis. The TOU and demand data can be shown in watthours and either apparent energy (VAh) or reactive energy (VARh).

The basic design, as shown in Fig. 4 with the components indicated, is compact. The chassis assembly houses the base, current and voltage blades, connecting cables to the circuit board, and lightning arrester. The electronic housing contains the meter and register electronics on a single circuit board. The circuit board includes the voltage range power supply and dividing resistors. The housing also includes the LCD, nameplate, and battery. The circuit board can also be provided with (optional) relaying outputs. The cover provides for visual metering and an optical port and demand reset. Further, with a wide voltage range capability, it becomes possible to reduce the need (and reduce inventory requirements) for the many form types shown in Table 1. The Alpha meter can meter both form 8s and 9s transformer-rated applications, and the self-contained version can meter form 14s, 15s, and 16s applications. Of the 18 typical types of mechanical meters used today, the solid-state meter shown in Fig. 3 consolidates the form number down to five—reducing inventories up to 50%.

THE FUTURE OF METERING

The future of revenue metering may be considered to be on our doorstep in that many of the components are here today but remain to be integrated into an acceptable system and developed with additional capabilities. For example, the ABB PowerPlus Alpha meter is capable of multiple functions, in addition to serving as a watt-hour meter, such as: voltmeter, ammeter, distortion indicator, power quality monitor, VAR meter, watt meter, phase rotation indicator, VA meter, phase angle meter, and circuit wiring checker. This increase in functionality opens many new applications branches up for the utility. The Alpha meter may be used for diagnostic testing, which involves determining the validity of the electrical service. The meter may be used as a power quality monitor. Such capabilities allow monitoring of voltage and current total harmonic distortion, time stamping of power quality disturbances, and recognition of momentary voltage sags. With regard to revenue metering, these meters record energy and demand values for both real and reactive, and real and apparent quantities. Further, load profile and event logs are available. The communications features included on the main circuit board allow for automatic meter reading and control. Depending on the pass code authority, the users (utility and customer) may access billing records, power quality events, and energy use and load

Figure 4. Main components of a solid-state polyphase revenue meter. (ABB Power T&D Company, Electric Metering Systems, Raleigh, NC)

profile information remotely via a telecommunications system to a personal computer. The telecommunications system may be telephone modem, radio, power line carrier, cable, or even satellite.

What the development of new telecommunications and metering infrastructure means is that it will become possible to market new services. This is of vital concern to utilities as competition and deregulation unfold. The telephone modem interfaces, with each meter being able to hold multiple encrypted passwords, will permit direct customer use metered data and support credit card dialing so that billing can be done to appropriate accounts. Further, the meters can also be programmed to follow a certain call in schedule, or call automatically if there are errors occurring. Several novel areas of future application are discussed in the following material. All these areas of meter applications are actively being studied by researchers and manufacturers.

Automation of the Home or the Smart House Concept

Revenue meters, such as the Alpha meter, which are designed for compatibility with protocols to access wide and local area networks like CEBus, permit great flexibility in load control. This then permits information to be transferred to home heating, ventilating, and air conditioning (HVAC) controllers and receivers. These elements then function as relays to the customers appliances. An entire new opportunity for sharing information with many home electronics-based devices ranging from pool pumps to televisions becomes possible."

Real Time Pricing

The utilities via the interactive network can communicate directly with home (and industry) electric systems. The customer would determine criteria for energy usage, and the utility would then via the telecommunications network download real-time pricing for the customer-specified energy usage. With a system such as this in place, it becomes possible to price-control appliances automatically to a customer's desired comfort and economic specifications.

Automatic Meter Reading

Automatic meter reading (AMR) technologies have been in existence for several years. The AMR techniques have typically been done by means of radio or power line carrier schemes. Novel methods under study now include the use of low earth-orbiting satellites. Two-way communication to meters in remote locations worldwide becomes feasible with the addition of communication elements installed in the meter. In general, the major manufacturers are intending to support several communications systems to enhance the application use of AMR. The main driving force behind AMR is the cost (when compared to standard ways of reading meters) and the need for having several items metered, monitored, and controlled. With the advent of retail and wholesale wheeling in a competitive electric utility environment, AMR becomes more of a necessity than an option.

Challenges in Metering

We have come full circle from the early days of metering, described at the start of this article, in that a new product is being offered. From the past to the present, the product has been electricity. We must look beyond electricity metering to combined service offerings of such items as television, energy management or load control of appliances, security, and computing. Figure 5 illustrates this concept. The communications gateway using AMR may be telephone, radio, power line carrier, cable (as illustrated), or satellite. The challenges in making this complex system work are great not only because there are hundreds of millions of customers potentially involved but also because of the limitations of communications bandwidth, measurement technology, and conflicting standards. For example, it may be implied from Fig. 5 that an explosive growth in the use of electrotechnologies is expected to occur. In large part, these electrotechnologies are power electronics based. Power electronics (PE) are incorporated in such elements as variable speed motor drives (used in HVAC and many other applications), PCs, high-efficiency lighting ballasts, process controls, and a full range of appliances. The proliferation of PE-based devices means a consequent increase of power system harmonic

Figure 5. Automatic meter reading, billing, and control/service provision to most electrical devices and communications via cable and the information super highway. Other communication gateways possible are telephone modems, radio, power line carrier, and low earth-orbiting satellites. (ABB Power T&D Company, Electric Metering Systems, Raleigh, NC)

and transient current and voltage waveform distortions and unbalance (6). Metering designed for 60/50 Hz operation may have errors under these conditions and this topic is addressed in the next section herein (7). There is a need to determine correct power definitions for nonsinusoidal and unbalanced conditions (3,4,8). Also there is a need to quantify properly and allocate equitably such costs as may be caused by these distortions so as to maintain a good level of power quality. In fact, it is noted in IEEE P1459 that “there is not yet available a generalized power theory that can provide a simultaneous common base for: energy billing, evaluation of electric power quality, and help in detecting the major sources of waveform distortion.” (2).

Calibration and Testing of Watt-Hour Meters. The term *calibration* is understood in the metering industry to define a process whereby the accuracy of the meter is adjusted. The term *testing* is used to define a process by which the accuracy of the meter is determined. Calibration is conducted carefully by each utility company, and results are traceable to the National Institute of Science and Technology. The traceability is accom-

plished by having the utilities transfer standard meters annually compared to known standards at NIST. Then the meters may be adjusted after a correction factor is determined using a watt-hour transfer standard in the utility meter departments primary measuring instrument, such as a Knopp model ST-31 automatic watthour meter testing system. Historically there have been two methods of calibrating polyphase meters: (a) series-parallel (single-phase) and (b) true polyphase. It has been considered to be acceptable for polyphase watt-hour meters to be adjusted using series-parallel calibration. However, in evaluating electromechanical watthour meters in Refs. 9 and 10 it has been found that under full load, three-element meters tend to run more quickly if used in polyphase loads than in series-parallel condition. On the other hand, two-element meters tend to run slow in polyphase load conditions when compared to series-parallel conditions. It should be noted that NIST standards and calibration are done for sinusoidal situations and that this does not necessarily apply very well to nonsinusoidal and unbalanced voltage and current conditions (11-13). These nonsinusoidal situations are becoming more prevalent as was previously discussed.

Figure 6. Watthour meter experimental setup for testing the meter’s performance under non-sinusoidal and unbalanced voltage and current waveform conditions. The unique test system at the Power Quality Lab at the University of Florida is capable of producing real-world arbitrary polyphase and synchronized voltage and current waveforms to apply to meters (and other power equipment such as relays, transformers, lighting, motors, and drives) under test to determine, for example, percent registration errors.

Table 2. Three-Phase Watthour Meter Percent Registration Errors^a

	Office Building		Pump Station	
	Magnitude (rms)	THD (%)	Magnitude (rms)	THD (%)
Volts-phase A	122.52	2.96	125.40	3.78
Volts-phase B	123.44	2.68	115.83	2.66
Volts-phase C	121.41	2.09	115.20	2.12
% Unbalance	0.85	18.8	5.55	32.5
Current-A	4.75	4.66	3.39	96.90
Current-B	4.72	4.51	5.03	104.2
Current-C	4.58	2.94	5.71	83.88
% Unbalance	2.21	27.0	28.0	11.7

Meters Tested	Office Building Registration Error (%)	Pump Station Registration Error (%)
Hybrid meter 1	-5.57	-8.75
Digital meter 2	-4.76	-10.09
Solid-state meter 3	-4.37	-9.54
Solid-state meter 4	-3.04	-7.27
Digital meter 5	-0.94	+0.52
TDM meter 6	-0.19	-2.26
Electronic meter 7	-0.18	-3.24
TDM meter 8	-0.13	-2.56
TDM meter 9	-0.04	-0.70

^a The meters were tested when subjected to unbalanced and nonsinusoidal voltage and current waveforms from a pump station (2 up to 150 hp adjustable speed driven pumps) and a typical office building (168,000 ft² with a 980 kW demand with a usual mix of lighting, personal computers, copy machines, and other office equipment loads).

The testing of watt-hour meters, as well as many other power elements, under nonsinusoidal situations may be accomplished with a test system as shown in Fig. 6. Voltage and current waveforms generated mathematically or through field measurements may be downloaded to the computers on the left-hand side of the figure. These computers then digitize the waveforms and send them through the IEEE-488 (GPIB) network to arbitrary waveform generators (one for current and one for voltage). Power amplifiers then boost the analog signals to high power levels so that they may be applied to the meter under test. The readings of the meter under test are compared with a high-speed data acquisition system that is calibrated for each harmonic measurement. The data acquisition system then feeds the signals to computers for analysis and modeling purposes. Results for testing several typical watt-hour meters discussed herein are shown in Table 2. These results are for various voltage and current unbalances and total harmonic distortions. Further results may be found in Ref. 7. Directions for research indicated by these results include development of meter technologies appropriate to nonsinusoidal situations, development and use of appropriate power definitions to process nonsinusoidal, and unbalanced waveforms when computing watt-hours.

Unbundled Power Quality Services: Revenue Metering Implications. Some utilities are expecting to be able to provide various levels of power quality services to customers. One type of service may provide "premium quality" or "UPS" grade power to a customer, and another may provide low grade power at a

lesser cost to the customer. In this situation, it becomes important for the utility to be able to have the metering technology available to meter appropriately and bill the load under nonsinusoidal situations (12). The pressing business and research challenge is to design meters and develop definitions of power and billing schemes that are correct for various grades of electric services (13–16).

ACKNOWLEDGMENTS

The author is grateful for serving as conference chairman for the Southeastern Electricity Metering Association and its annual conference, now in its 73rd year, for the information learned on metering practice and technology, which formed the inspiration to create this article. In particular, the author appreciates the fine talks given at a number of SEMA conferences by D. R. Knight, Metering Department, Jacksonville Electric Authority, on the subject of metering history, which formed the basis of the development of revenue metering material herein.

INSTRUMENTATION FOR CHEMISTRY AND PHYSICS

PHOTOMETERS

A *photometer* is an instrument for measuring light. The science of light measurement is called *photometry*. Light in the present context is electromagnetic radiation that can be detected by the human eye, extending from a wavelength of about 360 nm at the blue end of the spectrum to about 830 nm at the red end; the actual limits depend to some extent on the individual. The terminology of photometry is covered in Refs. 1 and 2.

THREE BASIC CLASSES OF PHOTOMETERS

The earliest form of photometers used the human eye as a detector. The eye, because of its accommodation to light and other physiological factors, cannot be used to quantify light with accuracy, but it does rather precisely discern differences in brightness. This is the basis of the *visual (subjective) photometer*. This type of photometer, first developed in the nineteenth century, allows an observer to visually compare light from two (test and reference) sources. The sources illuminate adjacent screens as they are viewed simultaneously. The distances between the sources and screens are adjusted until a match in brightness of the screens is observed. The light output of the test source can then be calculated from the known intensity of the reference (known) source and the measured distances between the sources and the screens using the inverse square law (explained below). One embodiment of visual photometer is called a *bench photometer*; shown schematically in Fig. 1.

Beginning in about 1940, another type of photometer using an electronic detector instead of the eye came into use, the *photoelectric (objective or physical) photometer*. In this type of photometer, a photoelectric detector converts light into an electrical current. In its most basic form, this current, which is proportional to the amount of incident light, is measured by observing the deflection of the needle of a galvanometer, as shown schematically in Fig. 2. Photoelectric photometers range from small, battery-powered portable instruments to

Figure 2. Schematic of the basic photoelectric photometer. An electrical current generated within the photodiode is proportional to the intensity of the light being measured. The deflection of the galvanometer is proportional to the light intensity.

large, precise laboratory instruments. Such physical photometers are made to mimic the human eye in terms of spectral response. The relative spectral responsivity of the average human eye was defined by the International Commission on Illumination (CIE) in 1924, and is generally called the $V(\lambda)$ function, see Ref. 3.

In addition to the two basic types of photometers, a number of specialized photometers have been developed. Rather than measure the quantity of light directly, these instruments either measure parameters that have some relationship to the amount of incident light or have some relationship to the amount of light absorbed or scattered from a light beam. Unlike the former two types of photometers, these specialized photometers may not necessarily measure light according to the spectral response of the human eye. All three types (visual, photoelectric, and specialized) are described in detail in this article.

UNITS OF PHOTOMETRY

The photometric quantities used in this article are *luminous flux* [light output of a source, in lumens (lm)], *luminous intensity* [luminous flux emitted per unit solid angle, in candelas (cd)], *luminance or brightness* [luminous flux emitted per unit area per unit solid angle, in candelas per square meter (cd/m^2)], and *illuminance* [incident luminous flux per unit area in lux (lx)]. The units are Système International (SI) (see Radiometry).

THE DISTINCTION BETWEEN PHOTOMETERS AND RADIOMETERS

The distinction needs to be made between a photometer and a radiometer. While the photometer is designed to have a spectral response range equivalent to that of the human eye, a radiometer generally has a spectrally uniform response and is used to make measurements at wavelengths outside and, in some cases, inside of the visible range as well. The equivalent to photometry in this sense is radiometry. In some countries, the translated word for photometer has the same meaning as radiometer. A few exceptional cases where a specialized photometer senses radiation outside of the visible range will be noted in this article.

Figure 1. Schematic of a bench photometer. The distances between the photometer head and the lamps, r_1 and r_2 , are adjusted until screens s_1 and s_2 appear to the observer to be of equal brightness.

VISUAL PHOTOMETERS

As described above, visual photometers depend on the ability of the human eye to match the brightness of two adjacent screens, one illuminated by a reference source, the other by a test source. We will describe the bench photometer mentioned above in more detail. The luminous intensity of the test lamp, assumed to be a point source of light, is calculated from the positions of the test and reference lamps and the known intensity of the reference lamp using the inverse square law,

$$E = I/r^2$$

This law states that the illuminance (E) at the given distance (r) from a light source is directly proportional to the luminous intensity of the source (I) and inversely proportional to r^2 .

When the observed illuminance levels on the two screens are the same, the unknown intensity can then be calculated using

$$I = I_0(r/r_0)^2$$

where I and I_0 are the luminous intensities of the test and reference lamps, respectively, and r and r_0 are the corresponding distances from the screen.

In addition to its use to measure unknown sources, the bench photometer can be used together with calibrated light attenuating filters to demonstrate the inverse square law. A commercially available bench photometer is shown in Fig. 3. This photometer is normally attached to an optical bench, which allows it to be moved between sources located near each end of the bench. Fluorescent disks are used as screens in

Figure 3. A commercially available bench photometer. The photometer is moved in relation to the two light sources located near the ends of an optical bench until equal brightness on two fluorescent disks is observed through the eyepiece. (Courtesy of PASCO scientific.)

the instrument shown in the figure; the conical tube is the eyepiece.

Another form of visual photometer, which is similar to the bench photometer, is called the *wax or grease-spot photometer*. A flat surface is coated with either wax or grease to make it translucent. Light coming from both sources can be observed from one side of the translucent material until both the greased (or waxed) areas have the same observed brightness.

The *Lummer–Brodhun photometer*, or contrast light box, is a more sophisticated and compact form of visual photometer. This instrument consists of a several prisms (as well as mirrors in some designs) arranged to allow a viewer to see adjacent screens through an eyepiece while moving the sight box between the two sources. This is a more compact, flexible configuration than the bench style of instrument, but works on the same principle. The basics of visual photometry, including the *Lummer–Brodhun photometer*, are discussed in Hausmann and Slack (4).

If the colors of the two lamps are not matched, it is difficult for an observer to compare to the brightness of the two screens. To solve this problem, the *flicker photometer* was developed. In this instrument, light from the two sources is alternately imposed on a screen at such a rate that the observer can no longer discern that there are two colors. Measurement is made when the sources are adjusted so that the observer is no longer aware of flicker.

Visual photometers are rather cumbersome to use and depend on the observer's subjective ability to make contrast or flicker distinctions. Photometry became a much more exacting and easily implemented science with the advent of the photoelectric detector. Photoelectric instruments have largely supplanted visual photometers; visual instruments are rarely used today except for educational purposes.

PHOTOELECTRIC PHOTOMETERS

Photoelectric photometers depend on the ability of certain non-metallic materials or combination of materials to generate an electric current in the presence of light. The first photoelectric detector used to any great extent was the selenium cell. Selenium is a polycrystalline, nonmetallic element and is used in photovoltaic (i.e. generating an electric current without an external electrical power source in the presence of light) detection devices. Selenium cells were widely used for illuminance meters, photographic light meters, and many other applications until the early 1980s. These early day detectors could drive a sensitive galvanometer movement without use of an external power source, making them ideal for portable light meters. The selenium detector has a spectral response (i.e., response as a function of wavelength) that overlaps the visible region and the spectral response of most photographic films.

Today the silicon detector has replaced selenium cells. Silicon is an element used as a detector in single-crystalline form. The material is doped with small amounts of impurities to form a barrier junction where current is generated by entering photons. Silicon has a significant response that overlaps the visible region. This detector can be used in either photovoltaic mode or photoconductive mode, the latter requiring an external current source. When used in either mode, the electric current is proportional to the incident light over several decades. A special optical filter is used to match the spectral

Figure 4. Photopic spectral luminous efficiency function, $V(\lambda)$, for CIE 1924 standard photometric observer.

response to that of the average human eye, the V - λ or $V(\lambda)$ function (see Fig. 4). An operational amplifier (also called a current-to-voltage converter or transimpedance amplifier) is generally used to convert the detector's output current to a voltage proportional to the light signal. This output voltage is detected using a calibrated readout device (analog or numerical display) (see Fig. 5).

Photomultiplier tubes may be used as detectors in place of silicon detectors for increased sensitivity, especially toward the short-wavelength end of the visible spectrum.

A representative high-accuracy laboratory photometer is shown in Fig. 6. This instrument may be configured to measure luminous flux, luminous intensity, luminance, or illuminance. The unit on the right is used to measure luminance or luminous intensity; the operator aims the detector head at the area to be measured by looking through a viewfinder. To measure illuminance, a cosine receptor

consisting of a transmitting diffuser or an integrating sphere is used as an alternative detector head. Some laboratory photometers can be computer-controlled and can be configured with a number of program-selected detector heads connected to one controller. An instrument designed to measure only illuminance or luminance is called an illuminance meter (or illuminometer) or luminance meter respectively.

An instrument for measuring the total luminous flux is called an *integrating sphere photometer*. It consists of two joined hemispheres coated on the inside with a light-scattering, diffuse white material, typically barium sulfate. The spheres can be opened so that a light source can be placed inside. After the hemispheres are closed to form a sphere, all of the light emitted by the source is captured inside of the sphere and scattered uniformly in all directions by a number of interreflections between the sphere wall surfaces. A detector is attached to the side of the sphere and produces a signal proportional to the total flux emitted by the source. One or more diffuse white baffles are placed inside the sphere, so the detector does not receive light directly from the source; only light that has been reflected from the sphere wall (i.e., the light scattered a number of times

Figure 5. Schematic of silicon detector operated in photovoltaic mode with operational amplifier and readout device. Resistors R_1 to R_3 are used to set the sensitivity range, and resistor R_0 is used to set the zero. Bypass capacitors, C_1 to C_3 , are used to suppress alternating-current noise.

off of the sphere's surface and baffles) will reach the detector. An example of an integrating sphere photometer is seen in Fig. 7.

The fundamentals of photoelectric detectors and transimpedance amplifiers are covered in Deboo and Burrous (5).

SPECIALIZED PHOTOMETERS

The word *photometer* has its roots in the Latin word *photometrum*, from *phot-* (light) + *metrum* (meter), and is used in the broadest sense to describe a number of instruments used to make light measurements. The visual or photoelectric photometers described previously are instruments for directly measuring one or more of the photometric quantities. The present section will describe examples of different types of photometers that measure quantities directly related to the amount of light or the amount absorbed or scattered by various substances.

The *photographic light meter* or *exposure meter* is an example of a photometer calibrated in other than photometric units. In one form of light meter, the deflection of a needle is proportional to light level. The instrument is constructed so that when a manually aligned pointer coincides with the needle, the photographic exposure (*f*-stop and exposure time) corresponding to the preset film speed can be read directly from a dial. One variant of this concept includes light meters integral to the camera itself, so that the aperture and speed can be adjusted to match needles while looking through the camera's viewfinder. Modern exposure meters, such as the one shown in Fig. 8, use digital displays to indicate exposure. Some light meters are manufactured to read either incident or reflected light; some are calibrated in photometric units as well as units of exposure.

Figure 8. A modern photographic exposure meter with digital readout. The translucent white diffuser is used for incident light measurements. (Courtesy of the Minolta Corporation.)

A number of photometers are designed for measuring the optical properties of substances. The word *colorimeter* is used to describe photometers for chemical analysis based on light absorption by either the test substance or a chemical product of the test substance obtained by use of a reagent. These instruments consist of one or more light sources, narrow band-pass interference filters for selecting wavelengths specific to the substance being measured, and a detection system. Some of them employ a transparent sample holder (cell, ampoule, or cuvette). A measurement is taken with an empty sample holder in place, and a second measurement is taken with a sample in the holder. The ratio of the two measurements is a measure of the opacity of the sample at the selected wavelength and can be converted to the amount of a specific substance in the sample.

An example of this type of photometer is the *water analysis photometer*. A typical instrument of this type has five filters in the visible region, uses a blue-enhanced silicon photodiode detector, and can measure 40 water parameters. An example is shown in Fig. 9.

Another example of this type of photometer is the *flame photometer*, also called an *atomic-absorption photometer*. Rather than using liquids, the flame photometer burns the test substance in propane or natural gas. Here the strength of absorption lines from the burned substance at filtered wavelengths are a measure of the amount of unknown in a given amount of substance. An *optical-emission spectrometer* is similar to a

Figure 9. A single-channel, microprocessor-controlled photometer used to measure impurities in water. The transparent cells shown on the right each hold 10 ml of water and reagent. (Courtesy of VWR Scientific Products.)

flame photometer except that an electric spark rather than a flame is used to vaporize the sample.

A *light-scattering photometer* makes use of the light-scattering properties of particles suspended in a jet of gas. Light from particles is primarily scattered in the forward direction, so the detector is aimed at angles looking toward the forward direction of the incident light. This technique can be used to obtain particle size distributions in clean-room environments, clouds, smoke stacks, and so on. Lasers are generally used in this application, because they are monochromatic (single wavelength) and highly collimated so that the scattering volume can be accurately defined. An instrument for measuring airborne particles is called a *nephelometer*.

Some photometers are very specific to a given profession or industry. For example, a specialized photometer for measuring blood hemoglobin is called a *hemoglobinometer*. A specialized photometer for evaluating the brightness of paper and similar products is called a *brightness meter*; it measures the diffuse reflectance of the paper in the blue range of the spectrum. A similar instrument, the *glossmeter*, is used to measure specularly reflected light from a flat sample, with the incident and reflected light making the same angle with the test surface. A *saccharimeter* is a type of photometer for analyzing the

concentration of sugar solutions based on the angle of rotation of plane-polarized light passing through the sample. Photometers utilizing polarization are known as *polarimeters*.

A *spectrophotometer* consists of a light source, a monochromator, a sample space, and a photodetector. In one type, wavelengths are selected by using a scanning monochromator, where a diffraction grating is rotated to select the appropriate wavelengths. Another version uses a grating and diode array detector, which simultaneously detects multiple wavelengths at discrete intervals. These instruments are made to operate in the infrared (*infrared spectrophotometer*), ultraviolet (*ultraviolet spectrophotometer*), and visible regions of the spectrum. Sometimes a spectrophotometer will have two independent channels (reference and test), referred to as a *dual-beam spectrophotometer*. A portable, abridged dual-beam, array detector spectrophotometer is shown in Fig. 10.

Additional information on specialized photometers can be found in Horton (6).

SUN PHOTOMETERS

The *sun photometer* is one of the more interesting and complex types of photometers and deserves special mention. This instrument is used to measure certain optical properties of the earth's atmosphere, and information about atmospheric constituents can be derived from these measurements. Since there is increasing interest in the effects of ozone depletion, atmospheric pollution, and water vapor on visibility, health effects, air quality, and global warming, there is increasing interest in this type of photometer. A sun photometer consists of a basic filtered photometer in which the viewing field-of-view has been limited (typically to about 2°) by use of a tube containing one or more apertures. Sun photometers can be used either on the ground (terrestrial) or from an airborne platform. The optical path between the instrument and the sun must be cloud-free.

The instrument is aimed at the sun either manually or with an automatic solar tracker, so that it is measuring

Figure 10. Portable, dual-beam, array detector spectrophotometer used for making precision color measurements. The sample material is illuminated by a pulsed-Xe lamp built into the instrument. incoming solar energy over a narrow wavelength band (typically 10 nm wide) of radiation coming directly from the sun (plus a small scattered component). Since certain atmospheric constituents attenuate and/or scatter solar radiation in a wavelength-dependent way, information about the atmospheric constituents can be measured at the appropriate critical wavelengths. Sun photometers are used to measure atmospheric aerosol optical thickness (turbidity), ozone, and water vapor. Measurements taken at discrete wavelengths can be entered into atmospheric transmission models that calculate an approximation to the entire solar spectrum.

Operation of the sun photometer is based on Beer's law, namely,

$$S(\lambda) = S_0(\lambda)e^{-\delta(\lambda)M}$$

where

$S(\lambda)$ = the terrestrial signal at wavelength λ

$S_0(\lambda)$ = the extraterrestrial (i.e., outside the earth's atmosphere) signal at λ

$\delta(\lambda)$ = the total optical depth at λ

M = the relative air mass

Taking the log of both sides of this equation gives,

$$\ln S(\lambda) = \ln S_0(\lambda) - \delta(\lambda)M \quad (1)$$

which in turn yields a linear equation with dependent variable $S(\lambda)$, independent variable M , slope $\delta(\lambda)$, and y -axis intercept $S_0(\lambda)$. A plot of this equation (Fig. 11) is called a Langley plot, in honor of its inventor.

The relative air mass M is defined as unity at the zenith; neglecting atmospheric refraction, it is the relative atmospheric path length through the atmosphere, namely,

$$M = 1/\cos(\theta)$$

where θ is the angle between the zenith and the solar position.

The total optical path, $\delta(\lambda)$, is composed of three components:

$$\delta(\lambda) = (p/p_0)\delta_R(\lambda) + \delta_0(\lambda) + \delta_a(\lambda) \quad (2)$$

where

p/p_0 = ratio of surface atmospheric pressure to reference atmospheric pressure, $p_0 = 101.3$ kPa

$\delta_R(\lambda)$ = Rayleigh (molecular) scattering optical depth at λ

$\delta_0(\lambda)$ = ozone optical depth at λ

$\delta_a(\lambda)$ = aerosol optical depth at λ , also called turbidity

Figure 11. Langley plot of log signal versus air mass. The y -axis interception of the best linear fit to the data gives the calibration constant V_0 for the instrument.

$\delta_a(\lambda)$ can be determined from any reading $V(\lambda)$ under cloud-free conditions, solving Eq. (1) for $\delta(\lambda)$ and calculating $\delta_a(\lambda)$ from Eq. (2) since $\delta_R(\lambda)$ values are available as a function λ and $\delta_0(\lambda)$ can be estimated based on location on the earth's surface and date.

A sun photometer is calibrated by taking successive readings throughout a clear, stable (pristine) day, determining a best-line fit to the Eq. (1), and then calculating $V_0(\lambda)$, the y -axis intercept. The World Meteorological Organization (WMO) recommended wavelengths are 368, 500, 778, 675, and 862 nm, with either 5 nm or 10 nm band pass (see Ref. 7). Typical field of view for these instruments is 2.3° . A four-channel sun photometer with solar tracker is shown in Fig. 12.

In addition to measuring aerosol optical depth, sun photometers can be used to measure the amount of water vapor in the atmosphere using channels centered in the near infrared at 862 nm and either 942 nm or 1020 nm. The 862 nm channel is an atmospheric transmission window; that is, there is no significant absorption of solar radiation by water vapor or aerosol, while there is a significant water vapor absorption band centered at 942 nm and 1024 nm. The amount of precipitable water vapor as a function of optical transmission can be derived from fundamental equations of optical transmission. A good reference on sun photometry is found in Ref. 8. Note that in this case the wavelengths used for water vapor determination are outside of the visible region.

A simple hand-held sun photometer can be constructed for around \$25. Rather than use an expensive filter and detector combination, a red light-emitting diode (LED) is used as

Figure 12. Automatic four-channel sun photometer. (Courtesy Eko Trading Co., Ltd.)

detector. In this reverse role, the LED generates a voltage proportional to the incident optical signal at its normal radiating wavelength. This instrument can be used to monitor atmospheric pollution and haze [see Carlson (9) and visit the Concord web site (10)].

CALIBRATION OF PHOTOELECTRIC PHOTOMETERS

Calibration of photoelectric photometers is based on a unit of luminous intensity, the candela. The candela was originally defined in 1948 by the Conférence Générale des Poids et Mesures (CGPM) as 1/60 of the luminous intensity per square centimeter of a blackbody at the solidification temperature of platinum (2042 K). This calibration was based on basic physical principles—that is, the Stefan–Boltzmann radiation law for blackbody radiators. A point source of 1 cd luminous intensity radiates one lumen of luminous flux into a solid angle of one steradian. However, this old definition using the platinum blackbody was difficult to achieve. The advent of the highly accurate electrical substitution radiometer made it possible in 1979 to redefine the candela as “the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} Hz and that has a radiance intensity in that direction of (1/683) watt per steradian.”

In the United States, the candela is maintained on a set of eight *standard photometers* maintained at the National Institute of Standards and Technology (NIST) in Gaithersburg, MD. Each standard photometer consists of an Si detector, a $V(\lambda)$ filter, and an electronic amplifier. The $V(\lambda)$ filter is matched to each detector to give a response representative of the average human eye. Each detector is calibrated for its radiometric response by interpolation of its spectral response (A/W) measured using a high-accuracy cryogenic radiometer (HACR) at selected stabilized laser beam wavelengths over the visible portion of the spectrum. The illuminance responsivity scale (A/lx) is realized by adding a precision aperture (to define the detector's sensitive area) and an accurately characterized $V(\lambda)$ filter. Since the illuminance can now be accurately measured and the geometry can be well established, luminous intensity (cd) of transfer lamps can be accurately measured using the standard photometers.

The NIST luminous flux unit (lm) is defined from the detector-based candela using a calibrated integrating sphere photometer. Calibration is implemented by introducing a precisely measured amount of flux into the sphere from external standard lamps. Lamp standards are then calibrated by placing them inside of the calibrated integrating sphere.

An NIST standard of luminance is realized by use of a calibrated integrating sphere source. Using the standard photometers, precision apertures at the sphere's exit port, and precise aperture-to-photometer distance, the luminance at the aperture plane is established. A reference luminance meter is used as a working standard for routine calibrations.

The NIST provides photometric calibration services for photometer heads, luminance meters, and illuminance meters. Artifacts used to calibrate photometers include lamps calibrated in units of luminous intensity, luminous flux, and illuminance at specified distances. Integrating sphere calibration sources are calibrated by NIST in units of luminance (see Fig. 13). Intercomparisons of photometers and artifacts between national standardizing laboratories are used to ensure the integrity

Figure 13. Integrating sphere uniform source for luminance calibration of photometers and imaging systems. (Courtesy of Labsphere Inc., North Sutton, NH)

of standards throughout the world. A detailed description of photometric units and photometric calibration techniques used at NIST can be found in Ohno (11).

PHOTOMETRIC LIGHT SOURCES

Any emitter of electromagnetic radiation is a photometric light source. Electromagnetic radiation is produced whenever a charged particle, such as an electron, is accelerated (synchrotron radiation) or decelerated (bremsstrahlung radiation). This occurs in a number of ways. For instance, heat is the irregular motion of electrons, atoms, and molecules. The higher the temperature, the more rapid the motion. Such thermal motion produces irregular oscillatory charge motion, and each oscillation at a particular frequency acts as a tiny “antenna” that emits and receives electromagnetic radiation. Other prevalent physical processes that produce electromagnetic radiation are the quantum energy transitions within materials by electron orbital energy transitions within atoms, recombination of free electrons with atoms, or transitions from excited bonding states of atoms within molecules. Absorbed energy raises a system to an excited state, and electromagnetic radiation is released upon transition to a lower energy state. The frequency of the radiation is related directly to the energy transition. As energy transitions are quantized characteristics of the material makeup, so is the frequency of the electromagnetic radiation produced.

Almost all photometric light sources used in practice result from one of two categories of physical phenomena: (1) incandescence and (2) luminescence. Light from incandescent bodies, such as burning wood or coal, molten iron, and filament wire heated by an electric current, results from thermal motion. Luminescence observed in fluorescent lamps, X-ray fluoroscope screens, organic substances found in fireflies and glowworms, lightning, high intensity discharge lamps, light-emitting diodes, lasers, and, electroluminescent phosphors results from light emission after energy has been absorbed by a material raising its energy state and then subsequently transitioning to a lower energy state. Luminescence is sometimes called “cold light” because a number of photometric light sources based on this phenomenon operate in the vicinity of room temperature. In some cases the distinction between incandescent and luminescent phenomena becomes blurred, such as in shock tubes at very high temperatures, where the collisions of atoms are so violent that electrons dissociate from the atoms and then recombine.

The functionality of a light source is largely determined from the wavelength (frequency) distribution of electromagnetic radiation that it produces. The top diagram of Fig. 1 shows the wavelength range (log scale) and standard nomenclature used

Figure 1. Nomenclature for important divisions and subdivisions of part of the electromagnetic spectrum.

for various spectra of electromagnetic radiation. The three diagrams below in Fig. 1 show further subdivisions of specific wavelength spectra. The term *photometric light sources* is applied to sources of electromagnetic radiation emitting at any of the wavelengths in Fig. 1, although the term “light” is usually only applied to electromagnetic radiation visible to the human eye.

The visible spectrum with a wavelength from roughly 400 to 700 nm produces different color perceptions which are chromatically completely saturated for single wavelength distributions. Multiple wavelength distributions in this range produce less saturated colors, white light, and other colors, such as earth tones. Longer wavelength infrared electromagnetic radiation comprises much of the thermal emission from materials at room temperature to well above 5000 K. The subdivision of infrared radiation into near, intermediate and far is standard terminology that has grown out of various measurement applications, although the divisions are arbitrary. Ultraviolet electromagnetic radiation has a wavelength shorter than visible light and the main difference of this type of radiation from that at longer wavelengths is its ability to ionize atoms by removing electrons. This gives ultraviolet radiation the ability to influence chemical reactions, such as in plant life, and it also makes this type of radiation potentially harmful to human and animal life. Photobiologists have assigned significance to the UV-A, UV-B, and UV-C subregions of the ultraviolet spectrum according to their interaction with biochemical phenomena. Of great importance to ultraviolet spectroscopy is the spectral region below 200 nm

in which ultraviolet radiation is absorbed by air. Hence the term *vacuum* ultraviolet requiring the almost complete evacuation of air from instrumentation measuring or producing such radiation. At still shorter wavelengths (higher frequency) is X-ray electromagnetic radiation. Infrared, visible, and ultraviolet radiation are produced by ionization/recombination in the outer valence electrons of atoms. The X-ray region occurs at the higher ionization/recombination energies involving the inner electron orbitals of atoms. X rays are energetic enough to ionize and also to penetrate many materials. "Hard" and "soft" X rays are differentiated by their penetrating power. The top diagram of Fig. 1 shows other important forms of electromagnetic radiation, longer wavelength millimeter and still longer radio waves to the right and high-frequency energetic gamma rays from cosmic sources to the left.

The generation of electromagnetic radiation by photometric light sources is classified into two categories: (1) systems and processes that produce electromagnetic radiation covering a broad continuous spectrum of frequencies and (2) those that emit electromagnetic radiation of discrete frequencies characteristic of the materials making up the light source. For most photometric light sources, the production of continuous and discrete spectra are concurrent. A classic example of a continuous spectrum-emitting source is an ideal blackbody radiator, which is used as a fundamental reference standard. The term blackbody refers to an object that absorbs all frequencies of electromagnetic radiation, and hence appears black when emitting little radiation at cooler temperatures. The rule of reciprocity states that a body radiates strongly at those frequencies it absorbs. Analogous to the oscillation of charges from thermal motion as "tiny antennas," an antenna is part of an electric resonance circuit that transmits and receives at the same frequency. A piece of black coal is a good example of a blackbody. When heated to increasingly high temperatures, it first glows red, then yellow, and finally white. The continuous distribution of frequencies depends solely on its absolute temperature and the frequency at which the maximum radiative energy increases in proportion to absolute temperature. When glowing red, a blackbody emits a large portion of infrared radiation. When glowing white, a significant amount of ultraviolet radiation is emitted.

Because of the inhibition of certain oscillatory modes of electric charges, in practice all materials are *selective* radiators with respect to emission at a particular wavelength compared with the emission from an ideal blackbody at exactly the same temperature. The ratio of the emission energy of a material to the emission energy of a blackbody at the same temperature and at a particular wavelength is called the wavelength *emissivity* of the material. Emissivity also depends on the direction in which radiation is emitted relative to the body. The closer the emissivity of a material to 1.0, the better the approximation to a blackbody at that wavelength. For instance, tungsten in incandescent filaments has high emissivity in the visible spectrum, but lower emissivity in the infrared. As a visible photometric light source, heated tungsten filaments closely approximate the output of a blackbody. Glass is transparent because it transmits (i.e., lacks absorption) visible light radiation and as a result has low emissivity in the visible spectrum. Heated glass looks relatively colorless compared with heated opaque materials. However glass has even higher emissivity than tungsten in the mid-infrared. References 1–3 provide thorough background on the topics discussed thus far.

Other sources of continuous frequency spectra of electromagnetic radiation are high-energy electron accelerators, appropriately called synchrotrons because they use magnets to accelerate free electrons in circular orbits. The first experimental investigation was conducted in 1947 on the 70 MeV General Electric synchrotron to produce visible light radiation. Subsequently higher energy synchrotrons were developed which produce broad continuous spectrums at higher frequencies into the ultraviolet and X-ray spectral regions.

Sources of discrete frequencies or line spectra are produced from energy transitions characteristic of the atomic and/or molecular structure of the material comprising the light source. Some important examples include the five principal visible spectral lines of mercury gas from a high-intensity mercury discharge lamp and the 589nm strong spectral line from a high-pressure sodium lamp. The intense line spectra for these lamps occur against a lower grade background of a radiative frequency continuum. Laser light is produced by light amplification by stimulated emission of radiation and is coherent (i.e., all emitted light is in the exact same phase), monochromatic or containing only a few monochromatic lines, and is intensely focused within a narrow aperture beam. Atoms of a material are stimulated to an excited state by using a noncoherent light source or with electricity, and synchronous radiative emission occurs from the corresponding synchronously generated energy transitions. An example is the red HeNe laser with its characteristic 632nm radiation.

BLACKBODY RADIATION

In the 1890s the German physicist Wilhelm Wien came up with the idea of constructing a good approximation to an ideal blackbody photometric light source by using an enclosed oven to create a cavity with a small hole through which the cavity can be viewed. The radiation coming out of this hole is very close to the equilibrium blackbody electromagnetic radiation corresponding to the oven temperature. Any external radiation that enters the hole is internally scattered and reflected within the cavity so that almost all of it is ultimately absorbed, and extremely little finds its way back outside the hole. Wien carefully measured the radiative energy dW per wavelength interval $d\lambda$ for the blackbody radiative distribution.

The theory to accurately explain the shape of this empirically observed blackbody radiative distribution came shortly later in 1900 when Planck used the radically new idea that internal electric charge oscillators within the blackbody emit only electromagnetic radiation in finite quantized amounts of energy of size $E = h\nu$, where ν is the frequency of the radiation. With $c = \lambda\nu$, the Planck radiation law accurately predicts that the radiative energy per unit wavelength for a blackbody is given by

$$\frac{dW}{d\lambda} = \frac{8\pi ch\lambda^{-5}}{e^{\frac{hc}{\lambda kT}} - 1}$$

where $k = 1.38 \times 10^{-23}$ J/K is Boltzmann's constant from thermodynamics. The value of Planck's constant $h = 6.626 \times 10^{-34}$ J·s is determined from the best fit with empirical data. The properties of this distribution are consistent with Wien's law which states that the product of the wavelength with maximum radiative energy and the absolute temperature is an

Figure 2. Spectral power distribution for a blackbody at various absolute temperatures, predicted by Planck's radiation law.

absolute constant $\lambda_m T = 0.2898 \text{ cm} \cdot \text{K}$ and are consistent with the Stefan-Boltzmann law that the total radiant energy emitted per second and per unit area W of a blackbody is proportional to the fourth power of the absolute temperature, $W = \sigma T^4$, where $\sigma = 5.67 \times 10^{-12} \text{ W}/(\text{cm}^2 \cdot \text{K}^4)$. Figure 2 shows wavelength distribution plots for a blackbody at various absolute temperatures.

LUMINESCENCE

In contrast to incandescence, radiative emission from luminescent phenomena occurs at relatively cool temperatures. The process by which an appropriate material absorbs energy and then subsequently releases electromagnetic radiation upon an electronic transition to a lower energy state or its original ground state occurs in a variety of ways depending on (1) how the electronic transitions occur and (2) in what form energy is initially absorbed by the material. In all cases the energy transitions involve the outer valence electrons of atoms comprising the material. The field of luminescence is very broad, so discussion here is limited to that most practically relevant to photometric light sources.

For luminescence there is an important distinction between two different types of electronic transitions upon absorbing energy, *fluorescence* and *phosphorescence*. The process of radiative emission from fluorescence occurs very quickly, on the order of 10 ns after initial excitation. The high-energy excited state upon absorption is unstable and therefore rapidly transits back to a lower state. Sometimes there are metastable excited states in fluorescent materials that are much longer-lived before transiting to a lower state. Radiative emission from such a phenomenon is called phosphorescence and, from the time of initial excitation, transition back to a lower energy state takes anywhere from milliseconds to several days.

The predominant sources of energy initiating luminescence in photometric light sources are ultraviolet or visible electromagnetic radiation and electricity. The former is called *photoluminescence* and the latter is called *electroluminescence*. In photoluminescence the wavelength of emitted light typically has a wavelength longer (i.e., lower frequency and therefore lower energy) than the incident radiation. Other sources of energy for luminescence are electron guns, such as in television

tubes, and particles emitted by radioactive materials which is called *radioluminescence*.

MEASUREMENT OF LIGHT SOURCES

The terms "intensity" and "color" of a light source are often used loosely, but each of these has a formal International Standard (SI) definition that is universal in practical application. Units of radiosity apply to energy of light radiation whereas units of luminosity apply to the perception of the energy of light radiation by the human eye. For instance radiant intensity from a light source refers to the radiant flux per unit solid angle, usually expressed in watts per steradian. The SI unit for luminous intensity is the candela. One candela is the perceived luminous intensity of monochromatic radiation at $540 \times 10^{12} \text{ Hz}$ (approximately 555 nm) at the radiant intensity of 1/683 watt per steradian. The *lumen* is the SI unit of luminous flux. One candela is equal to one lumen per steradian. The human spectral photopic response curve is approximately a bell shape which is maximal at 555 nm (yellow-green light) and falls to zero near 400 nm on one side and near 700 nm on the other side. Because the spectral response of the human eye is variable from 400 to 700 nm, the relationship between watts and lumens, therefore, is wavelength-dependent. The ratio of lumens to watts is termed *luminous efficacy*. Maximum efficacy of 683 lm/W is achieved at a wavelength of 555 nm and falls off in proportion to the spectral response to blue and to red. Many visible light sources are rated in terms of the luminous efficacy of their spectral outputs. See reference (7) for more details.

Instruments called *radiometers* are used to measure radiant power (watts) of light sources that is cumulative over wide ranges of wavelengths including the ultraviolet, visible, or infrared spectral regions. Radiometers employ a variety of detectors, such as thermocouples, thermopiles, and pyroelectric detectors. Visible radiometers use a filter transmitting light according to the human spectral photopic response for measuring luminous power (lumens). By incorporating a device called a *monochromator* which separates or disperses the various wavelengths of the spectrum through prisms or gratings, one can determine the radiant power in a very small range of wavelengths. Such an instrument called a *spectroradiometer* measures the spectral power distribution for a light source, which is the radiant power per unit wavelength, as a function of wavelength. From the spectral power distribution, one determines all radiometric, photometric, and colorimetric properties of a light source in the absolute sense.

Radiometers are limited to measuring light power within a small aperture. An instrument called an *integrating sphere photometer* measures the total radiant power emitted by a light source over the entire 4π steradian spherical solid angle. The most common is called the Ulbricht sphere which is about 3 m in diameter and whose inner coated surface, ideally, is coated by a perfectly diffusing substance with uniformly nonselective reflectance. White magnesium oxide and barium sulphate are coating materials that come close to these properties. The light source is placed at the center of the sphere, and every point on the inner surface then reflects to every other point so that the flux incident on each unit area along the inner wall is uniform regardless of the angular distribution of the emitted power from the source. The total flux E received per unit area of the sphere from reflection and multiple interreflections is related to the

total flux F emitted by the source inside the sphere, according to the following expression:

$$E = \frac{\rho F}{4\pi r^2(1 - \rho)}$$

where r is the radius of the sphere and ρ is the total energy reflectance coefficient of the material (4). In practice this formula requires a number of photometric corrections due to nonuniform reflectance in wavelength and nonuniformity across the interior surface of the sphere. Another way of computing total luminous flux is by comparing the measurement of flux incident on a unit area of the inner surface of the sphere for two light sources. If the total emitted power of one of the light sources is known, then the total power of the other light source can be determined.

COLORIMETRY

Perception of the color of light radiation by the human eye was first internationally standardized by the Commission Internationale de l'Eclairage (CIE) in 1931. A system for the CIE standard observer was defined in terms of color matching functions used to convert a spectral power distribution into tristimulus color values. A set of three color matching functions $\bar{C}\bar{I}X(\lambda)$, $\bar{C}\bar{I}Y(\lambda)$, and $\bar{C}\bar{I}Z(\lambda)$ convert a spectral power distribution $P(\lambda)$ into tristimulus values X , Y , and Z according to the following equations

$$X = \int_{\lambda} P(\lambda) \bar{C}\bar{I}X(\lambda) d\lambda$$

$$Y = \int_{\lambda} P(\lambda) \bar{C}\bar{I}Y(\lambda) d\lambda$$

and

$$Z = \int_{\lambda} P(\lambda) \bar{C}\bar{I}Z(\lambda) d\lambda$$

where integration is from 400 to 700 nm. For a given fixed set of color matching functions $\bar{C}\bar{I}X(\lambda)$, $\bar{C}\bar{I}Y(\lambda)$, and $\bar{C}\bar{I}Z(\lambda)$ there is an infinity of spectral distributions $P(\lambda)$ that produce exactly the same tristimulus values X , Y , and Z . Therefore each tristimulus set of values corresponds to an equivalence class of spectral distribution functions called *metamers* with respect to the color matching functions. The chromatic coordinates x , y , z for a color are defined as the ratio of each tristimulus value of the color to their sum:

$$x = \frac{X}{X + Y + Z}$$

$$y = \frac{Y}{X + Y + Z}$$

and

$$z = \frac{Z}{X + Y + Z}$$

Chromatic coordinates have two degrees of freedom because specifying x and y automatically determines z on the plane $x + y + z = 1$.

Figure 3. 1931 CIE chromaticity diagram showing chromatic coordinates for the pure spectral colors, CIE standard light sources A, B, and C, and the equal-energy source E (4).

The color matching functions developed for the 1931 CIE standard observer are based on earlier work on color matching for chromatic coordinates of the pure spectral colors. Details of the derivation for these color matching functions along with tabulated and graphed values are in (4). Two important criteria are (1) that the middle color matching function $\bar{C}\bar{I}Y(\lambda)$ is the photopic spectral response function for the human eye and (2) all three color matching functions are nonnegative for all wavelengths in the visible spectrum. The first criterion implies that the tristimulus value Y represents the photopic intensity. Figure 3 shows a plot of the pure monochromatic spectral colors in the x - y CIE chromatic space together with the plot of the CIE standard light source A at $x = 0.448$, $y = 0.407$, the CIE standard light source B at $x = 0.348$, $y = 0.352$, and the CIE standard light source C at $x = 0.310$, $y = 0.316$. The definitions and constructions of these CIE standard light sources are discussed in the subsection "Incandescent Sources." The "equal-energy" source at point E where $x = y = 1/3$ appears as an achromatic gray tone. In 1964 color matching functions were developed to improve performance for a CIE standard observer viewing colors over a wider field of view of 10° , compared with the 1931 CIE standard observer which performs well over a narrow field of view of 2° .

The trace of points in CIE chromatic space that represent x - y values for spectra produced by blackbodies is known as the *Planckian locus* depicted as a solid curve in Fig. 4 for absolute temperatures ranging from 1515 K up to infinity. An important parameter for a visible photometric light source, particularly an incandescent filament source, or a high-intensity discharge lamp is its correlated color temperature or simply its color temperature. The idea is that, given a spectral output for a light source, what is the absolute temperature of a blackbody producing the most similar spectral output sensed by a standard observer. For lamps emitting a spectrum with CIE x - y coordinates in the vicinity of the Planckian locus, the color temperature is the "nearest" point on the Planckian locus to this CIE point. This was formalized by Judd (6) using isothermal lines which were recomputed by Kelly (5) in the 1931 CIE chromatic space shown in Fig. 4. Most often the color temperature of a visible

Figure 4. 1931 CIE chromaticity diagram showing the Planckian locus and isotherm lines (4).

light source is not the same as the actual operating temperature of the source. Even for incandescent tungsten filament lamps heated to different temperatures which lie quite close to the Planckian locus, the filament temperature is always lower than the color temperature (e.g., by about 40 K at color temperatures around 2850 K) because of the wavelength-dependent emissivity of tungsten. Visible light sources producing CIE x - y coordinates far from the Planckian locus, such as some fluorescent lamps, are still assigned a color temperature although this is more for convenience in interior lighting design than for physical meaning.

VISIBLE LIGHT SOURCES

A diverse variety of designs are available today as sources of visible light radiation. These include incandescent filament lamps, high-intensity discharge lamps, short-arc lamps, fluorescent lamps, light-emitting diodes, electroluminescent phosphor lamps and even nuclear light sources. A number of these designs simultaneously produce a significant amount of electromagnetic radiation at wavelengths longer and shorter than visible light also making some of them good infrared and ultraviolet sources. The choice of design of a visible light source for a particular application depends on a number of factors including spectral output, radiant intensity requirements, power consumption, luminous efficacy, temperature conditions, and durability.

Incandescent Sources

Incandescent filaments are the most commonly used source of visible light radiation. An electric current is passed through a filament which glows because of thermal motion. The filament is encased in a glass envelope evacuated to prevent oxidation of the filament. The criteria for a filament material are high melting point, low vapor pressure, high strength, high ductility, and suitable radiative and electrical resistance characteristics. Earlier designs for incandescent filaments used carbon, osmium, and tantalum, but tungsten with its high melting point of 3655 K and good adherence to the other desirable properties for a filament is now the most widely used material. Subsequent designs

have alloyed tungsten with metals, such as rhenium, for desired spectral characteristics, and thorium is used in tungsten filaments for rough service applications.

More recently the tungsten-halogen lamp prolongs lifetime and operates at a higher filament temperature up to 3500 K. Metal halides are added inside the glass envelope at low pressures creating a cycle of dissociation and recombination that reduces gradual blackening of the envelope by tungsten evaporated from the filament. The filament heats the metal halide gas disassociating it into metal and halogen. Tungsten evaporated from the filament combines with the halogen. When tungsten halide contacts the hot filament, the tungsten recombines with the filament, disassociating it from the halogen and completing the cycle. Tungsten-halogen bulbs are available with power up to 1000 W using a power supply between 8 and 13 V at high current. Because the output varies roughly as the eighth power of the current, the stability of the power supply is quite stringent.

Standard sources for colorimetry use incandescence from tungsten filaments with added features. Standard source A is a tungsten filament operated so that the correlated color temperature is at 2856 K. Standard source B approximates noon sunlight with a correlated color temperature of approximately 4874 K. Standard source B uses the standard source A in conjunction with a special filter one centimeter thick consisting of layers which include compounds of copper and cobalt. Standard source C approximates daylight provided by a combination of direct sunlight and clear blue sky with a correlated color temperature of approximately 6774 K. Standard source C is of construction similar to standard source B except that the special filter has different concentrations of copper and cobalt compounds. In addition there are D-type standard illuminants D_{55} , D_{65} , and D_{75} which approximate different phases of natural daylight with respective correlated color temperatures of 5500 K, 6500 K, and 7500 K.

High-Intensity-Discharge Sources

When an electric arc is struck within a gas, some of the atoms and molecules of the gas ionize producing free electrons whereas others are excited to high energy states. Subsequent quantum electronic energy transitions within excited atoms and molecules to lower energy states causes the emission of various line spectra characteristic of the gas. A broad continuous spectrum of light radiation is also produced by a number of phenomena including (1) energy transitions from stable excited electronic states of a molecule to lower repulsive states, (2) the recombination of free electrons with ions, and, (3) the acceleration and deceleration of free electrons within the electric arc. Except for (3), all of these phenomena that produce light radiation are examples of electroluminescence. For light production in the visible spectrum, the most common high-intensity-discharge lamps are mercury, metal halide, and high-pressure sodium.

The basic construction of a high-intensity-discharge lamp consists of a starting electrode and a pair of operating electrodes contained in an evacuated glass tube. The tube contains the principal gas or gases responsible for light emission and a rare gas, such as argon or xenon, which is easily ionized, to help initiate the electric arc. The principal gas or gases have very low vapor pressure at room temperature and require very high voltage to create an electric arc between the operating

Figure 5. A 400 W phosphor-coated mercury lamp (7).

electrodes. Instead, an arc is initially struck by ionizing the rare gas with the starting electrode heated up. This produces heat which in turn raises the vapor pressure of the principal gas or gases facilitating the creation of an electric arc between the operating electrodes at lower voltages. Adding rare gases also reduces the warm-up time to full operational output.

Figure 5 shows the standard construction of a mercury lamp. The mercury lamp uses mercury gas and approximately 10 to 30 torr pressure of argon gas to initiate the electric arc. When in full operation, the vapor pressure of the mercury gas is usually between two and four atmospheres. The characteristic mercury spectrum consists of five visible principal lines at 404.7, 435.8, 546.1, 577, and 579 nm. This occurs against a continuous broad spectrum which extends well into the ultraviolet. Altogether a mercury lamp appears bluish-white. Increasing the operating vapor pressure of the mercury pushes the continuous spectrum to longer wavelengths (i.e., more red is added). Figure 5 shows the mercury lamp constructed with two glass envelopes. The inner envelope (arc tube) contains the electric arc and the outer envelope shields the arc tube from convection drafts and is usually filled with an inert gas, such as nitrogen, to prevent oxidation of internal parts. The outer envelope also provides an inner surface for a phosphor coating which converts the high amount of emitted UV radiation to visible light by photoluminescence (fluorescence), thereby increasing the efficiency of light power output.

Metal halide lamps are constructed similarly to mercury lamps. Combinations of metal halide gases are added with mercury and argon to produce the spectra of metallic elements. This improves color balance and increases luminous efficacy. Three typical combinations of halides used in metal halide lamps are (1) sodium, thallium, and indium iodides; (2) sodium and scandium iodides; and (3) dysprosium and thallium iodides. Because strong characteristic lines of sodium (589 nm) and thallium (535 nm) are so close to the maximum efficacy wavelength of 555 nm, these particular halides are added to increase efficacy. The use of metal halides in discharge lamps is to combine spectral lines of metals providing two desirable advantages. First, al-

though fused silica comprising the inner arc tube chemically reacts with some metals by themselves, it does not react with the metal halides when they are at the cooler wall temperature. The second advantage is that whereas some metals cannot be vaporized at temperatures which fused silica withstands, they are vaporized when they approach the high temperature central core of the arc tube.

High-pressure sodium lamps are produced by passing an electric current through sodium vapor above 200 torr pressure. Xenon is used as a starting gas. Because of the small diameter of the tube used for sodium lamps, no starting electrode is present, and an arc is initialized by a high-voltage, high-frequency pulse. A high-pressure sodium lamp is golden-white with all frequencies present and the strong 589 nm line characteristic of sodium. Low-pressure sodium lamps principally radiate the 589 nm spectral line and appear as an almost monochromatic yellow. For best efficacy, the vapor pressure for a low-pressure sodium lamp is about 0.005 torr. Although the low-pressure sodium lamp has very high efficacy, it requires much more power than the high-pressure sodium lamp per watt of output.

Short-Arc Sources

Short-arc lamps are basically high-intensity-discharge lamps with very high gas vapor pressure and a small interelectrode distance compared with the diameter of the enveloping tube. Depending upon rated wattage, the length of the electrode-stabilized arc varies from about 0.3 up to 12 mm. The output of these arcs has the highest luminance and radiance of any continuously operating visible light source (i.e., up to well above 30,000 W) and are the closest to a true "point" source. These lamps are used primarily in searchlights, projectors, display systems, and optical instrumentation, such as spectrophotometers.

Mercury and mercury-xenon short-arc lamps are available from 30 to 5000 W operating under the same principle as the mercury high-intensity-discharge lamp. With the same pressure of argon as a starting gas as the standard mercury lamp, the mercury short-arc lamp requires several minutes to achieve full operation. Adding over one atmosphere of xenon gas, the resulting mercury-xenon lamp reduces warm-up time to full operation by about half. The spectral power distribution for both the mercury and the mercury-xenon lamps are essentially the same in the visible spectrum.

Xenon short-arc lamps are filled with approximately five atmospheres of xenon gas and are available from 5 W up to 32,000 W output. Their appearance closely resembles a phase of daylight similar to the visible range of the blackbody spectral distribution at 6000 K. The time to full operational output is quite short, reaching 80% immediately after the initial start.

Fluorescent Sources

The most commonly used fluorescent sources combine light production from electroluminescence and photoluminescence to create a low-temperature discharge lamp. As with the mercury lamp, both mercury and argon gas fills a tube except at much lower pressure. At the operational temperature of 40°C, the vapor pressure of the mercury gas is maintained at about 0.008 torr, and argon gas used to initiate the electric arc is maintained at from one to three torr depending on energy-saving measures. At this low operating pressure, the mercury gas pri-

marily emits a strong characteristic line in the UV at 253.7 nm which is invisible to the human eye. The inside of the tube for the fluorescent source is coated with phosphors designed particularly to fluoresce when stimulated at this wavelength in the UV and reradiate visible light with desirable color properties. Two common phosphors are zinc silicate and magnesium tungstate. In addition to fluorescence, these phosphors exhibit the longer-lived phenomenon of phosphorescence which helps to reduce the stroboscopic effect of ac current operation.

Like most gas-discharge lamps, the electric arc of fluorescent sources must be carefully regulated with a current limiting device called a ballast. The two electrodes hermetically sealed at opposite ends of the tube are designed for either "cold" or "hot" cathode operation, more correctly, respectively, called *glow* and *arc modes* of discharge operation. The tradeoff for these modes of operation is voltage versus current. Electrodes for glow (cold cathode) operation are coated with an electron emissive material, and the standard operating current is on the order of a few hundred milliamperes at 50 V. Electrodes for arc mode (hot cathode) operation are constructed from tungsten wire and, in operation, the current is on the order of 1.5 A at about 10 to 12 V. The lower voltage for the arc mode makes lamp operation more efficient and this is used most frequently.

Light Emitting Diodes

The light emitting diode (LED) is a p - n junction semiconductor device which emits radiation when a forward applied voltage yields a flow of current (see Figs. 6(a) and 6(b)). The material comprising an LED is a specially prepared semiconductor of high purity to which small amounts of other elements are added as controlled "impurities." One type of impurity creates an excess of electrons to produce n -type material, and another impurity has a shortage of electrons (i.e., "holes") which act

as positive charges to produce a p -type material. When a dc voltage is applied to a p - n junction with polarity such that the n -type is negative and the p -type is positive, electrons are forced to meet at the junction and recombine with holes. Light radiation is produced by electroluminescence caused by the recombination of electrons in the conduction band with holes in the valence band. The energy gap crossed during this recombination determines the wavelength of the emitted radiation. Changing the energy gap and, therefore, the wavelength of emitted radiation is achieved by changing the composition of the added impurities. The ratio of the number of emitted photons to the number of electrons crossing the p - n junction is called the quantum efficiency. LEDs are made to produce electromagnetic radiation in various parts of the spectral range from 400 up to 2000 nm. Visible LEDs are used for numeric displays or for indicator lamps. Near-IR LEDs are used as opto-isolators or as sources in optical communication systems. LEDs generally operate in the range of 1 to 3 V at currents in the range of 10 to 100 mA.

The first visible LED with extensive applications and still in wide use today is based on gallium arsenide phosphide ($\text{GaAs}_{1-x}\text{P}_x$). The variable x controls the respective fractions as the elements used. One value used in practice is $x = 0.4$. For smaller values of x the spectral output is largely red light. As x is increased, the quantum efficiency is decreased but the wavelength distribution shifts lower toward 555 nm increasing efficacy. This LED can be made to emit longer wavelength radiation in the dark red and near-infrared by raising x above 0.45 and adding nitrogen. Other LED materials in use include aluminum gallium arsenide ($\text{Al}_x\text{Ga}_{1-x}\text{As}$), and, gallium indium arsenide ($\text{Ga}_x\text{In}_{1-x}\text{As}_y\text{P}_{1-y}$). Spectral output distributions are shown in Fig. 6(c) for some LEDs used in practice.

Semiconductor lasers are based on a variation of the light-emitting diode by carefully constructing structures at

Figure 6. (a) A semiconductor junction. (b) A cross-sectional view of a typical light-emitting diode. (c) Spectral output of several light-emitting diode semiconductor materials (7).

the p - n junction that promote stimulated emission and photomultiplication of photons which are then emitted in a single focused direction. One such laser uses ($\text{Al}_{0.3}\text{Ga}_{0.7}\text{As}$) where parallel mirrors perpendicular to the plane of the p - n junction are readily obtained by cleaving along this material's natural cleavage planes. Photons bounce back and forth between these parallel mirrors at opposite ends of the p - n junction causing electrons to recombine with holes and producing more and more photons which are partially transmitted as laser light by one of the mirrors.

Electroluminescent Phosphor Sources

Special phosphors exist that convert alternating current energy directly into visible light radiation purely by electroluminescence. This skips the intermediate step in discharge tubes of first having to create light indirectly to activate the phosphor. An electroluminescent phosphor, such as zinc sulfide or zinc sulfoselenide is placed between the two conducting layers of a plate capacitor. Standard 60 Hz alternating current at 120 V excites electrons within the phosphor that emit visible light radiation upon transition back to their ground state. The color of the visible light produced is controlled by adding different relative concentrations of activators, such as copper, lead, and, manganese. This produces low-luminance lamps for decorative lighting, night lights, switchplates, instrument panels, clock faces, telephone dials, thermometers, and signs. Colors of these lamps are blue, green, yellow, or pink. Rated wattage varies with applied voltage, frequency, and temperature.

Nuclear Sources

A nuclear light source is a self-powered device that uses a radioactive material to create light radiation. One design for such a source uses tritium gas, an isotope of hydrogen, to fill a sealed glass tube whose inner wall is coated with a phosphor. Tritium emits low-energy beta particles (i.e., electrons) which strike the phosphor causing it to fluoresce. This type of fluorescence is the same mechanism by which an electron gun creates a visible image on a television screen. Glass is impervious to the beta radiation so that it does not present a radiation hazard. The half-life of tritium is 12.3 years, although in practice half-intensity of these light sources is reached in about six to seven years, and they have a useful life of about 15 years (7).

INFRARED AND ULTRAVIOLET LIGHT SOURCES

Many of the same design concepts described for visible light sources are also employed as man-made sources of infrared and ultraviolet radiation. Incandescent tungsten filaments, in fact, radiate up to 70% of their power in the infrared region. Most of this is in the near-infrared between 800 and 1100 nm despite the lower emissivity of tungsten at these wavelengths. Tungsten-halogen lamps also have significant output in the 350 nm to 400 nm range. Figure 6(c) shows the spectral output for two types of GaAs light emitting diodes in the near-infrared. Synchrotrons are ideal for producing a broad continuum of radiation throughout the entire ultraviolet region, but the engineering of high-energy electron accelerators makes this practical primarily for research in ultraviolet spectroscopy. Only some commercial applications are becoming feasible.

Discharge lamps are tuned to emit different amounts of electromagnetic radiation in the ultraviolet and in the infrared depending on the type and vapor pressure of gas(es) used. Xenon has intense spectral lines in the range from 780 to 1000 nm. A xenon-discharge lamp is a good near-infrared source together with a continuous infrared emission tapering off at about 2600 nm. A xenon-discharge lamp also has good continuous emission in the 200 nm to 400 nm range. A mercury-discharge lamp is used as a good near-infrared and mid-infrared source with continuous emission up to 2600 nm. As exploited for photoluminescent stimulation in visible light fluorescent sources, mercury discharge lamps are good ultraviolet light sources. In addition to the intense 253.7 nm spectral line, mercury lamps have good continuous emission from 240 to 400 nm. The most commonly used source in absorption spectrometers is the deuterium discharge lamp which has three to five times more power output than the previously used hydrogen-discharge lamp. The deuterium-discharge lamp has good continuous emission from 180 to 400 nm in the ultraviolet. Most photometric light sources for the vacuum ultraviolet region below 200 nm are high-intensity-discharge tubes filled with rare gases including helium, neon, argon, krypton, and xenon. For more detailed information on ultraviolet light sources consult (8,9).

SOURCES OF X RAYS

X rays were first discovered by Wilhelm Conrad Roentgen in 1895 while observing the effect radiation emanating from a high-voltage vacuum tube had on a piece of barium platino-cyanide. Roentgen deduced that invisible radiation was emitted from the vacuum tube causing the barium platinocyanide to fluoresce. Even placing various materials between the vacuum tube and the barium platino-cyanide, such as black paper, wood, and cardboard, did not prevent the fluorescence. Roentgen then observed the bones of his own hand when placing it between the tube and a sheet of cardboard coated with barium platino-cyanide producing the world's first fluoroscopic screen. He called the invisible emissions X radiation before it was soon discovered that this was yet another form of electromagnetic waves only at higher energies.

The basic designs of X-ray sources widely used today for medical imaging are variations of the original *hot cathode tube* invented by W. D. Coolidge in 1913 at the General Electric Company Laboratories. A low-voltage heating circuit operates a hot filament cathode, and the intense heat produces a source of free electrons by thermionic emission. A second circuit creates a large kilovoltage potential difference between the negatively charged cathode and a positively charged anode target. The free electrons are accelerated toward the anode target striking the anode at high velocity, typically exceeding half the speed of light. The cathode, anode and the space between them are contained in a high vacuum to prevent collisions with gas atoms and therefore prevent slowing of electrons. Two physical mechanisms produce X-ray emission, bremsstrahlung (braking) radiation from the sudden deceleration of electrons as they strike the anode target and characteristic radiation resulting from high-speed electrons which displace inner orbital electrons of the atoms composing the anode. The bremsstrahlung radiation is emitted over a continuous and broad wavelength range whereas the characteristic radiation consists of limited discrete spectra.

Figure 7. Typical spectrum emitted by an X-ray tube showing the continuous bremsstrahlung radiation spectrum with some characteristic radiation lines superimposed. $\lambda_{\min}$ indicates the short wavelength limit of the spectrum (8).

The broad continuous range of wavelengths for bremsstrahlung radiation is caused by the nonuniform rate at which kinetic energy is lost when each free electron strikes the anode target. The minimum wavelength emitted (i.e., maximum frequency) is given by equating the maximum energy of an electron with charge e accelerating in a potential voltage V to the energy of light at frequency ν , namely,

$$eV = h\nu_{\max}$$

With $\nu\lambda=c$,

$$\lambda_{\min}(\text{angstroms}) = \frac{12400}{V(\text{volts})}$$

A typical spectral distribution emitted from an X-ray tube is shown in Fig. 7 showing strong discrete lines from characteristic radiation against the broad spectrum of bremsstrahlung radiation. For potentials between the cathode and anode exceeding 2000 V, the maximum intensity over the continuous spectrum occurs at $1.5\lambda_{\min}$ and the falloff at longer wavelengths is as $1/\lambda^2$. The most useful range in many radiological applications is 0.1 to 0.5 angstroms. For characteristic radiation with a short wavelength the material composing the target anode must have a high atomic number. Tungsten with an atomic number of 74 and a high melting point of 3655 K is generally used for the target anode. If the incident-free electrons were decelerated along their direction of incidence, classical electromagnetic theory predicts that the intensity maximum of bremsstrahlung radiation occurs at 90° . However, intensity maxima have been observed for different electron energies in the range from 50° to 65° , more consistent with that predicted by quantum mechanics. Good background reading is (10).

pH MEASUREMENT AND CONTROL

The acidity or alkalinity of solutions is indicated by a pH value which it is important to control in many chemical and biotechnical processes, especially in water and wastewater treatment. The significance of pH in industrial processes lies in the fact that many phenomena, such as flotation, precipitation, and coagulation, occur in a certain pH range. The inhibition of corrosion is another application of pH control. In industrial applications of biotechnology, such as fermentation, the pH is an essential factor in the growth process.

The neutrality of pure water is an important factor in human life. Municipal water is kept slightly alkaline (about pH 8) to avoid corrosion. The quality of wastewater has a significant influence on environmental water ecology. Changes in the acidity of water influences, for instance, the solubility of compounds and the growth of flora and fauna. The acceptable pH range of wastewater is usually pH 6 to pH 9. An important pH control application is the preparation of wastewater flowing through a sewer system to chemical or biological purification plants. Chemical purification occurs best at a pH of 5.5 in aluminum sulphate precipitation and at a value of 9 in ferrosulfate precipitation. Fast pH changes are unacceptable in wastes flowing in an active sludge purification plant because of the bacteria death risk. For these reasons reliable measurement and good control of pH are very important aspects of a wide range of systems.

GENERAL PROPERTIES OF LIQUIDS

Liquid phase systems consist of a solvent and dissolved components. The most common solvent is water, the properties of which are well known. Most chemical constants related to pH are connected with systems where water is the solvent.

When solid compounds are introduced into water, there is an upper limit of how much substance can be dissolved, called the solubility. When the solvent contains the maximum amount of dissolved component or more (the solid phase contains the excess component), the solution is saturated.

The concentration [.] of a solution is defined as the amount of dissolved substance per the amount of solvent. Concentration

is usually given in moles per liter (sometimes moles per cubic foot, grams per liter, mass or volumetric percentages, etc.).

Compounds that form ionic bonds dissolve into ions in water. A typical example is the dissolution of table salt, sodium chloride:

Many physical and chemical phenomena are related to the activity $\{i\}$ of a given ion. In dilute solutions activity coincides with concentration, but in more concentrated solutions there can be significant differences. In the literature the activity is sometimes called the efficient concentration. The relationship between concentration and activity of a substance i is often assumed to be the following:

$$\{i\} = f_i \cdot [i] \quad (2)$$

The activity coefficient f is assumed to be 1.0 in very dilute solutions. For somewhat more concentrated solutions the activity coefficient can be estimated with the help of ionic strength. For very concentrated solutions calculating f becomes rather complicated.

There are many excellent books in the field of ionic equilibrium and pH systems. The notations used in this article are close to those of Butler (1) and Bates (2). These books are also recommended for a more detailed treatment of the subject.

Chemical Reactions

Most chemical reactions are reversible. There are always two reactions taking place simultaneously, an advancing reaction and a reverse reaction. Consider the general reaction

A reversible reaction consists of an advancing reaction $aA + bB \rightarrow cC + dD$ and a reverse reaction $cC + dD \rightarrow aA + bB$.

A reaction that takes place in a single step is called a unit reaction. For unit reactions the rate of reaction depends on the activities of the participating components. For an advancing reaction the rate of reaction is given by the following:

$$r_1 = k_1 \cdot \{A\}^a \cdot \{B\}^b \quad (4)$$

Correspondingly for the reverse reaction

$$r_{-1} = k_{-1} \cdot \{C\}^c \cdot \{D\}^d \quad (5)$$

The reaction rate constants k_1 and k_{-1} are strongly dependent on temperature. In some cases the relationship can be described by the well-known Arrhenius equation.

At equilibrium the reaction rates of the advancing and the reverse reactions are the same ($r_1 = r_{-1}$), and the overall reaction does not go in either direction:

$$k_1 \cdot \{A\}^a \cdot \{B\}^b = k_{-1} \cdot \{C\}^c \cdot \{D\}^d \quad (6)$$

The ratio of the reaction rate constants is called the equilibrium constant K .

$$\frac{k_1}{k_{-1}} = \frac{\{C\}^c \cdot \{D\}^d}{\{A\}^a \cdot \{B\}^b} = K \quad (7)$$

A large value of the equilibrium constant indicates that the overall reaction (3) tends to go to the right toward the reaction products, and a small value that the overall reaction tends to go to the left toward the source materials. Similarly to reaction rate constants, the equilibrium constant also depends on temperature.

Acids and Bases

Acids contain hydrogen that is released under certain conditions. Acids are monoprotic or polyprotic (diprotic, triprotic, etc.) depending on the number of hydrogen ions H^+ that they can donate. The hydrogen ion H^+ forms different compounds with the water molecule, but usually in acid-base systems all of the hydrogen ion combinations (e.g., H_3O^+ , H_9O_4^+) are symbolized by a simple hydrogen ion H^+ or an oxonium ion H_3O^+ :

Acids are generally symbolized with letter A and bases with letter B. Polyprotic acids donate hydrogen ions in several stages, and therefore the latter reaction (9) can be separated into three unit reactions:

Bases accept hydrogen ions and similarly to acids they are also called monoprotic or polyprotic:

The hydrogen ion is actually a proton and therefore in the literature acids are defined as proton donors and bases as proton acceptors. Every acid HA has a corresponding base A^- , and together they form an acid-base pair. A substance that either accepts or donates a proton is called an ampholyte. The most important ampholyte is water (as can be seen from all of the previous examples).

Acid-Base Constants. Equilibrium constants can also be written for acids and bases. For monoprotic acids that react as in Eq. (8), the equilibrium constant is defined as follows:

$$K = \frac{\{\text{A}^-\} \cdot \{\text{H}_3\text{O}^+\}}{\{\text{HA}\} \cdot \{\text{H}_2\text{O}\}} \quad (12)$$

The reaction takes place in an aqueous solution and the activity (and the concentration) of water can be considered a constant

and is combined with the equilibrium constant:

$$K_a = K \cdot \{H_2O\} = \frac{\{A^-\} \cdot \{H_3O^+\}}{\{HA\}} \quad (13)$$

The modified equilibrium constant is called the acid constant. For bases a corresponding base constant is developed. For reaction in Eq. (11) the base constant is given by the relationship

$$K_b = \frac{\{HB^+\} \cdot \{OH^-\}}{\{B\}} \quad (14)$$

Polyprotic acids and bases have equilibrium constants for each dissociation step. The acid constants of a triprotic acid that reacts by the reaction mechanism Eq. (10) are as follows:

$$K_{a1} = \frac{\{H_2A^-\} \cdot \{H_3O^+\}}{\{H_3A\}}, K_{a2} = \frac{\{HA^{2-}\} \cdot \{H_3O^+\}}{\{H_2A^-\}}, \quad (15)$$

$$K_{a3} = \frac{\{A^{3-}\} \cdot \{H_3O^+\}}{\{HA^{2-}\}}$$

Acid and base constants describe the strengths of acids and bases. A large acid constant indicates a strong acid that donates practically all of its protons. Weak acids have a small acid constant, and only some of the protons that could be released are actually donated.

The equilibria of weak acids and bases can be moved to either side of the reaction by adding or removing reaction products or source materials. A typical method of removing reaction products is neutralizing a solution by adding bases to acids and vice versa. Neutralization is treated in more detail in the next section.

Neutralization. The oxonium ion H_3O^+ (hydrogen ion H^+) and the hydroxide ion OH^- neutralize each other and produce water:

Consider an example where sodium hydroxide and hydrochloric acid are mixed together:

The overall reaction is as follows:

Mixing equal amounts of sodium hydroxide and hydrochloric acid yields table salt and water.

Ionic Product of Water. The neutralization reaction in Eq. (16) is also reversible. The reverse reaction is called autoprotolysis of water:

The equilibrium constant is modified similarly to the acid and base constants:

$$K_w = K \cdot \{H_2O\}^2 = \{H_3O^+\} \cdot \{OH^-\} \quad (19)$$

The modified equilibrium constant is called the ionic product of water [at 25°C $K_w = 1.0 \cdot 10^{-14}$ (mol/L)²].

The Definition of pH. In acidic solutions there are more oxonium ions than hydroxide ions, and vice versa in alkaline solutions. If the system is neutral, there are equal amounts of both ions. The previous section stated that the product of oxonium and hydroxide ion activities (efficient concentrations) is constant.

$$\begin{array}{ll} \{H_3O^+\} > \{OH^-\} & \text{acidic} \\ \{H_3O^+\} = \{OH^-\} = \sqrt{K_w} = 1.0 \cdot 10^{-7}, \text{ (at 25 deg C)} & \text{neutral} \\ \{H_3O^+\} < \{OH^-\} & \text{alkaline} \end{array}$$

For practical reasons the logarithmic scale is more appealing (ten-base logarithm $\log_{10}$ is marked with lg). pH is defined as

$$pH = -\log_{10}\{H_3O^+\} = -\lg\{H_3O^+\} \quad (20)$$

At 25°C the neutrality of a solution is given as follows:

$$\begin{array}{ll} pH < 7 & \text{acidic} \\ pH = -\lg 10^{-7} = 7 & \text{neutral} \\ pH > 7 & \text{alkaline} \end{array}$$

The pH usually varies between 1 and 14, but higher or lower values are also possible.

Weak acids and bases have equal amounts of dissociated and undissociated forms when the oxonium ion activity is equal to the acid or base constant, as can be seen from Eqs. (13)–(15). There are important practical phenomena when this happens (such as maximum buffering, explained in the next section) and therefore the pH which enables that is significant. Often the equilibrium constants K_a and K_b are given in pK_a and pK_b values whose definitions are identical to Eq. (20):

$$pK_a = -\lg K_a, pK_b = -\lg K_b \quad (21)$$

pK_a and pK_b values indicate directly important pH ranges that have practical significance.

Buffer Solutions. In many practical situations the pH should be close to an optimal value. This is typically the case for biochemical processes. The solution should be insensitive to small additions of acids or bases and, if this applies, the solution is called a buffered solution. Many natural systems contain buffers (e.g., blood) but buffers can also be produced artificially from weak acids and bases and their salts.

A typical buffer solution is produced from acetic acid (HAc) and sodium acetate (NaAc). The resulting solution contains both acetic acid and acetic ion (Ac^-). The reaction is as follows:

Figure 1. The buffer index of acetic acid solution.

If acid is added, the free hydrogen ion (oxonium ion) reacts with excess acetic ion to form undissociated acetic acid (reverse reaction). The pH is not significantly affected until the buffer solution runs out of acetic ions. Correspondingly, if base is added, the free hydroxide ions react with hydrogen ions to form water. The acetic acid ionizes more (advancing reaction) to satisfy the equilibrium condition. The pH changes only a little until the buffer solution runs out of undissociated acetic acid. The buffer solution can be considered a reservoir of ions that are released when needed in the reaction.

The efficiency of a buffer solution is described by the buffer index β defined as follows:

$$\beta = \frac{d[B]}{dpH} = -\frac{d[A]}{dpH} \quad (23)$$

The differential change in the concentration of a strong base B versus the differential change in the pH (or negative differential change in the concentration of a strong acid A vs. the differential change in the pH) corresponds to the reverse of the titration curve's slope. In Fig. 1, the buffering index of the acetic buffer solution described earlier is presented as a function of pH. The maximum buffering is reached at $pH = pK_a = 4.75$. The curve (buffer solution) is compared to the corresponding curve of a solution (no buffering) that contains only water and strong acids and bases.

Gibbs Free Energy

Deep understanding of the chemical equilibrium can be achieved only by thermodynamics, but that is beyond the scope of this article. The elementary principles rely on the Gibbs free energy defined by the relationship

$$G = H - TS \quad (24)$$

where H is the enthalpy, T is the absolute temperature, and S is the entropy. Any free system is autonomously moving toward small values of G , and it does not stop until it has reached the minimum Gibbs free energy, that is equilibrium.

The practical significance of this fundamental truth is the fact that many parameters and constants related to Gibbs free energy are tabulated or easily calculated enabling the calculation of equilibrium constants in changing situations, such as varying temperatures.

The free energy of any substance X is calculated as follows:

$$G_x = G_x^0 + RT \ln\{X\} \quad (25)$$

where G_x^0 is the standard free energy and R is the gas constant. For Eq. (3) $aA + bB \rightleftharpoons cC + dD$ the change in Gibbs free energy is given by

$$\Delta G = cG_C + dG_D - aG_A - bG_B = G^0 + RT \ln \frac{\{C\}^c \{D\}^d}{\{A\}^a \{B\}^b} \quad (26)$$

ΔG is called the reaction work (work done by the chemical reaction).

Chemical Energy and Electrical Energy

Chemical energy is transformed into electrical energy in a galvanic element consisting of two electrodes in contact with liquid. If a metallic element is introduced into an ionized salt solution containing the same metal ion, there is an equilibrium. The electrons and metal ions remain in different phases close to each other creating an electrical potential.

The potential of the galvanic element is a direct measure of the cell work and correspondingly also of the change in the free energy. The free energy change is calculated as follows:

$$\Delta G = -nFE \quad (27)$$

where n is the number of electrons transferred in the cell reaction, F is the Faraday constant, and E is the cell potential. By combining Eqs. (26) and (27), Nernst's equation results:

$$E = E^0 - \frac{RT}{nF} \ln \frac{\{C\}^c \{D\}^d}{\{A\}^a \{B\}^b} \quad (28)$$

where the standard potential E^0 of the cell is defined as follows:

$$E^0 = -\frac{G^0}{nF} \quad (29)$$

The standard potential of any electrode is determined by combining it with a reference electrode in a galvanic cell. The standard hydrogen electrode (shown in Fig. 2) is arbitrarily chosen as a general reference electrode with a zero potential. The standard hydrogen electrode consists of a platinum plate that is constantly saturated with hydrogen by a continuous hydrogen gas stream.

The standard potentials of electrodes measured against a standard hydrogen electrode are found in numerous tables.

Figure 2. Standard hydrogen electrode.

PERMEABLE GLASS ELECTRODE

Permeable Glass Membrane

The most common pH measuring electrode is the glass electrode. Around 1906 Cremer found that some types of glass gave a potential difference whose magnitude depends on the acidity of the liquid in which the glass is immersed (3). Later Haber and Klemensiewicz proved that this potential difference, within a fixed pH range, follows Nernst's potential in the same way as the hydrogen electrode (4).

Corning Glass Works Inc. developed a well known glass material called Corning 015 consisting of 72.2 mol% SiO₂, 6.4 mol% CaO and 21.4 mol% Na₂O. This glass can be used for pH measurement in the range from 0 to 9. After that glasses containing Li₂O, Cs₂O, BaO, and La₂O₃ were developed. With these glasses more alkaline pH values could be measured.

Glass can be considered an "undercooled" electrolyte consisting of an irregular SiO₂ structure containing other components which move in the interspaces. These components give the membrane an electron balance; see Fig. 3. When immersed in aqueous solution, glasses exchange the metal ions in the glass with the H⁺ ions in the solution. As a result of this reaction a "gel layer" is developed on the surface of the glass membrane. This gel layer is the equivalent of the metal ion layer in Nernst's theory and therefore is essential for the operation of the glass electrode. After one or two days the electrode reaches an equilibrium, and the resulting gel layer has a thickness between 10 nm and 100 nm. This mechanism depends on several factors, such as the composition of the glass and the temperature at which the glass is immersed. Many theories have been developed on the subject of gel layer formation (2).

The electrical potential with the glass electrode is generated by a method somewhat different from that with metal electrodes. In glass electrodes only the ions change location not the electrons.

Figure 3. The texture of pH glass.

Construction of the Glass Electrode

The construction scheme of the glass electrode is shown in Fig. 4. The electrode consists of a glass tube, into which a bulb-shaped membrane of a specific pH glass is welded. The electrode is filled with a buffer solution containing Cl⁻ ions. Usually the pH of this electrolyte is 7. An inner electrode, constructed of a metal pin covered by its sparingly soluble salt, is connected to the output cable of the electrode. The inner electrode is immersed in the electrolyte containing anions of the salt.

A typical inner electrode is the silver-silver chloride electrode, in which AgCl salt covers the Ag pin. When the electrolyte contains Cl⁻ ions, the following electrode reaction occurs:

A potential difference between the inner electrode pin and the electrolyte is formed as a redox reaction Eq. (30); see Fig. 4. The potential difference is calculated from Nernst's equation.

Another common inner electrode is the calomel electrode in which the output cable has a galvanic connection with mercury, which is in contact with mercury chloride (Hg₂Cl₂). This compound is known as calomel. The electrode reaction is as follows:

The potential difference between the inner electrode and the electrolyte is calculated from Nernst's equation. A thallium amalgam-thallium inner electrode is used especially when the temperature of the process liquid to be measured is high. In the electrode thallium amalgam is in contact with thallium chloride.

As mentioned earlier the pH-sensitive membrane is produced from special glass. Its thickness is usually 50 μm to 200 μm, but in measuring very aggressive solutions it can even be 1 mm. After immersion in water, the glass electrode can measure the process solution. A potential difference between the process liquid and the glass surface is created, and this difference is a function of the activity of H₃O⁺ ions and thus also a function of the pH. Figure 5 shows the structure of a typical glass electrode with a calomel inner electrode.

As shown in Fig. 4, the following three potential differences (electromotive forces) are created in the glass electrode:

Figure 4. The construction scheme of the glass electrode.

Figure 5. The construction of the glass electrode.

E_1 between the inner electrode and the electrolyte

E_2 between the inner surface of the glass electrode and the electrolyte

E_3 between the outer surface of the glass electrode and the liquid to be measured

As mentioned earlier E_1 is a constant potential difference. The potential difference E_3 is the significant indicator of the pH. Nernst's equation holds quite well:

$$E_3 = E_0 + (RT/F) \ln\{H_3O^+\}_{OUTER} \quad (32)$$

where E_0 is constant at a specific temperature and $\{H_3O^+\}_{OUTER}$ is the activity of the H_3O^+ ions in the process liquid. A pH-sensitive gel layer is also developed on the inner surface of the glass membrane. The potential difference E_2 also obeys Nernst's equation:

$$E_2 = E_0 + (RT/F) \ln\{H_3O^+\}_{INNER} \quad (33)$$

where $\{H_3O^+\}_{INNER}$ is the activity of the H_3O^+ ions in the electrolyte inside the electrode. Because the electrolyte is a buffer solution, the potential difference E_2 is constant. At constant temperature only E_3 is a variable, and it changes when the H_3O^+ content changes in the measured process liquid. By noting that $\ln\{H_3O^+\} = \ln 10 \lg\{H_3O^+\}$ and $pH = -\lg\{H_3O^+\}$, Eq. (32) can be rewritten as

$$E_3 = E_0 - (RT \ln 10 / F) pH_{OUTER} \quad (34)$$

and Eq. (33) as

$$E_2 = E_0 - (RT \ln 10 / F) pH_{INNER} \quad (35)$$

The total potential in the output cable of the electrode is given by

$$E_M = E_1 - E_2 + E_3 \quad (36)$$

Now Eq. (36) can be rewritten as

$$E_M = E_{M0} - (RT \ln 10 / F) pH_{OUTER} \quad (37)$$

where

$$E_{M0} = E_1 + (RT \ln 10 / F) pH_{INNER} \quad (38)$$

Equation (37) shows that the potential of the glass electrode is a function of the pH and the temperature. If the glass electrode potential obeys Eq. (37), it is said to be ideal.

Resistance of the Glass Membrane

The definition of pH requires the potential difference of the measuring and the reference electrodes. If it is measured with a semiconductor converter, a small electric current is created through the electrodes. The current penetrates the pH-sensitive membrane whose resistance is quite high (about 10 MΩ to 500 MΩ at room temperature) and varies as a function of temperature. For instance, the resistance of a membrane produced from Corning 015 glass is about 200 MΩ at room temperature and 1000 MΩ at 10°C.

The high resistance of the glass electrode causes practical problems in constructing measuring circuits. Different kinds of glasses are developed for different measurement conditions. The important considerations are the acidity and temperature ranges of the liquids to be measured. The resistance of the glass membrane, however, should be as small as possible in all cases.

The Asymmetry Potential

The reason for the asymmetry potential is the difference in the behavior of the outer and inner surfaces of the glass membrane. If the inside and outside liquids are identical and there are identical electrodes on both sides, a potential difference still exists between the electrodes. This is called the asymmetry potential. It is only a few millivolts, but it changes slowly during aging of the electrode. Following are the reasons for the asymmetry potential:

Different strains in the inner and outer surfaces of the electrode

During production thermal effects decrease the cation content in the outer surface of the membrane and that is why the penetration of water differs on different sides of the membrane

The outer surface is vulnerable to mechanical and chemical effects

Fouling of the membrane

Alkaline and Acidic Errors

The pH measurement error in strong alkaline liquids is called the alkaline error or sometimes the sodium error. In alkaline solutions above pH 9, other monovalent cations, such as Na^+ and Li^+ influence the electrode potential causing measured values too low. Alkaline error increases with high temperatures. Nowadays special electrodes with a small alkaline error are available. They are well suited for measurements in strong alkaline conditions.

In very concentrated acid solutions the output voltage does not completely obey Nernst's law. Tests show that the gel layer absorbs acid molecules and consequently that the hydrogen ion concentration (and activity) increases, resulting an increase in

pH. Acid error is significant only at very low pH values, and it is relatively small compared to the alkaline error. Acid error does not depend very much on temperature.

REFERENCE ELECTRODE

Purpose

pH measurement requires both a measuring electrode and a reference electrode, which gives the reference potential against which the potential of the measuring electrode is compared. The reference potential has to remain constant when the properties of the process liquid change. On the other hand, the reference electrode builds a galvanic contact from the process liquid to the pH converter.

Silver–Silver Chloride (Ag–AgCl) Electrode

This electrode is named after its inner electrode. The inner electrode has the same structure as the corresponding measuring electrode, that is silver coated with silver chloride, and it is immersed in a KCl solution. The structure of the electrode is shown in Fig. 6. Galvanic contact is created through a diaphragm in the glass mantle of the reference electrode. The diaphragm is produced from ceramics, Teflon, or different kinds of fibers. The KCl solution flows very slowly through the diaphragm, and that is why care must be taken to ensure that there is always enough KCl solution. The pressure inside the electrode has to overcome the pressure of the process liquid at all times. Otherwise the flow through the diaphragm changes direction, and the electrode becomes poisoned.

The concentration of the KCl solution decreases in the diaphragm, and a diffusion potential exists. This potential disturbs the measurement, and its value must be minimized. KCl solution has been chosen as the electrolyte for the particular reason that the sizes and thus the mobilities of K^+ and Cl^- ions are almost equal, and thus the diffusion potential is very small. The usual electrolytes are 1 molal, 3 to 3.5 molal or saturated KCl solutions.

Calomel Electrode

Another commonly used reference electrode is the calomel electrode, also named after its inner electrode. Figure 7 shows two different calomel electrode constructions. Again the inner

Figure 6. The structure of the Ag–AgCl reference electrode.

Figure 7. Constructions of the calomel reference electrode.

electrode is immersed in KCl solution. In the construction of Fig. 7(a) the body of the inner electrode consists of a closed glass tube with mercury at the bottom. A platinum pin connected to the output cable is immersed in mercury, which is further connected to a paste prepared from mercury, calomel, and KCl. The electric contact with the KCl solution is realized with a diaphragm on the side of the inner glass tube. Figure 7(b) shows another construction. An amalgamated platinum pin is in contact with Hg-calomel paste, and the electric connection is realized with a diaphragm. In both cases calomel and mercury make up the electrode. The potential difference is the same as in the calomel measuring electrode.

Thallium–Thallium Chloride (Tl–TlCl) Electrode

The Ag–AgCl electrode operates up to temperatures of 100 °C and the calomel electrode up to 80 °C. The Tl–TlCl-electrode can be used for higher temperatures. It measures pH up to 135 °C or even 150 °C. The construction of the electrode is analogous to the other reference electrodes. The potential difference is created according to the following reaction:

Special Constructions

A steady flow of KCl solution out of the electrode is essential. The amount of the flow can be decreased by adding a gel to the KCl solution (5–7). Another technique is to impregnate the KCl solution into a piece of wood (5). Both techniques decrease the possibility of electrode poisoning.

If the process liquid includes compounds which react with the KCl solution, an additional chamber can be constructed between the KCl chamber and the process liquid. It is connected by a diaphragm in both directions and filled with a special electrolyte (6). There is also another approach to avoid KCl-reactions, a nonpermeable reference electrode [SOLPHET™ (26)]. In drossy circumstances the diaphragm must be constructed large enough to assure good functioning. In very drossy circumstances the diaphragm can be replaced by a capillary flow tube (6,8) or a cotton wool layer, (6). Then the consumption of KCl solution is increased, but the fouling effect is avoided. One manufacturer produces a special electrode which controls

Figure 8. A combined electrode structure.

the pressure of the KCl solution chamber with a bellows connected to the pressure of the process liquid. The elasticity of the bellows maintains the KCl solution chamber at a slightly higher pressure than the process pressure thus avoiding fouling of the diaphragm. Pressures below atmosphere are also possible (6).

COMBINED ELECTRODE CONSTRUCTION

As an alternative to the normal configuration with separated glass and reference electrodes, a system may be used that combines both electrodes into one unit. With this construction the high-ohmic glass electrode is screened by the electrolyte of the reference electrode, and the metal screen can be omitted. The advantage of the combined electrode is the ease of maintenance and the ability to measure pH in very small quantities of liquid. The construction of the joints into the pressurized flow tubes is also simpler. A major disadvantage is that because of the construction of the electrode it is not possible to provide the selection of glass types for many applications. Figure 8 shows the construction of a combined electrode.

MEASUREMENT OF THE pH

The Measurement Circuit

The measurement circuit includes the measuring electrode, the reference electrode, and the signal converter (Fig. 9). The electrodes constitute the voltage source, and if the measurement signal is a standard signal, say 4 mA to 20 mA, the converter is a pH transmitter. The following potential differences exist:

E_3 between the outer surface of the glass electrode and the process liquid

Figure 9. The pH measurement circuit.

Figure 10. The electric circuit for pH measurement: U_T is the voltage at the pole of the signal converter; R_T is the input resistance of the signal converter; R_E is the isolation resistance between the connecting cables; R_R is the resistance of the reference electrode; R_N is the resistance of the process liquid; and R_L is the resistance of the membrane of the glass electrode.

E_2 between the inner surface of the glass electrode and the electrolyte

E_1 between the inner electrode of the glass electrode and the electrolyte

E_4 between the inner electrode of the reference electrode and the electrolyte

E_5 the diffusion potential of the reference electrode

An electric circuit shown in Fig. 10 is created in the measurement system. The source voltage of the system is the sum of all of the potential differences:

$$E_S = E_1 - E_2 + E_3 - E_4 - E_5 \quad (40)$$

Usually the inner electrodes and the Cl^- -ion activities in the electrolytes of both electrodes are identical, and thus $E_1 = E_4$. In usual constructions E_5 is so small that it can be neglected and thus

$$E_S = E_3 - E_2 \quad (41)$$

The membrane resistance R_L is 10 M Ω to 1000 M Ω , and the resistances R_R and R_N are much smaller and therefore are neglected. The isolation resistance R_E between the connecting cables must be very large. If the decrease of the isolation resistance caused by moisture can be avoided, its value can be assumed insignificant in the circuit. With these assumptions the voltage in the input cables obeys the following equation:

$$U_T = [R_T / (R_L + R_T)] E_S \quad (42)$$

Because the value of the voltage U_T should be as equal as possible to E_S , the input resistance R_T must be very large, about 1 T Ω to 10 T Ω .

Table 1. Values of the Coefficient k

t (°C)	k (mV/pH-unit)
0	54.20
25	59.16
50	64.12
75	69.08
100	74.04

The Effect of Temperature

By substituting Eqs. (34) and (35) in Eq. (41), the following form is obtained:

$$E_S = [(RT \ln 10)/F](\text{pH}_{\text{INNER}} - \text{pH}_{\text{OUTER}}) = k(\text{pH}_{\text{INNER}} - \text{pH}_{\text{OUTER}}) \quad (43)$$

The electrolyte of the measuring electrode is a buffer solution, and thus pH_{INNER} is a constant with a usual value of 7. The coefficient k in Eq. (43) is a function of the absolute temperature T . When the temperature is constant, Eq. (43) defines a straight line with a negative slope. The values of the coefficient k as a function of temperature are listed in Table 1. Figure 11 shows the source voltage as a function of temperature for $\text{pH}_{\text{INNER}} = 7$. The lines intersect at the so-called isopotential point. Ideally this should be $E_S = 0$, $\text{pH}_{\text{INNER}} = 7$ per Eq. (43). In a real situation with existing electrodes, the isopotential voltage differs from zero as shown in Fig. 11. The pH of the intersection point can also differ from 7. The following conditions affect the isopotential voltage:

- Small differences between the inner electrodes
- The asymmetry potential of the glass electrode
- The diffusion potential of the reference electrode
- Fouling of the glass membrane

The temperature dependence of the electrodes can be compensated for by using a Pt 100 or a thermistor immersed in the process liquid. The sensor reads the temperature, and based on this information the signal converter compensates. The temperature sensor can be a third electrode in the conventional assembly, or it can be integrated into the same body as the two other electrodes in a combined electrode.

A more serious problem is caused by the temperature dependence of the pH of the process liquid to be measured. That cannot be compensated for easily because the effect is a function of the liquid composition which is why it is usually omitted.

Figure 11. $E_S = f(\text{pH}_{\text{OUTER}})$ of the real electrodes at different temperatures.

Signal Converter

The special properties of the pH measurement circuit establish some requirements for the signal converter or the transmitter, for example high input impedance, temperature compensation, and elimination of electrode ageing. Cheaper transmitters are realized by the analogue technique and the more sophisticated by the microprocessor technique. In both cases high input impedance is easy to realize by semiconductor techniques. Besides the temperature dependence the isopotential voltage must be compensated for. Automatic temperature compensation is included in almost all applications, and only in laboratory devices is compensation realized with a potentiometer. The output signal of the transmitter is usually 0.4 mA to 20 mA in industrial applications. If personal computers are used in on-line control applications, a voltage output signal can also be used, for example 0.1 V to 5 V or 0.2 V to 10 V.

The microprocessor technique improves functioning of the transmitters in many ways:

- The measurement scale can be changed during continuous use
- Advanced diagnostics are available
- The hold function of the signal works during maintenance
- Better possibilities for temperature compensation
- Improved measurement accuracy
- Digital signal transfer is possible

Diagnostics can include the functions of both the transmitters and the electrodes. By measuring the resistance of the glass membrane, the resistance of the reference electrode, the change of the isopotential voltage, and some other properties, conclusions can be drawn as to whether the electrodes are broken, fouled, aged, or not immersed in the process liquid (6,8–10). When the conventional analog transmitting technique is used, the diagnostic measurements necessitate additional wiring. The new fieldbus technique using digital data transmission makes the transmission of the diagnostic data possible without additional wiring, and thus it will be of great advantage in the maintenance of measurements in the future. In special cases when the composition of the process liquid is accurately known, the change of the pH of the liquid as a function of the temperature can also be compensated for. This is the case, for example, in alkaline turbine water including one base and demineralized water (6). When the conductivity of the liquid is very low, about 1–15 $\mu\text{S/cm}$ (in 25 °C), the addition of neutral salt improves the possibility of accurate pH-measurement. If the conductivity is yet lower, less than 1 $\mu\text{S/cm}$ (in 25 °C), the conductivity measurement is a more reliable choice to measure the concentration of the protolyte present in the liquid than pH.

Special Developments

If the process liquid is very drossy or contains glass etching substances (e.g., hydrofluoric acid, HF), an antimony measuring electrode can be used. When the antimony electrode is immersed in the process liquid, a potential is created which obeys Nernst's law. The applicable pH range is only from 2 to 9, but antimony electrode measurement is much faster than that of a glass electrode. A typical time constant (response time from 0 to 63% of the change) in glass electrode measurement is about 5 s. The antimony electrode is easy to clean because of its metallic structure.

To avoid the nonideal features of the conventional measurement-reference electrode pair, a differential pH measurement method was developed (11). This method uses two identical glass electrodes. One of these electrodes measures the process liquid, and the other is immersed in a buffer solution connected to the process liquid via a salt bridge. A metallic reference electrode is also immersed in the process liquid. The resulting source voltage is the difference between these two measuring electrode source voltages and the same reference potential, and thus the actual reference potential is suppressed. Thus fouling of the reference electrode and the small leakage currents in the liquid caused by the inaccuracy of isolation between the reference electrode and the liquid ground are avoided.

Some manufacturers have developed sensors using the semiconductor technology since the year 1970. pH can be measured with an ion-selective field effect transistor, ISFET, which is developed following the construction principle of the conventional MOSFET-transistor. The metal gate electrode has in this construction been replaced by a special oxide layer, which is sensitive to the concentration of ions (in the case of pH-electrodes to hydrogen ions) at its surface. There are many different oxide layer materials for hydrogen ion sensing, for example, silicon dioxide, silicon nitride, aluminium oxide, and tantalum oxide. A conventional reference electrode can be used. This kind of combined pH-electrode can be stored dry for long periods. Because it does not include glass material, it is suited to measurements of food and drugs. The electrode dynamic is faster than that of the glass electrode, and the time constant is less than 3 seconds. The measurement can be done successfully from very small samples and from very dry materials, for example, meat and jelly. Other benefits are the high input impedance making the conventional operational amplifier capable to function as the transmitter and the possibility of cleaning the electrode with a toothbrush. The main disadvantage is the smaller selectivity to hydrogen ions (7,27,28).

Another manufacturer has developed a combined enamel electrode consisting of an enamel measuring electrode and an enamel Na-selective electrode, used as the reference electrode. With this electrode the pH of a dough or paper mass can be measured up to 14% consistency (12). There is also a nonpermeable combined electrode for masses with very low water content [SOLPHET™ (26)]. The combined electrode can be filled with gel in order to avoid fouling of the measuring sensor part in very drossy circumstances. On the other hand, this type of construction, which does not include an air bubble, makes it possible to install the electrode in an upside down position, if needed, (29).

A technique which may be important in the future is optical glass fiber measurement. The color of light shows the pH. The fiber optic sensor can measure the resulting mean value from a large region not only pointwise. This technique is not yet ready for reliable pH measurement, but it is used in a moisture alarm for concrete structures.

PRACTICAL pH MEASUREMENT

Calibration of pH Measurement

Calibration is done with standard buffer solutions. Two or three different buffer solutions are needed. A buffer having a pH near 7 is always used because at that value the theoretical

voltage is about zero. When the measurement range is acidic, a buffer solution with a pH near 4 is used. On the alkaline side, a buffer with a pH near 10 is needed. Alternatively all three buffers are used. The buffer and the process liquid sample must be at the same temperature. The sensors must be rinsed with ion-exchanged water between immersions in the different buffers. The zero potential point is set with buffer 7, and the slope of the line is tuned with the other buffers. Specific electrical calibrators are sometimes used, but they do not take into account the individual differences of the electrodes.

The ionic strength affects the movement of ions in the diaphragm and, thus, the reference potential and pH-value to be measured. For this reason the ionic strength of the buffer solutions should be on the same level as in the sample to be measured. The buffer solutions are usually commercially available in two ionic strengths. The effect of the ionic strength can also appear in the growth of the activity coefficients. Thus liquids having the same hydrogen ion concentration can have different pH-measurement results. The most common buffer solutions with different ionic strengths are presented in Ref. 2.

Practical Definition of pH

Practical definition of pH compares the measured value of the process sample with that of the buffer solution. When these voltages are denoted as E_S and E_{SB} , the definition is constructed by using Eq. (43):

$$pH_{\text{OUTER}} = pH_{\text{BUFFEROUTER}} - F(E_S - E_{SB})/(RT \ln 10) \quad (44)$$

Installation, Use, and Maintenance of Electrodes

In an industrial environment electrodes must be protected against breakage with robust mounting chambers. The most common types, the immersing chamber and the bypass flow chamber, are shown in Fig. 12. The combined electrode assembly shown in Fig. 13 is often used in the pulp and paper industry. In this case the pulp flowing in the pipes can have even 15% consistency. In this case measurement is possible in the thin liquid film formed on the tube wall. In abrasive circumstances an automated sample system must be used. The system automatically takes a sample, measures the pH, ejects the sample, washes the electrodes, and takes a new sample. A cheaper possibility for these kinds of measurement cases is a measurement

Figure 12. Immersion chamber (a) and by-pass flow chamber (b). 1 = Measuring electrode. 2 = Reference electrode. 3 = Temperature sensor.

Figure 13. A combined electrode assembly in a tube line.

and maintenance assembly, which is installed on the process vessel wall by welding. The combined glass electrode is in the connection with the process liquid only during the measurement period and the connection is automatically closed when the electrode is moved to the rinsing position by a pneumatic actuator, (30). In the mounting grounding the process liquid is important. In mountings made of steel no problems exist. Otherwise a special ground electrode is often used. The glass electrode is very sensitive to pressure and flow changes in the system and therefore the installation has to be considered with great care. An ideal position is far away from any disturbing equipment, for example, pumps, and there should be straight pipe line before and after the measuring point. If there are severe pressure shocks in the system they should be filtered by using, for example, levelling equipment. A good example of advanced sampling, added pipe delay, and pressure filtering is given in Ref. 31.

Cleaning is important in industrial measurement. It can be automated to function periodically but in more demanding situations manual maintenance is also needed. The following automated cleaning methods are used:

- Mechanical spherical brushing of the sensor head
- Water spraying periodically
- Chemical spraying periodically
- Ultrasonic washing
- Small ceramic particles in a cage around the sensor head

The electrodes can be washed manually with different chemicals depending on the cause of fouling. Sterilization can be done chemically or physically with hot steam if needed. The form of the sensor head is important in fouling. A flat sensor head is suitable for measuring the pH of thick samples in pipes. Other sensor head profiles are useful for other reasons. For example, it is possible to measure very small liquid samples with a spherical sensor head.

The reference electrode consumes KCl solution, and additional solution must be added periodically. Microprocessor-based transmitters with diagnostics help in planning sensor maintenance. When the glass electrode is not used in measurement, it is usually kept in a buffer with pH 4. If it is stored dry, it must be soaked in distilled or ion-exchanged water for at least 24 hours before use.

pH MODELING

pH value is a significant factor in many chemical and biological phenomena. At the same time it is considered a basic measurement in industry and it can be measured on-line whereas many other important measures are still performed off-line. There are many different approaches to pH modeling for better understanding of chemical systems. pH models are divided into static and dynamic models. Modeling methods can be theoretical or experimental.

Static Modeling

A static model is obtained when a system has reached equilibrium and does not change further with time. Acid-base unit reactions can be considered instantaneous, and therefore static modeling is a very natural approach. Static models include titration curves and distribution diagrams. Experimental static models are often basic tools for product quality control and process state indicators. Experimental methods have been used for both qualitative and quantitative analysis.

Titration Curves. Titration curves are traditional pH models. They describe the pH as a function of the difference in the acid-base content. Experimental titration curves usually present the pH as a function of added acid or base volume. Titration curve pH vs. added reagent volume V_A depend on the sample volume, whereas pH vs. added reagent concentration $[HA]-[B]$ does not. The only difference is in scaling. The shape of the titration curve is determined by the participating chemical components. A group of typical titration curves is shown in Fig. 14 where mixtures of acetic acid (HAc), ammonia (NH_3), and water are treated with strong acids and bases. The solutions containing HAc have a titration bump at the pK_a of acetic acid, the solutions containing NH_3 have a titration bump at the pK_b of ammonia, and pure water shows a typical strong acid, strong base titration curve. Polyprotic acids donate more than one hydrogen ion, and the titration curves have correspondingly more than one step as in Fig. 15 which shows the titration curve for phosphoric acid (H_3PO_4).

Theoretical titration curves can be calculated from equilibrium constants and the total concentrations of acids and bases. An experimental curve, on the other hand, requires only a sample. Theoretical titration curves can be generated from the electroneutrality equation (also known as the charge balance equation). The electroneutrality equation takes into account all of

Figure 14. Typical monoprotic titration curves.

Figure 15. A polyprotic (H_3PO_4) titration curve.

the charged ions of the solution. The solution has no overall charge, and therefore the sum of all individual charges must be zero:

$$\sum_n \pm z_n \cdot [x z_n^\pm] = 0 \quad (45)$$

$z_n^\pm$ is the charge of an individual ion. Ions are usually divided into the components of water (oxonium and hydroxide ions), the components of strong acids (H_2A) and bases (B), and the components of weak acids (H_2a) and bases (b):

$$[\text{H}_3\text{O}^+] - [\text{OH}^-] + \sum_n z_n [\text{H}_{z_n} \text{B} z_n^+] - \sum_n z_n [\text{A} z_n^-] + \sum_n z_n [\text{H}_{z_n} \text{b} z_n^+] - \sum_n z_n [\text{a} z_n^-] = 0 \quad (46)$$

The titration curve shows the relationship between pH (a function of oxonium ion activity) and acid/base concentration. Strong acids and bases dissociate completely, so their ion concentrations are also total concentrations. Weak components dissociate only partially, so their ion concentrations have to be calculated from equilibrium constants. Each weak acid or base ion concentration can be replaced in Eq. (46) by a function of oxonium, hydroxide, and total ion concentrations calculated from equilibrium equations, such as Eqs. (13)–(15). Then the hydroxide ion concentration is replaced by a function of the oxonium ion concentration and the ionic product of water in accordance with Eq. (19).

After all this manipulation Eq. (46) contains only total acid and base concentrations and oxonium ion concentration (from which the pH is calculated by Eq. (20)). A more detailed modeling procedure is given in Ylén and Jutila (13).

Distribution Diagrams. Distribution diagrams give more information than titration curves. They are generated for specific compounds, and they describe the distribution of different forms of a compound as a function of pH. Figure 16 shows the distribution diagram of pure phosphoric acid (H_3PO_4) solution, and Fig. 17 shows the same diagram on a logarithmic scale.

Distribution diagrams are generated from the total balance of a compound. Consider phosphoric acid

$$[\text{P}]_{\text{TOT}} = [\text{H}_3\text{PO}_4] + [\text{H}_2\text{PO}_4^-] + [\text{HPO}_4^{2-}] + [\text{PO}_4^{3-}] \quad (47)$$

Each concentration in Eq. (47) is replaced by a function of equilibrium constants, oxonium ion concentrations, and total phos-

Figure 16. The distribution diagram of H_3PO_4 .

phoric concentrations. The distribution for component X is defined as follows:

$$\alpha_i = \frac{[\text{X}_i]}{[\text{X}]_{\text{TOT}}} \quad (48)$$

Distribution diagrams are useful for evaluating optimal pH ranges for specific reactions, such as separation processes. In separation processes a distribution diagram is often made for different phases of the compound. Figure 18 shows the distribution of calcium in solid and liquid phases of a calcium carbonate solution. A similar distribution diagram could be constructed for carbonate in the same solution. That would be a three-phase diagram (carbon dioxide in the gas phase, calcium carbonate in the solid phase and all carbonates in the liquid phase, consisting of dissolved carbon dioxide, carbonic acid, hydrocarbonate ions, calcium bicarbonate ions, and carbonate ions).

Distribution diagrams for reactions with different compounds do not usually reach a maximum value of one for each fraction. In Fig. 18 the maximum value of the CaCO_3 fraction is determined by the ratio of the total calcium concentration and the total carbonate concentration. There is more calcium than carbonate and thus the carbonate runs out and some of the calcium is left in the liquid phase.

Dynamic Modeling

Dynamic modeling is fundamentally more difficult than static modeling. Static modeling concentrates only on the equilibrium state where the system does not change with time. In dynamic

Figure 17. The logarithmic distribution diagram of H_3PO_4 .

Figure 18. The solid–aqueous distribution diagram of CaCO_3 .

modeling the behavior of the pH and related phenomena are considered as functions of time.

Dynamic pH systems can be divided into two categories, systems where chemical phenomena are significantly faster than flow and mixing phenomena and systems where this is not the case. These categories are treated in more detail in the following sections.

Separate Dynamics for Chemical Reactions and Flow Phenomena. In this simple case the reaction kinetics are much faster than the flow dynamics and can be treated separately. At every instant the chemical reaction takes place instantaneously, and therefore it can be treated as a static nonlinearity. The static models presented in earlier chapters can easily be embedded into flow dynamics. The simplest models are obtained when the weak acid and base component concentrations are constant throughout the system and only the strong acid or base concentrations change. If this applies, the shape of the titration curve does not change. Only the position on the curve changes. In this case the acid–base concentration difference is driven by flow dynamics, and the output is filtered by the titration curve that is presented as pH versus acid–base concentration difference.

The dynamic model is somewhat more complicated if weak components also change. In this case the titration curve of the system can also change arbitrarily and no fixed nonlinearity can be used. The pH value has to be iterated at each step. Two widely used methods are iteration of the aqueous solution's electroneutrality equation or minimization of the Gibbs energy function. Both methods require that each participating chemical component is driven by flow dynamics before the iteration is performed to find the pH.

Interconnected Chemical and Flow Dynamics. Models become even more difficult when chemical kinetics and flow dynamics have approximately the same timescale. In these cases the two phenomena cannot be separated, and the models have to be treated simultaneously. Systems requiring this kind of model are typically multiphase processes or they have slow side reactions that bring the overall chemical reaction rate up to the same level as the flow dynamics. Very often there are slow phenomena in practical systems that slow the otherwise instantaneous chemical kinetics down. The equilibrium assumption has to be modified so that the slow reacting components and their slow kinetics are eliminated from the equilibrium

equations and taken into consideration in the dynamic model. This methodology is described in more detail in Ref. 32.

pH CONTROL APPLICATIONS

Difficulties With pH Control

Difficulties can arise in pH control from the quality of the process liquid or the reagent, the dimensioning of the reactor, pH electrode problems, or because the process liquid has rapid and wide variations in quality and quantity.

Calcium hydroxide [$\text{Ca}(\text{OH})_2$] is a cheap chemical, so it is widely used in neutralization as a base reagent. Because its solubility is quite low, 1.16 g/L at 25 °C, sufficiently large continuous flow reactors are needed to complete the neutralization reactions before the flow reaches the output point of the reactor. The dominating time constant in a stirred tank reactor must be at least 15 min. Calcium hydroxide is supplied to the reactor as a lime slurry, for example 10% by weight. The preparation of the lime slurry calls for large equipment investment. When very large amounts of base are needed, solid lime, quicklime CaO , or even limestone (CaCO_3) can be used as the reagent. In these cases the accuracy of the supplying devices limits the quality of pH control (14). If process liquids including sulfuric acid (H_2SO_4) are neutralized with lime, precipitation of calcium sulfate may cause problems. Sodium hydroxide (NaOH) is an easy-to-handle base, but it is four times as expensive as lime. Sulfuric acid is widely used as an acid reagent. Its use is inhibited by the maximum allowed concentration of sulfates (in wastewater, about 300 to 400 mg/L). The cheapest source of acid reagent, carbon dioxide (CO_2), is flue gas. Its use in the neutralizing alkaline wastes is limited by the high cost of the equipment needed.

When the process liquid is either acidic or alkaline, both acid and base reagents are needed for neutralization. This requires additional investment in supply devices. When acidic and alkaline waste amounts alternate, it is often beneficial to construct an assembly vessel before the neutralization reactor for maximal self-neutralization and to avoid using two reagents; see Fig. 19.

In many basic scientific papers, the large sensitivity of the pH-process is said to be the main problem in the pH-control (15). This is based on the simplest model of the pH-process—the strong acid–strong base model in dilute water solutions. In this theoretical case no buffering components exist, and the very high demand of the rangeability of the reagent supply devices is connected to the enormous sensitivity. When reactors with good mixing include a dead time of 5% to 10% of the dominant

Figure 19. A wastewater neutralization plant in a dairy.

Figure 20. A neutralization reactor with a holding tank and recycle.

time constant and the accuracy of the reagent supply devices is limited while the pH-sensor has a small time constant, the whole task seems impossible. However, the situation is never quite so difficult.

For instance, the alkalisation of turbine water consists of adding strong base to demineralized water. There is always soluted carbon dioxide present, which decreases the demand of reagent addition accuracy considerably. In this case, the pH step is 3 units from ca. 5 to 8. Because of the buffering, the dosage accuracy demand is much less than three decades. In almost every practical control task many additional buffering salts are present, and many decades of the accuracy demand are left away.

In practical sensitive pH-processes, the S-shape of the titration curve is still quite strong, and the sensitivity is high near the neutral point. However, in most cases the high frequency oscillation around the setpoint (usually the neutral point) in the pH-control is less dangerous than long period offsets far from the setpoint. For this reason the authors have the opinion that the main difficulty from the algorithmic point of view is the nonlinear dependence of the pH-value on the reagent amount. In practice, two parallel reagent supply devices are enough to meet the largest demands of the rangeability in the control of the most sensitive pH-processes.

pH Control in Stirred Tank Reactors

Different Algorithm Types. The difficulty of controlling neutralization processes in continuous-flow, stirred, tank reactors

arises from two basic features: the nonlinearity of the process and the changes in this nonlinearity based on the buffering effects caused by varying species. Poor pH control can be improved by adding mixing capacity in series with the neutralization reactor, thus attenuating oscillations that exceed allowable limits. When the process flow is very large, this method is very expensive; see Fig. 20.

If the process sample titration curves are not steep and do not vary in shape (large but constant buffering), the usual PID-feedback can be used for pH control. Even on-off control or ratio control using the throughput flow may be adequate. If the titration curves are quite nonlinear but do not vary much in shape (small but constant buffering), a fixed nonlinear reshaping element in the feedback PID-control can be used. Feedforward control based on a fixed titration curve shape can also be combined with feedback control. When the titration curve shapes change significantly, adaptive controls strategies that take into consideration changes in the process gain on-line give the best results.

Constant Parameter Algorithms. Based on electroneutrality, it can be shown that when the concentrations of weak (buffering) components are constant and only concentrations of the strong component change, all of the titration curves (pH vs. strong reagent concentration) have the same shape. When the concentration of the strong reagent is very high compared to the other concentrations, the pH titration curves versus the reagent flow also have similar shapes. These kinds of titration curves can be used in the constructing the feedback or feedforward-feedback control. Construction of the feedforward control is presented in Fig. 21(a) and (b). The amount of acid reagent with different values of input pH, pH_1 , pH_2 , and pH_3 , can be read from the horizontal axis. The quantity pH_{ref} is the set point value of the pH. Now the reagent demand Q_C can be calculated as $Q_C/Q_P = f_1(pH_{ref}) - f_1(pH_{input})$. The process liquid flow Q_P can change and thus the feedforward control action Q_{CFF} obeys the following equation:

$$Q_{CFF} = [f_1(pH_{REF}) - f_1(pH_{INPUT})]Q_P \quad (49)$$

The function f_1 (the titration curve shape in Fig. 21(b)) is easy to realize with a microprocessor by defining a suitable

Figure 21. (a) Titration curves with similar shape. (b) Determination of the feedforward control from a titration curve.

Figure 22. Linearization of the feedback control loop with a constant titration curve shape.

number of points and using interpolation. In constructing the feedback, the same titration curve shape can be used (Fig. 22). If the process flow Q_P changes markedly the feedback PID-algorithm can be flow-adaptive:

$$Q_{CFB} = \frac{Q_P(k)}{Q_{PNM}} K_P \left[e(k) + \frac{T_D Q_{PNM}}{Q_P(k)} \cdot \frac{e(k) - e(k-1)}{\Delta T} \right] + \sum_{i=1}^k \frac{K_P Q_P^2(i)}{T_I Q_{PNM}^2} e(i) \Delta T \quad (50)$$

where K_P , T_I , and T_D are the tuning parameters of the PID-controller, Q_{PNM} is the operating point value of the process flow (the point at which the controller has been tuned), and $Q_P(k)$ is the instantaneous value of the process flow. If the feedforward and feedback algorithms are connected, the final control is given by $Q_C = Q_{CFF} + Q_{CFB}$. If the input pH value cannot be measured, the operating point value can be added to this position PID-algorithm. The final control law is given by $Q_C = Q_{CFB} + Q_P(k) Q_{CFBNM} / Q_{PNM}$, where Q_{CFBNM} is the operating point value of the feedback control Q_{CFB} .

The suitable size for the time constant of the mixing reactor with soluble reagents is about 0.5 min to 3 min. Only in cases of constantly highly buffered process liquids can the neutralization reactor consist of the chamber of an efficient pump or static mixer.

Adaptive Algorithms. When shape of the titration curve changes significantly, feedforward control is not very effective, and consequently adaptive algorithms are needed. Analysis of the past trajectory is the basis for the adaptive feedback control method developed by Welfonder et al. (16). The method is realized with a minicomputer, and it has been tested in an actual wastewater treatment plant. Foxboro Inc. has presented a commercially available adaptive unit controller Exact (17) that also examines the past trajectory (during a waiting period) whether it is oscillating or overdamped. If needed, a new PID-tuning (using a specific tuning algorithm) is used after each waiting period. A narrow deadband around the reference pH value avoids adaptation to noise. This controller has been widely used in pH control, but it is suited only to systems with continuous pH measurement. Subsequently, other instrument manufacturers have made their own versions of this type of controller.

Another adaptive method that does not include any modeling knowledge was developed by Kurz (18). In this method

the adaptation mechanism tries to manipulate the gain of the PID-controller so that the measured pH approaches the reference value along a reference trajectory. This method has been applied in industrial wastewater treatment plants.

The commercially available ASEA Novatune controller has also been applied to pH control. Its function is based on identifying a nonphysical time-series model, and it uses the self-tuning control principle (19). Another method which does not include an exact model is the self-organizing fuzzy controller. It has two fuzzy logic hierarchies. The higher hierarchy adapts the ordinary lower level fuzzy controller to meet changing process conditions. This control method has been applied to the control of an ammonia gas scrubber (13). The self-organizing Kohonen map has also been successfully applied to pH control (20). On the other hand, neural back-propagation algorithms do not apply as well to adaptive pH control.

Kaesser has developed an adaptive feedback control algorithm based on an approximate process model. In his method the slope of the titration curve is estimated and used in tuning the feedback PI-control loop (21). This method has also been applied in neutralizing industrial wastewater. Gustafsson and Waller (22) and Jutila and Visala (23) used more complex physicochemical models closer to practical processes. In these papers model knowledge was also included in designing adaptive control algorithms. The variables to be identified were concentrations of reaction invariants or hypothetical species, and with this knowledge it was possible to construct an instantaneous titration curve and to linearize the PID-control loop. These algorithms were tested by simulation and laboratory-scale pilot plants. Later on Henson and Seborg used the reaction invariant concept in model reference adaptive control algorithms (33).

Lee et al. constructed an algorithm including the physicochemical model of one weak acid. Both the dissociation constant and the concentration of this weak acid were identified and used in the linearizing the control. Only simulation tests were made with a process model differing slightly from the identification model (24). The model reference approach of the pH control made by Pajunen includes a Wiener model (25). Simulation and pilot plant control results are presented in that paper. Many simulation articles have been published, in which advanced control concepts are developed for simple, precisely known processes. Problems may occur in real-life application of such methods, because an accurate model is included in the control algorithm. Model predictive algorithms may turn out to be an interesting choice for pH control, but there are still few actual applications.

Tracking Control

The control of batch fermenters in producing enzymes is a good example of tracking control of pH. Both the growth of the biomass and the production of the enzyme can be controlled with the pH and temperature. It has been shown that keeping these factors constant lowers production compared to the case where these factors change based on optimizing certain growth and production models.

PULSE HEIGHT ANALYZERS

The pulse height analyzer (PHA) was originally developed to measure the amplitude of pulses from nuclear radiation detectors. It is therefore an important part of most systems that are used for analyzing event energies from alpha, beta, gamma, and X rays, for analyzing the time between events (from a time-to-pulse-height converter), and for ensuring orderly storage of count information in sequential time periods. PHAs are ideally suitable in system configurations for experimental and production applications in nuclear, chemical, medical, and materials analyses. PHAs are an outgrowth of the single-channel analyzer, which counted amplified electrical signals of a given pulse height created by nuclear events occurring within a detector. The amplitude was accepted by a peak voltage within a “window” or channel defined by two discriminators—referred to as a differential discriminator. Some of the first PHAs stacked 10 or 20 of these discriminators to form a multichannel PHA (1). (Reference 1 is one of the first articles addressing the need for PHAs that process fast pulses required in nuclear spectroscopy.) These early PHAs were commonly referred to as kick-sorters. By 1956 Schumann and McMahon (2) had developed a 256-channel PHA by using a Wilkinson analog-to-digital converter (ADC) and a random access magnetic core memory. This PHA was very successful and led to the first commercial design of this type (manufactured by RIDL—Radiation Instrumentation Development Lab).

PULSE PROCESSING WITH THE PHA

The input signals to the PHA must be optimally processed to achieve the best signal-to-noise ratio (3). Pulse-processing electronics convert the burst of charge, produced when a radiation particle or photon is absorbed by the detector, to a shaped pulse (usually Gaussian). The quantity of charge produced is related to the energy of the incident radiation. A charge-sensitive preamplifier/voltage amplifier combination serves to amplify and shape the charge into a pulse with an amplitude (peak voltage) proportional to this charge, hence to the energy lost in the detector. The pulses, which are random in both time and amplitude, are fed to an ADC. The pulses are digitized and recorded in an address register and their number stored in a memory. The ADC produces this number, informs the memory, and the memory selects the address and tallies one count. This process occurs each time an event is recorded. The pulse from the detector, created by each random event, is digitized with one count added to the channel corresponding to the digitized value. This is the basis of the PHA and pulse height analysis. This process really lends itself to a computer, therefore,

special-purpose computer systems that provide a variety of functions for the acquisition, storage, display, and interpretation of information from random events are referred to as multichannel analyzers (MCAs). The terms PHA and MCA are often used interchangeably; however, MCA is a broader term signifying a computer system that can be configured in a number of ways (including operation in the PHA mode). The term spectrometer refers to a detector, pulse conditioning electronics, and the MCA that is capable of rendering a spectrum describing the detected source and having the capability of performing analyses.

In the early 1960s, ADCs (e.g., the 4096 channel successive approximation ADC) (4) were used with Digital Equipment's (DEC) minicomputer, the PDP-1 (5) and later the more familiar PDP-8 (6). Pulse-height analyzer technology and computer technology merged in a major way during the 1970s. With the advent of DEC's minicomputer, the PDP-11, and later DEC's microcomputer, the LSI-11, data acquisition and analysis systems using MCAs were well on their way. The earliest MCAs came shortly after the development of the ADC but did not become sophisticated until the 1970s. The major components of the MCA are the CPU, memory, control program, acquisition interface, display controller, keyboard, display, and input/output (I/O) interface. Many early designs and references are given in the text by Robert Chase (7).

PRINCIPLES OF OPERATION

A block diagram of a typical firmware-controlled MCA system is shown in Fig. 1. In the PHA mode the ADC provides a channel address proportional to the input pulse amplitude and transfers the digitized peak voltage information to the channel address register. The count information in that channel is placed in the data register and updated by one count. The updated data are then placed in memory. The CRT display shows that a pulse has been processed by flashing the channel (horizontal) and

count (vertical) information in the appropriate location. The time required by the ADC to digitize the pulse height is called the conversion time and the time required to store the data in memory is called the memory cycle time. A typical gamma-ray energy spectrum is shown in Fig. 2.

The ADC

The ADC must be capable of processing the pulses rapidly without erroneous measurements in the pulse height. The Wilkinson method (8) has been the most popular over the years because of its excellent combination of linearity, temperature stability, and speed. Successive approximation ADCs are fast (typical conversion time of about $1 \mu\text{s}$), however, steps must be taken to improve the differential nonlinearity (see discussion below). The fastest conversion time is accomplished today with the Flash ADC (typically 200 ps for a 256-channel unit). This design is similar to a stack of single-channel analyzers but also requires steps to improve the linearity. One of the fastest PHAs reported in the early 1980s used a Flash ADC with a postexperiment, differential nonlinearity correction scheme (9). This method used a bin correction table and had the capability of histogramming the data at 15 MHz.

One of the most important specifications of an ADC (and likewise the PHA) is its linearity. There are two terms used in describing linearity or, more precisely stated, its nonlinearity: (1) integral and (2) differential.

Integral nonlinearity can be described as the maximum deviation of any address from its nominal position described by a straight-line plot of address versus input pulse amplitude, and is shown graphically in Fig. 3. The address with the maximum deviation is identified by N ; the pulse amplitude that is converted to the address N is identified as V_N ; and the nominal voltage corresponding to N is V_{nom} . The integral nonlinearity is then given by the expression

$$\% \text{ integral nonlinearity} = (V_{\text{nom}} - V_N / V_{\text{max}}) \times 100 \quad (1)$$

where V_{max} is the maximum value of the input voltage.

Since the slope of the straight line has a zero intercept of voltage and address this definition may be more conservative than definitions that define the slope and the intercept by the best fit to actual values. Integral nonlinearities should be less than 0.05% in an ADC so that the centroid position of spectral peaks will not be significantly displaced.

Differential nonlinearity describes the nonuniformity of address widths over the entire number of addresses in the ADC. Therefore, differential nonlinearity is the percent deviation of the maximum and minimum address widths (W_{max} and W_{min}) to the average width (W_{avg}) of all addresses, as shown in Eq. (2).

$$\% \text{ differential nonlinearity} = \frac{1}{2} \times (W_{\text{max}} - W_{\text{min}}) / W_{\text{avg}} \times 100 \quad (2)$$

The factor $\frac{1}{2}$ is used in Eq. (2) so that the differential nonlinearity may be expressed as a plus or minus deviation. For good performance differential nonlinearity should be less than $\pm 1\%$ over the top 99% of full scale.

Steps to improve linearity began in the 1950s with improvements by a randomizing method in the 1960s and 1970s

Figure 1. This simplified MCA block diagram illustrates the use of an analog-to-digital converter to digitize the analog signal from PHA to generate the spectrum channel number. The spectrum is displayed on the CRT or transferred to the computer.

Figure 2. Cobalt 60 (^{60}Co) spectrum, including background radiation, taken with a 50% relative efficiency COAX high purity germanium (HPGe) detector. The high energy resolution typical of HPGe detectors allows for accurate identification of individual energy peaks.

(10,11). Today there are linearization and integrated circuitry techniques that allow performance, economy, and small size. Further discussion on improvement of linearity is presented by Knoll (12).

A typical ADC operation (Wilkinson) is briefly described using the timing diagram of Fig. 4. An input pulse, with an amplitude exceeding the lower-level discriminator threshold, charges a capacitor with a constant-current source. The capacitor voltage is directly proportional to the pulse height as shown in Fig. 4. When the peak of the pulse is sensed the capacitor is discharged by a constant-current. The time required to discharge the capacitor to the baseline, called the rundown time, is proportional to the pulse height. When the discharge is begun a gate is opened to allow the address scaler to count clock pulses from an oscillator (typically 100 MHz clock). The number of clock pulses counted during the rundown time represents the desired address or channel. At the end of the rundown time the address in the scaler is strobed into the memory address

register. An input gate prevents the acceptance of additional input pulses from the start of rundown until the address transfer is complete.

The resolution of the ADC is typically equivalent to the conversion gain which is the number of channels over which the full input voltage will be spread. For example, a 12 bit ADC is normally subdivided into 4096 channels for an input voltage range of 0 V to 10 V. In this example the resolution and conversion gain is 4096. The ADC busy time or dead time is shown in the timing diagram as the total processing time of the input pulse. These pulses can provide a percent dead-time indication and therefore a live-time determination of the MCA. The dead time of the MCA has two components: (1) the processing time of the ADC and (2) the memory storage time. A clock in the MCA that records elapsed time of an analysis is gated off by the busy signal so that the analysis time will not include the time that is spent processing pulses. Accurate dead-time correction (providing accurate live-time) is very important for the analysis of some data. This subject is given further detail by Knoll (13).

Figure 3. Integral nonlinearity spectral distortion function. Note the significant difference between the idea and actual performance. Integral nonlinearity results in spectral distortion and energy calibration and spectral analysis problems.

The Computer-Controlled MCA

The strong growth of the personal computer has had a major impact on the MCA. Many of the functions of a traditional MCA can be performed as well as or better by a PC. These include spectral display, data analysis, and control functions. Some features of an MCA are unique, including the need for high-speed conversion and excellent linearity. By coupling the unique features of an MCA to a PC, the power of MCAs has dramatically increased as the power of PCs has increased.

The block diagram of a typical PC-based MCA is shown in Fig. 5. A microprocessor controls the ADC functions and communicates with the PC. The microprocessor is controlled by an internal program memory stored in firmware. The output of the ADC is stored in the data memory, which can be accessed both by the ADC and the PC. A modern data memory can store as many as $2^{32}-1$ counts per channel, or over two billion counts per channel. Commands and data are sent from and to the PC using a variety of protocols including serial port, parallel port, dedicated link and, most recently, via Ethernet. Mass storage

Figure 4. Typical ADC timing sequence. The charge capacitor follows the input pulse until the peak is sensed. The capacitor then discharges during a clocked period to determine the peak amplitude.

of the spectrum files is controlled from the PC using either its internal hard drive or floppy disks. One advantage of the PC-based MCA is that data can be collected and stored in the data memory while the PC is used to analyze a previously collected spectrum.

The hardware of a PC-based MCA takes many forms. One popular format is a plug-in card containing the ADC, microprocessor, data memory and control memory. Communication with the PC is via its internal bus. Other formats include NIM

modules, especially for very-high-performance systems. Stand-alone boxes are also available, which combine the MCA function with other parts of the spectroscopy chain including the spectroscopy amplifier and detector bias supply. Many modern PC-based MCAs are available with this general architecture. Other useful variations include the segmentation of the data memory. This allows spectra to be stored from multiple ADCs and is especially useful in alpha spectroscopy, where there are often many detectors requiring relatively low conversion gains (64 to 1024 channels each). Another variation is to precede the ADC with an analog FIFO (first-in first-out) memory to enhance the data conversion rate.

Preset controls are used during PHA operations to terminate an accumulation period automatically. This provides a convenient method of normalizing the data collection of individual accumulation periods. Additionally, one or more sections of the spectrum, each defined as a region of interest (ROI), can be analyzed for specific information. Some common presets include real time, live time, ROI peak count, ROI integral count, data overflow, and required statistical accuracy on a peak net area.

Figure 5. A typical PC-based MCA architecture requires an ADC of appropriate bit length (resolution dependent), a microprocessor, sufficient program memory to store the MCA program, and data memory to store the acquired spectrum.

Integrated Spectrometers

A recent trend has been the integration of all components of a spectrometer into a single package. In addition

to the ADC program, and data memory, these integrated spectrometers include a spectroscopy amplifier and detector bias supply. These integrated spectrometers can be general purpose and support a variety of detectors including germanium, silicon, and NaI(Tl). Alternately, they may be designed for a single detector such as NaI(Tl) to reduce cost and size. Some systems include a spectrum stabilizer and additional data memory to store multiple spectra. Spectrum stabilization is a useful feature when making long term, high-precision measurements with detectors that exhibit characteristic energy peak drift over time. Peak drift can be the result of various factors including temperature fluctuations and component aging. Stabilization is a process by which the system gain and a user-defined energy peak in the spectrum are continuously monitored for channel location. The system gain is adjusted if the energy peak varies from the user-defined channel location. Many implementations of spectrum stabilization include the permanent insertion of a weak, non-interfering radioactive source (typically ^{241}Am in the case of NaI) to provide a continuous, stable, and reliable calibration peak. All major functions of the spectrometer are set via the computer including the amplifier gain, shaping time, and pole-zero; bias supply control; and spectrum stabilizer parameters.

A special form of the integrated spectrometer is the portable spectrometer. These portable versions can be as powerful as their line-powered counterparts, except that they are battery powered. The world-wide need to control special nuclear material has been a strong driver in the development of portable systems. A high-end system will feature a 16 k channel ADC with $<10\ \mu\text{s}$ conversion time, an amplifier with multiple shaping times, bias supply to support both solid-state and scintillation detectors, data memory to store multiple spectra, multiple computer interfaces, and operate on internal batteries for over eight hours. The portable spectrometers are most often operated with the new portable PCs to form a fully portable spectrometer. Because of requirements for light weight, small size, and long battery life, some portable spectrometers are specialized and support a limited number of detectors and applications. Examples include systems developed for the International Atomic Energy Agency.

Future Trends

The future power of the MCA is linked to the future power of the PC. Indications are that PCs will continue to enhance their performance in speed, size, and computational capability, resulting in improved MCA performance. The uniquely nuclear portion of the MCA will also show improvement as integrated circuits continue to become more complex and dense, resulting in increased speed and reduced size. Portable spectrometers should benefit from advances in battery technology driven by other industries such as cellular phones.

Perhaps the most exciting prospect for the future of MCAs is the advent of digital signal processing, or DSP. In a DSP-based MCA, the signal from the detector is converted to a digital word early in the signal processing. Digital filters replace the traditional analog filters and are capable of optimum filter functions that are not realizable with analog circuits. DSP-based MCAs can better match the signal processing electronics to the charge-collection properties of the detector. System throughput and resolution are both enhanced as well as temperature

stability. The first DSP-based integrated spectrometers show this promise (14).

DSP technology offers additional promise. The shape of the signal from the detector contains information about the type and location of the interaction in the detector. As DSP-based systems improve, it may be possible to extract this shape information from the detector signal to improve the overall performance of the spectrometer.

SCINTILLATION COUNTERS

Scintillation counters employ a phenomenon known as luminescence: a particle passing through a medium excites or ionizes atoms along its path, and, upon deexciting, these atoms emit photons. Such a medium, whether solid, liquid, or gaseous,

which has the property of emitting luminous light, is called a scintillator.

HISTORY OF INSTRUMENTS

Sir William Crookes built the first scintillation counter in 1903, employing a microscope for visual observation of light flashes from a zinc sulfide screen. The physiological limit of this tiring procedure is a counting rate of about one per second (1). Nevertheless, this setup was used in 1909 by Geiger and Marsden (2) to study the scattering of α particles and resulted in Rutherford's discovery of the atomic nucleus (3). Visual scintillation counters were used up to the 1930s. In 1941 Krebs (4) invented the first electrical counter for scintillation events in the form of a Geiger-Müller tube sensitive to luminous photons. This device had a response time of about 10^{-4} s, which is typical for gas counters. The application of the scintillation method greatly increased in the 1950s after the development of the photomultiplier in 1944 by Curran and Baker (5), which enabled the automation of the tedious manual counting and at the same time allowed much higher counting rates. Another advantage over the previously used zinc sulfide screen came in 1947 and 1948 with the discovery of luminescent materials that are transparent to their own scintillation light, such as naphthalene by Kallmann (6), anthracene by Bell (7), and thallium-activated crystalline sodium iodide by Hofstadter (8). It was found that, due to their transparency, these materials can be used as scintillators in large volumes to detect even the only weakly interacting γ rays. Moreover, naphthalene and anthracene exhibit pulse decay times on the order of 10^{-8} s and hence, in conjunction with a photomultiplier, allowed the construction of detectors that were much faster than any gas-filled counter.

APPLICATIONS

Today, scintillation counters are widely used for the detection of α and β particles, γ rays, and neutrons in many fields, such as in high-energy physics research, environmental radiation protection, dosimetry, and medicine. They can be operated (1) as pulse counters to measure the activity of a radioactive source or the dose received by food items or biological tissue, (2) as spectrometers to determine the energy of the incident particles mentioned, and (3) as timing devices for the investigation of cosmic rays or for lifetime measurements on unstable particles.

Examples of applications are monitoring the exhalation of the radioactive noble gas radon from soils and rocks and examining beam profiles in accelerators. Scintillating materials are also used as screen coatings—for example, in television picture tubes.

When compared to other counter types, scintillation counters show the highest counting efficiency, because of their large volumes and their high absorption. Scintillation counters are also much faster than gas counters and semiconductor counters and can handle counting rates of up to 10^8 s $^{-1}$. However, semiconductor counters show better energy resolution (below 1%) than scintillation counters (on the order of 10%). The performance characteristics of scintillation counters are discussed in detail later on.

A detailed treatment of the applications of scintillators as well as the physical processes therein is contained in the standard work by Birks (1). The usage of scintillation counters in high-energy physics experiments such as coincidence measurements is described in Ref. 9. A comprehensive introduction into the detection of nuclear radiation with various detector types can be found in Refs. 10 and 11.

STRUCTURE OF A COUNTING SYSTEM

A modern scintillation counter (as shown in Fig. 1) consists of three main parts: a scintillator, a photomultiplier, and signal-processing electronics.

In the scintillator the energy of the incident particle is converted into light pulses. This scintillation light travels through the scintillator volume and eventually hits the photocathode of the photomultiplier, where it releases photoelectrons. In order to increase the number of photons incident on the photocathode, the scintillator can be covered with a reflecting layer.

In the photomultiplier, a system of electrodes, called *dynodes*, accelerates the electrons towards the anode by means of a high voltage. Upon impact on a dynode, each electron can release additional electrons, a process called *secondary emission*. Hence, the number of electrons in the pulse is multiplied between subsequent dynodes, leading to a large current at the anode. Since the photomultiplier can easily be destroyed if this current is too large, both the scintillator and the photomultiplier have to be screened from ambient light (see Fig. 1). Good optical contact has to be made between them in order to minimize optical losses due to total reflection. A light-guiding structure can also be inserted if the geometry of the application requires the scintillator and the photomultiplier

Figure 1. Schematic diagram of a counting system employing a scintillation counter. The incident particle triggers luminous photons, which are converted into photoelectrons and multiplied. The resulting electron pulse is amplified and shaped before being measured or counted.

to be at some distance from each other. The anode pulse of the photomultiplier is fed into a pulse amplifier. In order to minimize background noise, the connection between the photomultiplier and the amplifier has to be kept as short as possible. Therefore, the amplifier is usually contained in a housing, which is directly connected to the photomultiplier socket. In most cases, this housing also contains a voltage divider circuit, which distributes the high voltage to the dynodes of the photomultiplier.

The final constituent of a complete detection system is the signal-processing and data acquisition electronics. The design of the signal-processing electronics depends on the type of application. For measurements of the particle energy, the amplifier output signal is connected to a pulse discriminator/digital counter or a multichannel pulse height analyzer. In measurements requiring a low background, two or more photomultipliers are coupled to the same scintillator. Their pulse amplifiers are connected to a coincidence circuit, which passes a signal to a counter only if the pulses delivered by different photomultipliers arrive within the resolving time of the circuit. In this way, random, spurious pulses generated independently in the photomultipliers can be excluded. In many cases, a digital counter or a multichannel pulse height analyzer is connected to a digital data storage system, for example a computer, where the counts are stored to memory.

The physical processes leading to scintillation are dependent on the scintillator material. The nature of these processes also determines important performance characteristics of scintillation counters, such as the *response time*, the *sensitivity*, the *proportionality*, and the *energy resolution*. This is described in the following sections. A more detailed treatment of these aspects can be found in Refs. 1 and 12.

SCINTILLATOR MATERIALS

Scintillators can be classified into inorganic crystals, glasses and gases, and organic compounds.

The most commonly used inorganic materials are alkali halides such as NaI, CsI, or KI. These are doped with about 0.1% of thallium, which acts as a center for the emission of luminescent photons. Thallium-activated sodium iodide, NaI(Tl), is the most commonly used scintillator; it can be produced in large crystals. Zinc sulfide crystals doped with silver, ZnS(Ag), are used as a scintillating coating. Silicate glasses scintillate when doped with lithium or cerium.

Among the organic substances are anthracene and stilbene crystals, and terphenyl dissolved in liquids (for example xylene or toluene) or incorporated in plastics (for example polystyrene).

Finally, the noble gases helium, neon, argon, krypton, and xenon can be used as scintillators.

The wavelength of maximum intensity of the emitted scintillation light varies among different scintillator materials and is typically between 300 nm and 500 nm for inorganic crystals and organic compounds, and in the ultraviolet region for noble gases.

PROCESSES IN SCINTILLATORS

Producing a scintillation event in one of the materials mentioned involves two steps: the interaction of an incident particle and the subsequent emission of luminescent light.

In general, a part of the energy of the incident particle is absorbed, causing excitation or ionization of scintillator molecules. Luminescent light is emitted during transitions of excited electrons to lower energy levels. The interaction depends on the type of the particle, and the emission process varies between different scintillator materials. Incident particles can be either primary or secondary, examples of the latter being photoelectrons and Compton electrons produced by a γ ray, and secondaries of neutrons. In addition to luminescent light, erenkov radiation can be emitted by a charged particle traversing matter at a speed greater than the speed of light in the respective medium. However, this effect will not be treated in this article.

The energy loss of charged particles in matter, as given by the Bethe-Bloch formula, and the probability for photoelectric absorption, Compton scattering, and pair production by γ rays all increase with increasing density ρ and atomic number Z of the scintillator. Therefore, materials with high values of ρ and Z show high absorption of incident particles per unit volume. In this respect, inorganic crystals ($3.0 \text{ g cm}^{-3} < \rho < 7.5 \text{ g cm}^{-3}$; e.g. $Z = 53$ for iodine) have advantages over organic compounds ($0.8 \text{ g cm}^{-3} < \rho < 1.2 \text{ g cm}^{-3}$; $Z \leq 6$) and noble gases ($\rho \leq 10^{-3} \text{ g cm}^{-3}$ at atmospheric pressure and room temperature). However, because of their low absorption efficiency for γ rays, organic scintillators are predominantly used for the measurement of charged particles at low γ background counting rates.

Charged particles usually deposit all their energy, especially in solid or liquid scintillators, because the range of α particles and electrons in these scintillators is in the order of micrometers and millimeters, respectively. In contrast, γ rays attenuate exponentially by a factor of two over several centimeters and more, and it is therefore possible that they leave only a fraction of their energy in the scintillator. This circumstance is reflected in characteristic features in the spectra observed with scintillation counters suitable for detecting γ rays. This will be briefly explained in the following (with high Z).

If the detector is dense (with high Z) and large enough, some γ rays can be totally absorbed in the scintillator due to the photoelectric effect. It is also possible that they undergo a number of Compton scattering processes before leaving the scintillator, which implies that only the energy of the Compton electrons is transformed into scintillation light. Finally, a γ ray with an energy of more than two electron rest masses (1.022 MeV) can produce an electron-positron pair. The positron is likely to recombine with electrons in the scintillator, producing two 0.511 MeV photons, one or both of which can leave the scintillator.

Figure 2 shows a typical count spectrum of monoenergetic γ radiation measured with a scintillation counter. The peak denoted by E_γ contains events where γ rays deposit their total energy in the scintillator, which includes photoelectric absorption and positron annihilation without the escape of an annihilation photon. The broad spectrum at energies below E_γ is the Compton distribution, resulting from scattering processes involving variable amounts of energy transfer. Within this distribution, there are two distinct peaks at $E_\gamma - 0.511 \text{ MeV}$ and $E_\gamma - 1.022 \text{ MeV}$, which are due to the escape of one or two annihilation photons. It should be pointed out that both the Compton distribution and the single and double escape peaks decrease in height with increasing absorption (that is, with increasing atomic number, density and volume of the scintillator). Hence, a γ spectrum of many different energies is easier

Figure 2. Energy spectrum of γ rays obtained with a scintillation counter.

to interpret when measured with a large and highly absorbing detector.

Neutrons can be detected with scintillation counters by means of secondary reaction products. In (hydrogen-containing) organic scintillators, for example, fast neutrons can produce recoil protons in a collision with hydrogen nuclei (*hydrogen knock-on* reaction). Boron trifluoride (BF_3) counters can detect slow neutrons via nuclear capture according to $^{10}\text{B} + n \rightarrow ^7\text{Li} + \alpha + 2.78 \text{ MeV}$ (11). Europium-activated lithium iodide [$\text{LiI}(\text{Eu})$] crystals have also been successfully used for the $^6\text{Li}(n, \alpha)^3\text{H}$ reaction.

It is possible to distinguish between two types of luminescent emission, depending on how energy is transferred from the excited particle to the luminous photon. A process is called *phosphorescence* if it involves deexcitation of scintillator molecules from relatively long-lived, metastable energy levels. If this is not the case, the process is termed *fluorescence*. Historically, these two variants were distinguished by the typical *relaxation time* τ_r of the pulses, which characterizes the decrease of the scintillation intensity $I(t)$ (number of luminous photons per unit of time t). This decrease can be approximated by

$$I(t) = I(t=0) \exp(-t/\tau_r) \quad (1)$$

These relaxation times are on the order of 10^{-6} s to 1 s for phosphorescence and 10^{-7} s to 10^{-9} s for fluorescence. For further details about processes in scintillators, see Ref. 1.

PERFORMANCE CHARACTERISTICS

The type of emission process depends on the scintillator material. Since a typical photomultiplier spreads a pulse by about 10^{-9} s, the choice of scintillator determines the response time of the whole detector. Organic scintillators and noble gases, for example, show fluorescence, and are therefore predominantly used for applications requiring a fast response. In inorganic crystals, the energy deposited by the incident particle has to be transferred thermally to the luminescent centers (thallium or silver atoms). This leads to longer relaxation times, or, if these luminescent centers have metastable energy levels, to phosphorescence. The scintillation processes in inorganic and organic scintillators and their influence on the response time are described in detail later on.

The *sensitivity* S of a scintillation counter can be written (see Refs. 12 and 13) as the product

$$S = \eta_s T_s f_1 s_\lambda f_2 \eta_c G \quad (2)$$

of (1) the *quantum yield* or *conversion efficiency* η_s (the ratio E_s/E_p of the energy E_s of the emitted luminescent photons to the energy E_p deposited in the scintillator by the incident particle), (2) the *transparency* T_s of the scintillator to its own scintillation light (dependent on the distance traveled through the scintillator volume), (3) a factor f_1 representing the *optical loss* due to reflection and absorption in the windows of the scintillator and the photomultiplier as well as the optical contact between them, (4) the maximum *spectral sensitivity* s_λ of the photocathode (the ratio of the photoelectron current to the power of luminescent photons), (5) a factor f_2 for the *spectral match* of the photocathode material to the wavelength of the scintillation light, (6) the *collection efficiency* η_c of the first photomultiplier dynode for photoelectrons, and finally (7) the *photomultiplier gain* G . All quantities mentioned above are dimensionless, except for the spectral sensitivity s_λ , which has units of milliamperes per watt. The overall sensitivity S can thus be expressed as the current at the photomultiplier output per unit energy flux of the incident particle current. It has units of $\text{mA}/(\text{MeVs}^{-1})$.

The output pulse of a scintillation counter shows *proportionality* to the energy E_p of the incident particle only if this energy is completely deposited in the scintillator and if the conversion efficiency η_s is constant. In this case, the pulse charge released in the photomultiplier from the last dynode to the anode is determined by the sensitivity S of the counter according to

$$Q = SE_p \quad (3)$$

It is this charge Q that is measured with the signal-processing electronics and then multiplied by the counter sensitivity S (usually obtained from calibration) in order to obtain E_p . However, in some circumstances [as in measuring γ rays with a small $\text{NaI}(\text{Tl})$ crystal or α particles with a scintillation chamber, as will be discussed later], only a variable fraction of E_p is deposited in the scintillator. In this case, the charge collected at the photomultiplier anode does not reflect E_p , but only the fraction deposited.

The *energy resolution* describes the uncertainty occurring in the energy measurement described above, and hence is a measure of the ability of the counter to distinguish two different particles even if their energies E_p are very close together. It can be obtained from a measured pulse height or particle energy spectrum as the ratio of the full width of the corresponding peak at half maximum height to the energy E_p . The spread of a pulse height or energy peak is due to two factors: (1) statistical fluctuations in the numbers N_γ , N_p , and N_s of released luminous photons, photoelectrons, and secondary electrons, and (2) variations in the counter sensitivity S . Since the relative statistical fluctuations are proportional to $1/\sqrt{N}$, and since $N_p < N_\gamma$ and $N_p < N_s$, the largest fluctuations are introduced during the release of photoelectrons. Furthermore, the light collection (and hence the transparency T_s) is not uniform over the scintillator volume, and the photomultiplier gain G fluctuates due to instabilities in the high voltage (14), both of which affect the counter sensitivity. For the detection of 1 MeV γ -rays with a $\text{NaI}(\text{Tl})$ crystal, for example, the energy resolution is in the order of 7%.

Table 1. Physical Properties of Some Common Inorganic Scintillators

Scintillator	Light Output [% of NaI(Tl) for Bialkali PMT]	Wavelength of Maximum Emission (nm)	Decay Time (ns)	Density (g · cm ⁻³)

DETECTOR TYPES AND ACCESSORIES

This section will deal with the most common types of scintillation counters, such as inorganic and organic scintillation counters and crystal, liquid, and gas scintillation counters, as well as scintillation chambers. In addition, details on photomultipliers and optical contacts are presented. Since the early visual and Geiger–Müller scintillation counters have no relevant applications anymore, they will not be described here. A detailed treatment of these types can be found in Refs. 1 and 15.

Inorganic Scintillators

Inorganic scintillators can be classified into three main groups: crystals, glasses, and gases (including liquefied noble gases). The most commonly used are the crystal scintillators, which are mainly alkali halides. Inorganic scintillators are generally characterized by high quantum yield (and therefore good resolution and sensitivity), high density, and high Z (and therefore high efficiencies). See Table 1 for the physical properties of some common organic scintillators. They are therefore ideal as high-energy-electron and γ -ray detectors, and they are used as such in medical imaging applications, γ -ray spectrometry, and radiation dosimetry and as general-purpose radiation detectors for nuclear and particle physics research.

Scintillation Mechanism. Details of the scintillation mechanism for inorganic crystal scintillators vary from one material to another, but the general principle is similar. The scintillation mechanism depends on excitation and deexcitation of electrons between energy states determined by the crystal lattice of the material. The large number of atoms in the crystal leads to energy *bands* (consisting of large numbers of very closely spaced energy levels). Most electrons are in the *valence band* (ground state). A charged particle passing through the material will excite some of the electrons to the *conduction band* (excited state). The electron may emit a scintillation photon and return to the valence band or lose its energy to nonradiative thermal motion. In a pure crystal the scintillation photon can be readily absorbed, since it corresponds to the energy difference between the valence and conduction bands and there are many electrons in the valence band. Absorption leads again to an excited electron that can either emit a photon or lose its energy to non-

radiative thermal motion. At each stage further energy is lost to the nonradiative process, so generally pure crystals are not efficient scintillators.

This problem is solved by adding small amounts of impurities, called *activators*, to the crystals. The activators modify the energy band structure of the crystal by introducing activator ground states that are at a higher energy than the crystal valence band and excited states that are at a lower energy than the conduction band; see Fig. 3. When an electron is excited from the valence band to the conduction band, a hole (vacancy) is formed in the valence band. The electron can move freely through the crystal, whilst the hole can do the same. The hole will quickly drift to a site in the crystal lattice occupied by an activator atom. An electron from the ground state of the activator atom will drop down to the valence band of the crystal, releasing thermal energy. The excited electron (in the conduction band) can now drop down to the excited activator state, also releasing thermal energy. It then emits a scintillation photon as it deexcites to the activator ground state. This has two important consequences. First, the energy of the scintillation photon is less than that required to excite a valence electron (most electrons) to the conduction band, so it is not readily absorbed. The scintillator is therefore transparent to the photons it emits. Second, the energy difference between the ground and

Figure 3. Energy band structure of an activated inorganic scintillator. The presence of activator sites introduces new energy levels. Transitions between these levels lead to photons that are not readily absorbed by the scintillator.

excited activator states corresponds to photons in the visible range that are better matched to the spectral response of photomultiplier tubes. The energy difference between the valence and conduction bands is higher, corresponding to ultraviolet (UV) photons.

Under certain conditions pure (or intrinsic) crystals can, however, be used as efficient scintillators. The difference in the emission and absorption spectra for scintillation photons is attributed to the Franck–Condon principle, which states that any transition between electron energy states happens very quickly compared to atomic or ionic vibrations. This is important because the minimum energy for the conduction band occurs at a larger interionic separation than for the valence band. When an electron is excited to the conduction band, the interionic separation initially remains the same. This means the electron is left with excess energy. It loses it as thermal energy to the crystal lattice while the interionic separation increases. It then emits a scintillation photon and deexcites to the upper levels of the valence band. The energy of this scintillation photon is slightly less than the energy required to excite an electron from the valence band to the conduction band. Pure crystals are efficient only if the number of electrons in the higher valence states is small, and this is usually achieved by cooling the crystals. At room temperature electrons can be found in the higher valence state due to thermal motion and cause reabsorption of the scintillation photons. As long as the pure crystals are cooled, their quantum yield is high and pulse decay time short (16).

In some cases the excited electron is left in a state that cannot decay directly to the ground state (forbidden transition). The electron must obtain some extra energy (usually from thermal excitation) and move to a higher state from which it can decay to the ground state. This process is slow, and the emission is known as phosphorescence.

Crystal Scintillators. By far the most common general-purpose γ -ray detectors are the alkali halide crystals. Sodium iodide crystals with 0.1% thallium as an activator, NaI(Tl), are readily available commercially and are the standard detector used for comparisons with other scintillators. The notable features of NaI(Tl) are its high quantum yield, good energy resolution, and linear response over a large energy range of incident radiation. Unfortunately, it is also hygroscopic, which requires the crystal to be hermetically sealed, usually together with the photomultiplier tube. If not sealed, the crystal quickly deteriorates due to the absorption of moisture in the air. It also has a relatively long scintillation decay time of 230 ns, which may be a problem for very high counting rates, and a phosphorescence component with decay time of 0.15 s. In most applications the phosphorescence is not important, since each phosphorescence photon is detected as a single event giving rise to a single photoelectron. Such a small signal can be ignored by using a discriminator set to the appropriate level. NaI is also fragile and can be easily damaged by mechanical or thermal shock.

For low-energy γ rays the efficiency of a scintillation detector can be increased by using a *well crystal*. This is a circular cylinder with a well, or cavity, along the axis of the cylinder. The source or sample to be measured is placed inside the well, and the scintillator almost completely surrounds it. The counting efficiency is therefore close to 100%.

Cesium iodide is also a popular, readily available scintillator, activated with either sodium or thallium, CsI(Na) and

CsI(Tl). Both types are slightly denser than NaI(Tl), resulting in a larger absorption coefficient. They are only slightly hygroscopic and not as susceptible to shock and vibration. A useful property of CsI(Tl) is its variable decay time for different incident particles (17). This allows *pulse shape discrimination* between heavy charged particles such as α particles and protons on the one hand and electrons and γ rays on the other. However, the emission spectrum is at a much longer wavelength than NaI(Tl) and is poorly matched to the spectral response of most photocathodes. The response is greatly improved by using photodiodes (semiconductor devices) that are sensitive to these longer wavelengths.

Lithium iodide activated with europium, LiI(Eu), and enriched with ^6Li is often used for the detection of slow neutrons. A slow neutron interacts with ^6Li in the crystal and produces tritium and an α particle. The total energy of the reaction products is fixed, and so the response is characterized by a well-defined peak. However, this response also corresponds to that for electrons or γ -rays of energy 4.1 MeV. Therefore, any electron and γ -ray background at these energies is important when making neutron measurements. Lithium iodide is also highly hygroscopic and must be sealed.

A high-density pure crystal scintillator that is commonly used is bismuth germanate (BGO), $\text{Bi}_4\text{Ge}_3\text{O}_{12}$. Its high density is an advantage in applications where a compact high-efficiency counter is required. It is also mechanically and chemically robust and therefore easy to handle. The scintillation emission is characterized by a fast component with a decay time of 60 ns and a dominant slower component of 300 ns making its timing characteristics similar to NaI(Tl). The quantum yield, however, is only about 10% to 20% of that of NaI(Tl), and so the resolution is much poorer. This means it is appropriate for counting applications, such as PET positron emission tomography) scanners, but unsuitable for spectrometry.

One of the first scintillators used was zinc sulfide activated by silver, ZnS(Ag). Unlike other crystal scintillators, it can only be produced as a polycrystalline powder rather than a single crystal. It is opaque to its own scintillation light, so it is used as a thin layer or screen between 20 μm and 60 μm thick. It is primarily used for counting very low-energy electrons, α particles, or other highly ionizing charged particles. Its quantum yield is comparable to that of NaI(Tl), making it very efficient. It is sometimes used to coat layers of plastic, or some other material high in hydrogen, in order to detect recoil protons due to incident fast neutrons (16). If the plastic contains ^6Li or ^{10}B , it can also detect slow neutrons.

Glass Scintillators. Most glass scintillators are made from silicate glasses and activated by cerium. The decay time for the scintillation emission is typically between 50 ns and 100 ns. They can be produced cheaply and easily in many different shapes and sizes, and they are mechanically and chemically very robust, making them suitable for extreme environments such as high temperatures or the presence of corrosive chemicals. Their quantum yield is only about 10% of that of NaI(Tl), so they are not suitable for spectrometry. Glass scintillators containing lithium are widely used as fast-neutron detectors. Their short response time means they are suitable in neutron time-of-flight spectroscopy.

Gas Scintillators. Gases can also be made to scintillate and serve as useful detectors for certain applications. The most

efficient scintillating gases are the noble gases and nitrogen (18). Several different processes give rise to the scintillation light, of which the most efficient is the formation of excited molecules that radiate when returning directly to the ground state. For the noble gases the emission spectrum is usually in the UV and forms a continuum. To detect such photons requires the use of special UV-sensitive photocathodes, photodiodes, or wavelength shifters, such as a small amount of nitrogen gas. The quantum yield is quite low compared to that of NaI(Tl), but the decay time for the emission is generally short, in the order of 20 ns or less. The quantum yield also depends on the purity of the gas, as any impurities can reduce the light output. This is because the impurities absorb the excitation and ionization energy without emitting scintillation photons. Such a process is termed *quenching*. The response of gas scintillators is also very linear with energy over a large range. At low pressures (<10⁵ Pa = 1 atm) they have very low efficiencies for γ rays, so that they are used almost exclusively as heavy-ion detectors, most notably for fission fragments. In most practical applications the gas is used at high pressure, increasing the efficiency of the detector.

Gas scintillators are also used in a hybrid detector called the *scintillating proportional detector* (19). A large electric field between two electrodes accelerates any electrons produced from ionizing interactions in the gas. As these electrons move towards the anode, they collide with neutral gas molecules, exciting them. The gas molecules deexcite, emitting scintillation photons. This is a source of secondary scintillation. The quantum yield is greatly increased, approaching or even exceeding that of NaI(Tl), but the drift of the electrons is slow and the secondary scintillation photons are emitted a few microseconds after the prompt scintillation photons and last for a few microseconds, resulting in a relatively slow response.

The noble gases also scintillate when condensed cryogenically to a liquid or solid. In fact, their quantum yield is then comparable to that of NaI(Tl). Liquid argon (LAr) ionization chambers have been used for many years, but only recently has the need for fast detectors prompted their use as scintillators because of their fast scintillation response. Liquid xenon and krypton detectors, which have high *Z*, can also be used as γ -ray detectors. Being liquid, they can be produced in any shape and size, which is also advantageous.

Organic Scintillators

Organic scintillators can be classified into three types: crystal, liquid, and plastic. Compared to the inorganic scintillators, they have lower densities and *Z* values, resulting in lower detection efficiencies, especially for γ rays. The quantum yield is also lower, resulting in poorer energy resolution. (See Table 2 for the physical properties of some common organic scintillators.) They do, however, have several advantages. They are very cheap, can be produced in many shapes and sizes, and are mechanically robust. They are also characterized by extremely short response times, whence their use in fast timing applications and at high event rates. Addition of boron or gadolinium produces scintillators that can be used for neutron detection and spectrometry.

Scintillation Mechanism. The luminescence process in organic scintillators is due to energy transitions in individual molecules, rather than the lattice structure of the material as in inorganic crystals. Any particular molecule can therefore be observed to scintillate, regardless of its physical state (solid, liquid, or gas). Almost all organic scintillators contain at least one benzene ring (or benzene-ring derivative) and it is this structure that is responsible for the scintillation.

Benzene is an organic molecule that contains six carbon atoms arranged in a closed ring. Each carbon atom forms four bonds with its four valence electrons. Three of these bonds are σ bonds that are close to the carbon atom and hence strong bonds. The fourth electron forms a π bond that is further away and only weakly bound. This electron is therefore easily excited or ionized and is responsible for the scintillation mechanism. The π electron is usually found in the ground state, but it can be excited into any of the higher energy states. The structure of these electronic states is shown in Fig. 4. It consists of the basic electronic states S_0 (the ground state), S_1 (first excited state), S_2 (second excited state), and so on. The typical difference in energy between S_0 and S_1 is about 3 eV or 4 eV. These states are further split into substates with slightly different energies due to vibration of the molecule, the difference between adjacent states being about 0.15 eV. They are denoted by S_{00} , S_{01} , S_{10} , S_{11} , and so on. These states are actually split even further by different molecular rotational energy substates, but

Figure 4. Energy levels of an organic molecule with π electron structure. Electron transitions are indicated for fluorescence and phosphorescence.

the difference of such energy levels is much smaller and can be ignored when considering scintillation. Together these energy levels form the singlet states (spin 0) for the π electron. There is a similar set of states called the triplet states (spin 1) that the π electron can also occupy. These are indicated as T_1 , T_2 , T_3 , and their splitting has not been included in Fig. 4 for simplicity.

Three types of luminescence have been identified for organic scintillators that differ in either their emission spectrum or their decay time. They are fluorescence, phosphorescence, and delayed fluorescence. The most important process that is responsible for most of the scintillation light emission is fluorescence.

The spacing of the vibrational and rotational substates means that at room temperature nearly all the molecules of a scintillator are in the S_{00} state. A charged particle incident on the scintillator can either excite such a molecule to any of the higher energy level states or ionize it. An excited molecule quickly ($\sim 10^{-12}$ s) loses energy through internal nonradiative processes until it reaches one of the S_1 substates and then thermally deexcites to the S_{10} state. The molecule then emits scintillation light (fluorescence) as it deexcites from the S_{10} state to one of the S_0 substates. This process occurs on a time scale of nanoseconds and determines the decay time of fluorescence. Since the higher vibrational substates of the ground state are not occupied, the emission and absorption spectra overlap only slightly and the scintillator is transparent to its own emission. An ionized molecule, on the other hand, usually recombines with the electron and ends up in one of the excited states. In most cases this is a triplet state.

In some cases the excited S_{10} state can undergo a nonradiative transition to the T_1 triplet state. This is called *inter-system crossing*. The lifetime of the T_1 state is characteristically much longer (10^{-4} s) than that of the S_1 state. The molecule deexcites to an S_0 state by emitting light that is usually of slightly longer wavelength than that emitted during fluorescence, due to the

difference in energy between the T_1 and S_1 states. This emission is also much slower and is called phosphorescence. Whilst in the T_1 state, a molecule may absorb some energy and be excited back to the S_1 state. This molecule may then deexcite to a S_0 state, just as in normal fluorescence. The emission spectrum is the same as in fluorescence, but the process is delayed ($\sim 10^{-6}$ s) due to the time spent in the T_1 state. Such emission is called *delayed fluorescence*.

Organic Crystals. There are many organic crystal scintillators, but only three are widely used: anthracene, trans-stilbene, and quaterphenyl. Anthracene has the highest scintillation efficiency of all organic scintillators, yet still only about half that of NaI(Tl). The fluorescence of both trans-stilbene and quaterphenyl has a decay time that depends on the incident particle. Fast fluorescence is produced by γ rays, slower fluorescence by neutrons, and even slower fluorescence by α particles. Pulse shape discrimination can therefore be used to identify the incident radiation and perhaps reduce or eliminate any background. Since organic scintillators contain a large amount of hydrogen, they are efficient fast-neutron detectors when used in pulse shape discrimination mode. Organic crystal scintillators are, however, fragile and difficult to obtain in large sizes. In addition, the quantum yield is known to depend on the direction of the incident particle with respect to the crystal axis (20). The difference in response with direction can be as much as 20% to 30%, which severely degrades the energy resolution of such detectors.

Liquid Organic Scintillators. Liquid organic scintillators form a very versatile and useful category of detectors. The liquid state allows easy addition of other materials to improve and optimize the efficiency of such detectors. Addition of boron or gadolinium allows the detection of slow neutrons. To enhance the probability of photoelectric conversion of γ rays, lead or tin is added, which results in a very efficient and fast scintillator (21). Low-energy γ rays or β particles can be easily detected by dissolving or incorporating the sample in the liquid organic scintillator. This reduces losses due to absorption by the scintillator outer covering or the source itself, resulting in very high detection efficiencies. In addition, further fluorescent compounds can be added to shift the scintillation light spectrum to longer wavelengths in order to match better the spectral response of most photocathodes.

The simplest type of liquid organic scintillator consists of a fluorescent material, called the *primary solute*, dissolved in the solvent that makes up the bulk of the scintillator. Common solvents include toluene, xylene, and 1,4-dioxan. These compounds fluoresce when exposed to ionizing radiation; however, the quantum yield is low, and self-absorption can be a problem for large detectors. The addition of a primary solute has several effects that increase the efficiency of the scintillator. Firstly, the primary solute is a much more efficient scintillator, so that energy is transferred from molecules in the solvent (most energy loss occurs in the solvent, since it constitutes the bulk of the material) to molecules of the solute. This can occur by one of the following means: radiative transfer (scintillation light emission by solvent and absorption by solute), nonradiative dipole-dipole exchange, or collision exchange via diffusion of excited solvent molecules. Secondly, scintillation emission from most solvents is usually at short wavelengths that are not easily detected by most common photocathodes. The solute,

therefore, also acts as a wavelength shifter with an absorption spectrum well matched to the emission of the solvent and an emission spectrum well matched to the spectral response of most photocathodes. This wavelength shift also eliminates the problem of self-absorption by the solvent. In some cases it is necessary or desirable to add a secondary solute to act purely as a wavelength shifter, absorbing the scintillation light of the primary solute and emitting at slightly longer wavelengths. This achieves an optimum match with the spectral response of the photocathode and reduces self-absorption by the primary solute if the dimensions of the detector are large. Popular primary solutes include PPO (2,5-diphenyloxazole), PBD (2-phenyl-5-(4-biphenyl)-1,3,4-oxadiazole), and PTP (paraterphenyl), a common secondary solute is POPOP [1,4-di-(2-5-phenyloxazolyl)benzene].

The quantum yield of liquid organic scintillators is affected by the presence of impurities. Such impurities, especially dissolved oxygen, can serve as quenching agents significantly reducing the quantum yield of the scintillator. Dissolved oxygen is generally removed by bubbling nitrogen through the liquid and kept out by sealing the liquid in an airtight container.

A popular use of liquid scintillators is as anticoincidence shields to reduce unwanted background events. Such shields are effective at detecting high-energy cosmic rays or high-energy γ rays that may mimic a real event. When an event is detected by the anticoincidence shields, any signal in the main detector is vetoed. Liquid scintillators can be of any shape or size and hence provide complete coverage at a very low cost.

Liquid organic scintillators are also routinely used to measure the activity of biological or chemical samples containing ^{14}C or ^3H . The low-energy electrons from such sources are most easily measured by dissolving the sample in the liquid scintillator. This may introduce problems such as low solubility of the sample, quenching by the sample, and reactions with the solvent or solute. However, stable solutions for most cases can be obtained by the appropriate choice of solvent and solute (22). Once the solution of liquid scintillator and sample has been prepared, it is placed in a light-tight enclosure and counted by a photomultiplier tube.

Plastic Scintillators. Organic plastic scintillators can be thought of as solid solutions, and hence they are very similar to organic liquid scintillators. They are prepared by using a solvent that can be polymerized (such as polystyrene or polyvinyltoluene), a primary solute, and perhaps a secondary solute. The solutes that make efficient scintillators for liquid solutions are also efficient scintillators in solid (plastic) form, so that PPO, PBD, and PTP are used. POPOP is a common secondary solute used as a wavelength shifter. For plastics the quantum yield of the scintillator can also depend on the method of preparation as well as its constituents (23). In addition, transfer of energy from the solvent to the solute is not as efficient as for solutions (solvent molecules cannot diffuse), and therefore greater concentrations of solute must be used to obtain comparable quantum yields.

Due to their mechanical strength, plastic scintillators are easy to handle and can be cut to any shape and size. They are relatively cheap and therefore practical in large-volume coincidence or anticoincidence counters. They are used extensively in nuclear physics, for lifetime and time-of-flight measurements, because of their fast response. Although, like the other organic

Model 110A

Figure 5. Lucas cell. This type of counter is used for measuring α radiation in gases.

scintillators, they can be used to detect both fast (scattering from protons) and slow (loading with boron or gadolinium) neutrons they do not have such good pulse shape discrimination characteristics.

Plastic detectors can be produced as very thin film scintillators with thicknesses down to $10\ \mu\text{m}$ (24). This allows the detection of low-energy highly ionizing particles such as heavy ions without complete loss of energy. Such detectors are known as *transmission detectors*.

Scintillation Chambers or Lucas Cells

A *Lucas cell*, named after its inventor (25), is a scintillation chamber used for the measurement of α radiation in gases. The cell is a cylinder of volume 0.1 L to 2 L, with a $\text{ZnS}(\text{Ag})$ coating on the internal surfaces. One end of the cylinder is a quartz window, while at the opposite end two connectors are mounted for the exchange of gas samples (see Fig. 5).

Because of their high counting efficiency (about 75% for the measurement of 6 MeV α particles in a standard 150 mL cell), Lucas cells allow the measurement of gas samples with small volumes and activities as low as $1\ \text{Bq m}^{-3}$. The $\text{ZnS}(\text{Ag})$ scintillator material has its maximum emission at a wavelength of $\lambda = 450\ \text{nm}$, with a bandwidth of about 55 nm. Because of its high density and atomic number ($\rho = 4.1\ \text{g cm}^{-3}$, $Z = 23$), it has a high conversion efficiency of $150\ \text{eV/keV} \leq \eta_s \leq 200\ \text{eV/keV}$. In order to ensure a maximum yield of luminous photons, the coating thickness has to be larger than the range of the α particle, which, for ZnS , is about $15\ \mu\text{m}$ at energies around 6 MeV. The only disadvantage of Lucas cells is that $\text{ZnS}(\text{Ag})$, as a phosphorescent material, has a long relaxation time $\tau_r \approx 20\ \mu\text{s}$.

The efficiency of Lucas cells depends on their geometry and size. This is because the distance which the α particle has to travel to reach a cylinder wall depends on the location of the α decay within the cell and the direction of emission of the α particle. The efficiency of the cell is equal to the fraction of decay events where the distance between the decay location and the cylinder wall for a given direction is less than the range of the α particle in the gas (26). This circumstance also implies that, even for monoenergetic α particles, the amount of energy

deposited in the scintillator ranges from zero (the particle does not reach the cylinder wall) to E_p (the particle is emitted at a location directly adjacent to a wall). Therefore, Lucas cells are unsuitable for energy measurements.

Lucas cells are extensively used to detect radon, a naturally occurring radioactive noble gas. They can monitor the radon concentration in air either as a passive device with radon diffusing into the sensitive volume (27), or actively with air being continuously forced through the cell (28) or periodically exchanged (29). Radon is produced in the decay of radium in soils, rocks, and building materials. From there it enters residential buildings or workplaces such as mines, and, together with its progeny, forms a significant source of the human radioactive dose. In addition to surveys of the radon concentrations in the human environment, Lucas cells have also been employed to investigate the migration of radon in the earth's crust. Radon is released into the pore space of the rock preferentially under mechanical stress, and is then transported to the surface along fractures and faults. Thus, field studies have demonstrated a correlation of the radon exhalation from the ground with periodic stresses caused by tidal forces as well as with transient stresses before and during seismic events. Due to the latter fact, a sudden increase in the radon exhalation can be utilized as an earthquake precursor. In contrast, a constant regional anomaly of the radon exhalation can indicate the presence of an underground uranium ore body.

Photomultipliers

The photomultiplier is an essential constituent of every modern scintillation counter, because it enables the scintillation light pulse to be converted into an electrical signal, which can be electronically processed for further purposes.

A photomultiplier, as shown in Fig. 6, is a vacuum tube with a window for the entry of light at the top and a socket with electrical connectors at the base. The inside of the window is coated with an either opaque or semitransparent photoemissive layer,

the photocathode. Photons incident on the photocathode release up to five photoelectrons, which are collected by an electron—optical system and focused onto the first of several electrodes. In the case of a photomultiplier, these electrodes are called *dynodes*. Since a high voltage (≈ 100 V to 150 V typically) exists between each pair of subsequent dynodes, the electrons are accelerated from one dynode to the next. Upon impact on each dynode, an electron causes the emission of further secondary electrons, thus amplifying the pulse from one stage to another. The secondary electron yield depends on the impact energy of the primary electrons and therefore on the accelerating high voltage. Electrons emitted from the last dynode are collected on the anode, which forms the output stage of the photomultiplier. The transit time of a pulse from the photocathode to the anode is in the order of 50 ns, but the pulse is spread by less than 1 ns during its passage. During operation the photomultiplier has to be shielded from ambient light in order to avoid its destruction due to an excessive anode current. Furthermore, the electrostatic focusing of the dynodes and hence the pulse shape can be adversely affected by external magnetic fields. Therefore, the light shield can also serve as a magnetic shield when made of Mumetal (9).

Photomultiplier tubes vary mainly with regard to the number of dynodes and the photocathode material. Tubes with ten or more dynode stages are common. The wavelength λ_m of maximum photocathode sensitivity should be within the spectral range of the scintillation light. It depends on the photocathode material and ranges from 200 nm to about 450 nm. At wavelengths above 600 nm, the photon energy is below 2 eV and is hence lower than the energy E_a that is needed to release a photoelectron from the surface of a typical photoemissive material ($2 \text{ eV} \leq E_a \leq 4 \text{ eV}$). The sensitivity at short wavelengths is limited by the absorption of photons in the window glass. The cutoff wavelength is about 350 nm for normal glass, but can be extended to 160 nm by using a quartz window (14). The maximum sensitivity s_λ is typically 80 mA/W. With h being Planck's constant, c the speed of light, and e the electron charge, this corresponds to photocathode quantum efficiency

$$\eta_c = s_\lambda \frac{hc}{\lambda_m e} \quad (4)$$

of about 25%.

Two further important characteristics of photomultipliers are the *gain* and the *dark current*. The gain is the ratio of the amplified anode current to the initial photoelectron current. It depends on the number and design of the dynodes and also on the high voltage applied. In order to ensure a constant gain, the high voltage should be well stabilized. The gain is typically very high (between 10^5 and 10^8), so that single photons incident on the photocathode can be registered. The dark current is mainly the anode current at zero photocathode illumination. It consists of very short pulses (≈ 1 ns, the transit time spread), which are due to the thermally activated emission of electrons from the photocathode. The dark current is therefore dependent on the operating temperature. Typical values range from 1 nA to 100 nA, depending on the high voltage.

Since the gain is determined by the high voltage, particular attention has to be paid in designing a suitable high-voltage divider circuit. The voltage distribution along the divider can vary widely, depending on the desired pulse shape. Figure 7

Figure 6. Internal structure of a photomultiplier. (Courtesy of Photonis, France)

Figure 7. A simple high voltage divider circuit used with a photomultiplier. Photoelectrons generated at the photocathode c are accelerated toward the anode by a high voltage U_H .

shows a simple divider circuit supplying a high voltage to the dynodes d_1 to d_{10} as well as to the cathode c and anode a of a photomultiplier tube.

The anode has to be positive with regard to the photocathode in order to accelerate the photoelectrons. This can be achieved by either (1) connecting the high voltage to the anode and grounding the photocathode, or (2) vice versa. The second polarity option has the disadvantage of a high voltage across the glass housing, which can induce spurious pulses due to electroluminescence in the glass (14). However, the anode can be connected directly to the input of the pulse amplifier. This is not the case in the first option (as shown in Fig. 7), where a high-voltage capacitor C_{HV} has to be inserted in order to protect the pulse amplifier from the high dc voltage while still allowing the signal pulse to pass.

The gain and therefore the signal current I_a at the anode of the photomultiplier is adjusted via the high voltage U_H . If A is the maximum count rate and Q is the charge per pulse [see Eq. (3)], then

$$I_a = QA \quad (5)$$

I_a should be much higher than the dark current.

The electrons transiting between the dynodes cause a mean current across the divider resistors R_d in the opposite direction. Hence, the divider voltage is reduced during a pulse passage, giving rise to variations in the photomultiplier gain. To minimize the effect of a variable mean anode current on the gain, these resistors are chosen so that the divider current $I_d \geq 100 I_a$.

Furthermore, a pulse current across the last dynodes with a decay time equal to the relaxation time τ_r of the scintillation pulse causes a sudden reduction of the voltage U_d across the corresponding divider resistor R_d of about $\Delta U_d = QR_d/\tau_r$, leading to gain fluctuations. These fluctuations can be attenuated by using *reservoir capacitors* (C_r in Fig. 7). During a pulse these capacitors instantaneously supply enough charge to keep the interdynodal voltage almost constant. They are subsequently recharged with a current through the corresponding divider resistor R_d with a time constant $\tau_d = R_d C_r$. If $\tau_d \gg \tau_r$, the pulse current across R_d is spread out in time and has a much lower peak amplitude of about $\Delta U_d = Q/C_r$ (9).

Similar considerations apply for the shape of the signal pulse at the photomultiplier output. This stage consists of an effective anode resistance R_a and a capacitance C_a , forming an RC circuit with a time constant $\tau_a = R_a C_a$. Here C_a is usually not

a physical capacitor, but the stray capacitance of the anode to ground (and hence drawn in dashed lines in Fig. 7). Note that R_a and C_a include resistances and capacitances at both the photomultiplier output and the input of the following pulse amplifier (22). Two cases can be distinguished. If (1) $\tau_a \ll \tau_r$, the pulse charge is quickly passed to ground through R_a and the duration τ_o and height ΔU_o of the output pulse are determined by the relaxation time τ_r , with $\tau_o = \tau_r$ and $\Delta U_o = QR_a/\tau_r$. This mode of operation is called the *current mode*. It ensures a minimum response time and is therefore used in applications requiring fast timing. In this mode, the thermally activated pulses of the dark current can produce quite large output pulses because of their short duration. This background can be effectively eliminated in *coincidence measurements*, where two photomultipliers are coupled to the same scintillator, and a pulse is counted only if it occurs in both photomultipliers within a very small time window. If (2) $\tau_a \gg \tau_r$, the whole pulse charge is integrated on C_a before it can flow to ground through R_a . Then $\tau_o = \tau_a$ and the pulse height $\Delta U_o = Q/C_a$ is proportional to the charge Q and independent of τ_r . Hence, if the sensitivity of the counter is a constant, the energy E_p of the incident particle can be calculated from ΔU_o [see Eq. (3)]. This mode is called the *voltage mode* and is suitable for the measurement of particle energy spectra (30).

Further details about pulse amplifier and high-voltage divider circuits can be found in Ref. 31.

Optical Contact

When transiting from the scintillator to the photocathode of the photomultiplier, the luminous photons can be lost from the light pulse due to reflection from the window surfaces (see Fig. 1). These optical losses can be avoided by coupling the scintillator and the photomultiplier windows with a transparent optical grease or oil, which should have a refractive index that is in between that of the scintillator (1.45 to 1.85) and that of the glass of the photomultiplier window (≈ 1.5).

Some applications require the photomultiplier to be mounted at some distance from the scintillator, for example, because of geometrical constraints in the experiment or because of the presence of strong magnetic fields near the scintillator. In these cases, the scintillator and the photomultiplier are connected with a light guide made of Perspex or Plexiglas or a similar transparent material. Light guides are also used in order to couple scintillators and photocathodes of different sizes and shapes.

PRESENT STATE OF TECHNOLOGY AND OUTLOOK

The widespread use of scintillators has ensured that advances and improvements in scintillator technology continue. Research into new scintillating material with higher quantum yield, better-matched spectral response, improved radiation hardness (deterioration of response with exposure to radiation), faster response, or a combination of these properties is actively pursued. In addition, new methods for using scintillating materials are being developed.

The new generation of nuclear and particle physics experiments require beams of even higher energy and higher fluxes. This means the new detectors must be radiation-hard, very fast, and dense (to provide compact detectors). A very likely candidate for such a scintillator material is barium fluoride BaF_2 (32). It has a fast (subnanosecond, 0.6 ns to 0.79 ns) decay component and a slower (100 ns to 1000 ns) component. These components have different emission spectra (195 nm and 220 nm for the fast component and 310 nm for the slow component) and a large difference in decay constants, so that it is very simple to select the fast component only. A disadvantage is that the fast emission is in the UV, requiring special photomultiplier windows and photocathodes that are sensitive at these lower wavelengths but insensitive to higher (>300 nm) wavelengths. Attempts to decrease the relative contribution of the slow component include doping the BaF_2 with lanthanum. This has proved to be successful.

Other possible candidates for fast, dense, radiation-hard scintillators include cerium fluoride (CeF_3) (33) and gadolinium orthosilicate doped with cerium [$\text{GSO}(\text{Ce})$] (34). They both show excellent radiation hardness, good quantum yield, and a good spectral match with most existing photocathodes. Their main disadvantage is their relatively long decay times: 20 ns to 35 ns for CeF_3 , and even longer for $\text{GSO}(\text{Ce})$, depending on the doping concentration of Ce. Along with lutetium orthosilicate doped with cerium [$\text{LSO}(\text{Ce})$], these new scintillating materials have already been used in positron emission tomography (PET).

Advances have also been made with organic scintillators. Scintillators that are radiation-hard and have a higher quantum yield and better-matched spectral response have been developed. Radiation hardness depends on how the optical transmission properties of the base are affected by radiation and also on damage to fluor molecules. Radiation-tolerant bases have been developed by some manufacturers (35), and the effect of radiation damage to the fluor molecules can be minimized by increasing their concentration. New polystyrene bases have also been produced and tested regarding radiation hardness, quantum yield, and stability of response with time (36). To produce scintillators with better spectral response and longer attenuation length, a new class of fluors with a large Stokes shift (difference in the absorption and emission spectra) have been developed, such as 1-phenyl-3-mesityl-2-pyrazoline (PMP) and 3-hydroxyflavone (3HF). They enable the construction of larger detectors and longer scintillating fibers.

A recent application of scintillators is in *scintillating fiber trackers* (37). Such detectors consist of a large number (10^5 to 10^6) of scintillating fibers that can be either glass, plastic, or capillaries filled with liquid scintillator. The fibers can be square, circular, or hexagonal in cross section and are typically 20 μm to 50 μm across and up to several meters in length. The

scintillating fibers provide fast and efficient charged-particle tracking with position resolution down to 20 μm combined with the flexibility of instrumenting large and unusually shaped volumes. Such trackers have been used in many particle and nuclear physics experiments. Glass fibers doped with cerium oxide were the first to be implemented and produced fast and efficient trackers. However, the short attenuation length of such fibers limits their use in larger detectors. Plastic scintillators and capillaries with liquid scintillator show more promise for such applications, although a disadvantage of plastic scintillators is crosstalk between nearby fibers. The light output of such huge arrays of fibers can be detected using several different types of photosensors. If the event rate is low, image intensifiers and charge-coupled devices (CCDs) can be used. Otherwise, multianode photomultipliers, avalanche photodiodes, or visible-light photon counters (VLPCs) must be used. The last are the preferred choice, due to their spectral response, high quantum yield (70% to 80%), high gain, gain stability, and low noise level. Although for the present scintillating fiber trackers are used only in research detectors, it is only a matter of time before their excellent resolution, speed, and efficiency are made available in medical imaging (PET detectors) and other areas.

An alternative to scintillating fibers is *scintillating pads* (38). Such pads are rectangular pieces of organic plastic scintillator of area 1 cm $\times$ 2 cm and about 3 mm thick. They are coupled to photodetectors by wavelength-shifting fibers. They do not have the position resolution of scintillating fibers, but can be effectively used for triggering and tracking over large volumes.

A further method of using scintillators is in *scintillation proximity assay* (PSA). This is a technique used to trace biological molecules and analyze biomolecular interactions. Small beads of scintillator about 5 μm across are chemically coated to allow molecules such as antibodies or proteins to become attached to the bead. These molecules are labeled with a radioactive tracer such as tritium. The beads and molecules are placed in aqueous solution. When the molecule becomes attached to the scintillating bead, the radiation from the tracer causes the scintillator to emit light that can be detected by a photomultiplier or other light-sensitive device. The tracer is chosen to emit low-energy radiation, so that a bead will only emit scintillation light if the tracer molecule is very close. The scintillating beads are usually made from cerium-doped glass or some organic plastic scintillator.

Current research and development of new scintillating materials and scintillation techniques will ensure that scintillators will continue to be an important part of radiation and particle detection. New devices based on semiconductor technology have not replaced but rather enhanced the use of scintillators by providing alternative and more sensitive photosensors.

THIN FILM ANALYZERS

The term *thin films* has been applied to coatings whose thicknesses range from less than an atomic monolayer to films on the order of 1 mm thick. In addition to their well-known use as decorative or protective finishes, thin films of various types have found extensive use in the fields of electronics and optics.

This article describes a number of different thin film analyzers. Stated properly, since each film analyzer uses a number of different instruments, this article treats a number of different techniques of film *analysis* (i.e., methods and instruments used to determine experimentally such parameters as film thickness, structure, optical behavior, and material content of various types of films).

A very important application of thin films is in the field of semiconductor electronics. Although semiconductor circuits are generally fabricated on chips that are on the order of 0.5 mm thick, it is a combination of thin layers at the top of the chip that performs the electronic functions. Though structurally integral with the rest of the chip, these active layers can therefore be considered to be a set of thin films. Consequently, experimental methods of determining the structural and material content of such top layers are also those used in the analysis of thin films.

OPTICAL METHODS OF ANALYSIS

Reflectivity

The partial reflection of light at the interface between two materials of different index of refraction permits the measurement of the thickness of a transparent film. Specifically, when light of a range of wavelengths from a source in air strikes the front surface of a film of index of refraction n_1 and thickness t_1 , some of this light is reflected, and the rest is transmitted. Similarly, if the slab is either free standing or mounted on a medium of refractive index different from n_1 , some of the transmitted light is reflected from the back surface, reaches the front surface, and is again partially reflected and partially transmitted toward the source. This process is repeated ad infinitum, so that the total amount of light reflected toward the source is the sum of these individual waves, each with a phase determined by the index of refraction of the film, its thickness, and the frequency of the light. The result of this interference effect is a reflectance (i.e., the ratio of reflected to incident light), with peaks at frequencies governed by n_1 , t_1 , and the angle of incidence of the

incoming light. The film thickness can be extracted by determination of several of these peak frequencies (1,2). By using a white light source and dispersing the reflected light with a spectrometer unto a diode array, the technique can be set up for automatic data acquisition (3,4).

Alternative methods exist, such as the use of interference of light reflected from a variable thickness reference with that from the film under test, the use of a Fourier transform spectrometer, and the use of a monochromatic light source with variable angle of incidence (5–7).

For visible light, the interference technique is effective for films of thickness greater than 2000 Å.

Because of the relation of the color of light to its wavelength, the interference technique is well known in the semiconductor industry, where the thickness of a film of SiO₂ or Si₃N₄ on a silicon wafer can be easily determined by observation of the color of the light reflected from the wafer.

Transmission

Because of wave interference effects, the transmittance of a free-standing transparent film oscillates with wavelength λ . Maximum transmission for normal incidence of light occurs when the thickness of the film is an integral number of half-wavelengths (in the film). As a result, for transparent films it is found that the film thickness t_1 is given by $t_1 = (1/2n_1)(1/\lambda_a - 1/\lambda_b)^{-1}$, where λ_a and λ_b are free-space wavelengths corresponding to two adjacent maxima of transmission in the plot of transmittance versus λ (1).

If the film contains materials that absorb energy at certain frequencies within the spectrum of electromagnetic waves, these absorption peaks manifest themselves as attenuation peaks of the transmitted signal. *Transmission spectroscopy*, a technique that is very popular in the chemical industry, is the method of detecting the presence and quantity of such materials by finding the presence and magnitude of such absorption lines. Methods for converting the attenuation to the density of the absorbing material are given in the literature.

While absorption lines can be found by scanning through the spectrum with a broad spectrum source and a monochromator, a preferred method, with a great improvement in signal-to-noise ratio, is Fourier transform infrared spectroscopy (FTIR), which uses a broad spectrum source (8–10). The spectral distribution of the transmitted signal is found by taking the fast Fourier transform of the interferogram that is obtained when the transmitted signal is used as the source of a Michelson interferometer. (The interferogram is the signal output versus location of the movable mirror of the interferometer.)

Ellipsometry

The technique of ellipsometry is suitable to measurement with great precision of the thickness and index of refraction of thin, nonabsorbing films on highly absorbing substrates.

In basic ellipsometry, a beam of light that is linearly polarized at an angle with respect to the plane of incidence impinges on the film/substrate system. The components that are vertically and horizontally polarized with respect to the plane of incidence are reflected with different intensities and phases, thereby combining into an elliptically polarized beam. If the complex index of refraction of the substance is known, the reflection coefficients (i.e., the complex ratio of reflected to incident electric field for each of the two polarizations) can be used to compute the index of refraction and thickness of the film.

Films as thin as 10 Å, as well as others thousands of angstroms thick, have been measured by this ellipsometric method (11,12).

A convenient method of ellipsometry uses calibrated computer-controlled stepping motors to vary polarizations until a null output is found. Another system, the rotating analyzer ellipsometer, has high speed and high accuracy but makes more stringent demands on the optical system (13,14).

In a dynamic application of the technique, ellipsometry carried out at several frequencies has been used to monitor and control growth rate, layer thickness, substrate temperature, and ternary alloy composition in a III–V semiconductor molecular beam epitaxy system (15).

STRUCTURE

Profilometry

For some applications of thin films it is important to know the degree of flatness or the contours of a surface. An instrument used to carry out such measurements is called a profilometer.

Profilometer. A mechanical instrument that has been in use for a number of years plots a contour map by running a stylus along a surface with constant force. As an example of the performance of such an instrument, following are specifications given for the Dektak IIA Surface Profile Measuring System, distributed by Sloan Technology Corp., Santa Barbara, California:

Vertical resolution: 5 Å
Horizontal resolution: 500 Å
Stylus force: 50 mg (adjustable)
Scan length: 25 μ m to 30 mm

Scanning Tunneling and Atomic Force Microscopes. A great advance in resolution occurred with the invention of the scanning tunneling microscope (STM) (16) and atomic force microscope (AFM) (17). (The latter is also known as scanning force microscope.)

In the STM a sharp metal tip is scanned a few angstroms above an electron-conducting surface. With a few volts applied between tip and surface, an electron tunneling current flows, of magnitude exponentially dependent on the separation. As the tip is scanned over the surface, a feedback circuit maintains constant tunneling current by adjusting the tip height via a piezoelectric transducer on which the tip is mounted. A plot of the voltage applied to the transducer results in a contour image that has atomic resolution.

Alternatively, with the feedback turned off and scanning performed at constant height, variations in the tunneling current can result in an atomic resolution "current image."

Differences in the contour heights can be revealed to better than 1/100 of an atomic diameter. The lateral resolution is determined by the radius of protrusions at the tip. (A tip terminating in a single atom will have atomic lateral resolution.)

Since an STM yields a very detailed image of a surface, it can be used for surface metrology, such as measuring the line widths of lithographic patterns.

An atomic force microscope is an ultrasensitive profilometer that can produce contour images of both conducting and insulating surfaces with atomic resolution. A tip of a material such as silicon or silicon nitride that has been fastened to

the end of a cantilever of a light material, such as aluminum foil, is placed in contact with the surface to be scanned. As the surface is moved under the tip, the cantilever deflects with the topography. In one configuration, a laser beam reflecting off the cantilever falls on a two-element photodetector, which provides a feedback signal to a piezoelectric transducer that controls the tip height so as to maintain a constant (small) force between tip and surface. A plot of the piezoelectric voltage necessary to maintain this constant force is a contour map of the surface, with atomic resolution.

Extensions of the STM and AFM have resulted in a magnetic force microscope that is capable of mapping the domain pattern of thin magnetic films (18) and in an electrostatic force microscope that can measure potential or doping variations in semiconductor circuits (19–21).

Low-Energy Electron Diffraction

Low-energy electron diffraction (LEED) uses the wave nature of electrons to reveal the crystal structure of the very surface of a film (22). In LEED an electron beam of energy range 20 eV to 300 eV and of narrow energy spread is shot normally at the film. A fraction of the incident electrons is backscattered (reflected). Those that are backscattered elastically from the top few atomic layers form an electron diffraction pattern that reveals the geometry of the surface. To display this pattern in a LEED instrument, all of the backscattered electrons are first caused to pass through a set of retarding grids, to remove those that have lost some energy. The remaining ones are accelerated, to strike a fluorescent screen and display the desired diffraction pattern. Since changes in the surface, such as by adsorption of foreign molecules, often introduce new periodicities in the surface placement of atoms, these changes can be detected by observation of the displayed pattern.

Since even at a relatively good vacuum of 10^{-6} torr a surface will become contaminated in seconds, LEED measurements must be carried out with the surface that is being probed in an ultrahigh vacuum (10^{-10} torr or better).

Reflection High-Energy Electron Diffraction

In reflection high-energy electron diffraction (RHEED), also called HEED, electrons of energy of around 10 keV to 100 keV are shot at a surface at a glancing angle. The resulting diffraction pattern of these forward-scattered electrons provides information about the smoothness of a surface. Since electrons are scattered forward, it is possible in some cases to use RHEED for continuous monitoring during controlled growth of a film, such as in the deposition of thin films by molecular beam epitaxy (23).

Scanning Electron Microscopy

In scanning electron microscopy (SEM) an electron beam of approximately 10 Å to 50 Å diameter is scanned across the surface of the film that is to be analyzed. The incident electrons cause secondary electrons to be emitted. By collecting these secondaries or the backscattered incident primary electrons and displaying their intensity on a monitor, an image that relates to the film's surface structure is obtained (24–26). Since an electron's DeBroglie wavelength can be much smaller than wavelengths of visible light, the so-called far field resolution of an electron microscope is much finer than that of an optical microscope. (The wavelength of a 10 keV electron is $0.000012\ \mu\text{m}$,

while the wavelength of visible light is in the range $0.4\ \mu\text{m}$ to $0.7\ \mu\text{m}$.)

Transmission Electron Microscopy

In transmission electron microscopy (TEM), electrons are accelerated to energies of 100 keV to 500 keV, for transmission through and imaging of structures of films of thickness from a single monolayer up to a few thousand Ångströms (27). TEM is therefore analogous to optical transmission microscopy (OTM), but with a higher degree of resolution. However, unlike in OTM, where images are formed principally because of absorption, in TEM image formation is due to electron scattering or diffraction by the film.

The electrons that pass through a film in TEM form a diffraction pattern in the so-called focal plane and an image in another plane, the corresponding image plane of the electron lens system. Both can be displayed on a fluorescent screen with additional electron lenses, to provide information on crystalline phases, amorphous regions, and crystalline imperfections.

To obtain detailed local information, electrons are focused to a small spot and scanned across the film. This method is thus the transmission equivalent of SEM.

MATERIAL ANALYSIS

The preceding text has discussed what can be called the mechanical structure of a film or its surface. The following deals with determining the material composition or chemical structure of films.

Photoluminescence

Photoluminescence (PL) is a nondestructive technique that can detect the presence of certain materials, such as impurities in semiconducting films (28). To carry out PL, the specimen of interest is cooled to near liquid helium temperature and illuminated with light whose photon energy exceeds the semiconductor's bandgap, to create electron-hole pairs. When recombination takes place, the determination of the wavelengths of the recombination radiation produced identifies the impurities.

Raman Spectroscopy

In the analysis technique based on the Raman effect, a film is illuminated with a laser, the "pump," and the radiation emitted by the sample is examined for the presence of light whose frequencies differ slightly from the pump frequency (29). The amounts of the frequency shifts between the laser light and the emitted light, which are due to the parametric conversion of some of the pump energy into energy of phonons, reveal information about content and structure of the film. Spectroscopic examination of the emitted light and comparison to known shifts allow the determination of composition, degree of crystallinity, strain, alloy fluctuations, and other imperfections, such as damage due to ion implantation. This technique has been found most successful in detecting organic contaminants and in detecting stress in materials.

Electron Beam Analyzers

Auger Electron Spectroscopy. In Auger electron spectroscopy (AES), electrons of 1 keV to 25 keV are injected into the surface of a film, and the kinetic energies of electrons emitted from the

surface are measured, to form a plot of $N(E)$ versus E . Here E is the electron energy and $N(E)$ is the number of electrons emitted per unit energy increment per second. The display of the derivative of this plot, $d[N(E)]/dE$, will generally have one or more outstanding features, such as nearly vertical sharp lines. These are due to the so-called Auger electrons that are characteristic of and reveal the presence of elemental species (identified by the value of energy at the position of the sharp line) lying within the first 50 Å of the surface (30,31). In addition, slight shifts in the positions from those expected for elemental atoms or changes in line shape indicate chemical binding information.

To determine concentrations of the various species, peak-to-peak heights of the features in the derivative spectrum are used, corrected for elemental sensitivity factors.

Several ways of measuring the energy of collected electrons can be used. A preferred instrument is the cylindrical mirror analyzer spectroscopy (CMA). Its basic structure consists of segments of two coaxial cylinders, across which a variable dc voltage is applied, to select electrons of the desired energy that are to be collected (32).

Depth profiling can be carried out by alternating Auger analysis with removal of layers of material by sputter etching with an inert ion beam. Scanning AES has been carried out with electron beams focused into spots as small as 130 Å in diameter. All elements other than hydrogen and helium can be detected.

Electron Microprobe/Electron Probe Microanalysis. In electron microprobe analysis (EMP), electrons of energy 5 keV to 20 keV are injected into the surface, and identification of the elemental species is by measurement of the spectrum of emitted X-rays (33,34). In addition to a continuum in this spectrum one finds one or more sharp X-ray "lines." The latter are characteristic of the elements emitting them. For example, the presence of copper is revealed by its K-alpha line of energy 8.048 keV, corresponding to a wavelength of 1.54 Å.

Two types of X-ray spectrometers are in use: (1) energy dispersive (EDS) and (2) wavelength dispersive (WDS). Energy analysis in EDS is by a cooled lithium-drifted silicon diode that generates electron-hole pairs (ehp's). These are converted into voltage pulses, which are stored in the "bins" of a multichannel analyzer. Since the number of ehp's generated per X-ray pulse is a function of its energy, the output of the multichannel analyzer is the desired spectrum.

In WDS one or more crystals diffract(s) the X-rays to angles determined by their wavelengths. Detection is by a Geiger-counter-type of gas-filled tube.

EDS is more rapid than WDS and is therefore used more frequently for quick surveys or spatial maps. However, it has poorer energy resolution (e.g., 150 eV versus 5 eV).

Spatial resolution of EMP is on the order of 1 µm to 10 µm. While therefore not used for detecting surface contaminants, it is well suited for locating impurities within a film and determining alloy composition.

Electron Energy Loss Spectroscopy. The transmitted electrons in scanning transmission electron microscopy (STEM), in which a fine electron beam is raster-scanned across a film, can be analyzed for energy loss by sensing the current collected for different retarding voltages applied to the electrode that collects the transmitted electrons. This technique, electron energy loss spectroscopy (EELS), has been used to locate precipitates con-

taining elements that are not readily located by other techniques such as EMP (35,36).

Secondary Ion Mass Spectrometry/Sputtered Neutral Mass Spectrometry

The term *secondary* refers to particles emitted from a surface because this surface has been struck by other, or "primary," particles.

In contrast to most other methods of analysis in use, secondary ion mass spectrometry (SIMS) and secondary neutral mass spectrometry (SNMS) are destructive methods of analysis, for in these techniques ions of energy in the 1 keV to 20 keV range bombard and erode the surface of a film. Most of the products of this erosion are electrically neutral particles; a small fraction is ionized.

In SIMS these ions are sent through a mass spectrometer that reveals their charge-to-mass (Q/M) ratio and therefore identifies the composition of the emitted material. SNMS makes use of the neutral particles by ionizing them either with a strong laser beam or by sending them through a plasma chamber prior to directing them to the mass spectrometer. Progressive erosion and analysis provide information of relative density of the elements and isotopes versus depth of the film (37-43).

In an instrument called an *ion microprobe*, spatial analysis is carried out by focusing the bombarding beam to a small spot and scanning the sample, while simultaneously displaying on a screen a signal indicative of the spatial distribution of the relative density of a particular ion. To carry out the ion analysis, electrostatic quadrupole ion spectrometers, magnetic sector spectrometers, and time of flight tubes are in use. The quadrupole spectrometer comprises four parallel rods to which both a dc voltage V_{dc} and an ac voltage V_{rf} of a certain frequency are applied. Ions of a desired Q/M that will pass through the spectrometer are selected by adjustment of V_{dc} , V_{rf} , and the frequency.

In the *ion microscope*, a primary ion beam is used to flood a surface. The emitted secondary ions are passed through a "magnetic sector spectrometer." This unit preserves information of their spatial distribution while also permitting only ions of the Q/M selected by the intensity of an applied magnetic field to reach a so-called microchannel plate detector. The electric output signal of this distributed detector is used to generate a display on a fluorescent screen that is a map of the spatial distribution of secondary ions of the selected charge-to-mass ratio emitted by the surface.

To carry out depth profiling, in *static SIMS* a sputtering rate of about 1 Å/h will generally record a complete mass spectrum of the top 5 Å of a film. In *dynamic SIMS* a depth profile of the relative content of a particular ion is carried out at the rate of around 10 µm/h.

Lateral resolution of SIMS is generally around 100 µm, though it can be made as small as 1 µm. Depth resolution is on the order of 50 Å to 100 Å.

Rutherford Backscattering Spectrometry

Another technique for determining atomic composition and depth information is Rutherford backscattering spectrometry (RBS), also called high-energy (back)scattering ion spectrometry (HEIS). In RBS a film is bombarded with a beam of 1 MeV to 3 MeV He^+ or He^{++} ions, generally accelerated to this energy by

a tandem accelerator, and an energy analysis is carried out on the small fraction that undergoes elastic collisions with atomic nuclei within the film and are returned with a velocity that has a component in direction opposite to the primary beam (37–44).

The energy of a backscattered ion can be measured by a silicon surface barrier detector, which generates voltage pulses of amplitude proportional to its energy. These pulses are fed to a multichannel analyzer, which stores them in different “bins,” depending on their height. The number of pulses in a particular bin is an indication of the relative density of the particular species of atom near the surface of the film and permits calculation of the actual area density.

For atoms on the surface of the film, the ratio of the energy of a backscattered ion to the energy it had when incident on the film at a specified angle depends only on the ratio M_1/M_2 . Here M_1 is the mass of the bombarding ion, and M_2 is that of the nucleus of the atom in the film that caused it to be backscattered. Ions backscattered by atoms below the surface generally lose some energy during their passage to the surface. When these ions leave the surface, the curve of their yield versus energy is a series of quasi-rectangles, whose positions and widths provide information of the depth below the surface at which the detected atoms that backscattered the incident ions are located. It has been found that for film thicknesses less than 2000 Å the typical depth resolution is around 100 Å to 200 Å.

Applications of RBS are measurements of film thickness, uniformity, stoichiometry, and distribution of impurities. RBS has been found particularly suitable for detecting heavy elements in an environment of light elements. RBS can also be useful in determining crystallinity, through the phenomenon of *channeling*. For when a crystal is aligned so that an incident ion passes through it without colliding, the backscattering yield can decrease by as much as two orders of magnitude.

X-Ray Fluorescence

X-ray fluorescence (XRF), also known as X-ray fluorescence spectroscopy (XRFS), X-ray fluorescence analysis (XRFA), and X-ray secondary emission spectroscopy, is a nondestructive technique that can rapidly give average sample composition, including impurities. It can also be used for measuring film thickness (as thin as 100 Å) by comparing the intensity of X-ray fluorescence with that from a known standard (45,46).

In XRF a primary X-ray source illuminates the specimen, causing secondary X rays of lower energy to be emitted. As in EMP, the energy of the emitted X rays can be measured by either EDS or WDS systems. The energies identify the emitting substances; the relative intensities of emitted X-ray lines provide the information for calculating the concentrations of the emitting species. XRF can analyze areas as small as 10^{-6} cm².

X-Ray Photoelectron Spectroscopy

X-ray photoelectron spectroscopy (XPS), also known as electron spectroscopy for chemical analysis (ESCA), is a method for identifying chemical (not just elemental) species within a film (47–49). It is based on the well-known photoelectric effect, except that the incident radiation used is in the X ray, not the visible range of the electromagnetic spectrum.

In XPS a source of 1 keV to 2 keV X rays of narrow line width, obtained by using light elements (Al, Mg) as targets in the X-ray tube, illuminates a film, causing electrons to be

ejected. Since the kinetic energy of an ejected electron depends on the energy that bound the electron to the atom whence it originated, measurement of this kinetic energy reveals the type of atom or compound of origin. The resulting curve of collected electron current versus energy provides the information of the density of the various chemical species present.

Since the “escape depth” of electrons is around 50 Å, XPS is a surface analysis technique. By combining XPS with sputter erosion of a surface, a film may be depth profiled.

An advantage of XPS over methods based on the use of electron beams is that there is less danger of charging a surface with X rays, so that XPS is often a preferred choice for analysis of insulators.

X-Ray Topography

In X-ray topography (XRT) X rays are used to detect faults in the structure of single-crystal wafers or films. Basically, the film is placed at an angle with respect to the X-ray beam, to form a diffraction pattern on a photographic plate. Both film and plate are now moved perpendicular to the direction of the X-ray beam. A change in the diffraction pattern indicates a change in the crystal structure (50,51).

Neutron Activation

Neutron activation analysis is a method that can be used to find certain trace elements in a film. The method consists of placing the film into a nuclear reactor for several hours, to allow the nuclei of the trace elements to reach an excited state. After removal from the reactor, these excited nuclei “relax” by giving off gamma rays. Measurement of the energy and intensity of these with a germanium detector provides information on the presence and density of the atoms of these trace elements.

For this method of analysis to be successful, it is necessary that the host elements of the film have a half-life that is much shorter than that of the trace elements (52). An example of the use of the neutron activation technique is the detection and measurement of gold in silicon.

MACROSCOPIC FILMS

Although the term *thin film* generally refers to films whose thickness is a few microns or less, it has also been used to describe films of thickness on the order of 1 mm. Such films can be analyzed by the use of some of the techniques discussed in the previous sections, as well as by common microscopic and macroscopic techniques. Very rapid measurement of the height of a macroscopic film of liquid or solid, on the other hand, may require some special techniques, such as those discussed next.

Ultrasonic Systems

The methods of using mechanical waves of ultrasonic frequencies to measure the thickness of thin sheets or thick films are based on either “resonance” or “time of flight” measurements (53).

Techniques based on resonance utilize the fact that when an acoustic (ultrasonic) transducer is coupled to the sheet whose thickness is to be measured and the electrical input signal supplied to the transducer is swept through a frequency range, the electrical input impedance “seen” by the transducer exhibits resonance effects. If, for example, frequencies f_n and f_{n+1} are

two adjacent resonances of the same type, the thickness of the sheet is found to be $c/2\Delta f$, where c is the velocity of the ultrasonic wave in the material and Δf is the difference in frequency of the two adjacent resonances.

In time-of-flight-based instruments an ultrasonic transducer is mounted to send ultrasonic pulses through the film. If the velocity of propagation in the film is known, a measurement of the time interval between echo pulses received from the discontinuities of ultrasonic characteristic impedance at the bottom of the film and at the top of the film reveals the film thickness.

Microwave Microstrip Method

A noncontacting system for measuring the height of a film on a metal plate is based on the fact that v , the velocity of propagation of microwaves along a transmission line, depends on the dielectric constant of the medium in the line. The effective dielectric constant of a modified microstrip transmission line that has the metal plate as one conductor and a metal strip some distance above the film as the second conductor depends on the height of the film. Consequently, the determination of v by measurement of the wavelength at a fixed frequency or of the resonant frequency of a section of this line, after calibration with a "standard," provides information on the film height. In a refinement that eliminates the need for an external source of microwave energy, a section of this modified microstrip line is used to control the frequency of a transistor oscillator, thereby creating a compact, inexpensive instrument (54).

Fluorescent Dye System

To measure the instantaneous local height of a film of water, a fluorescent dye is mixed into the water. The dye is excited with a light source, causing it to fluoresce. The height of the film is determined by measuring the relative amount of light emitted from the film (55).

RADIOMETRY

Radiometry is concerned with the measurement, analysis, and interpretation of radiant electromagnetic energy. The simplest and most common measurement, made using an instrument called a radiometer, is of received electromagnetic power in a given frequency band. Some instruments, however, analyze the received energy's spectral distribution (spectroradiometers), its polarization (polarimeters), or its angular distribution in space (imaging radiometers). The usual objective of radiometric measurements is the inference from them of the physical and/or chemical state of the material from, or through, which the received electromagnetic energy has been emitted, reflected, or transmitted. Radiometry is therefore a branch of remote sensing and could be considered to include radar. In practice, however, the term *radiometry* is usually used to describe the measurement and characterisation of naturally occurring radiation, or (unlike radar) scattered radiation originating as a narrowband signal. The former, called passive radiometry, deals principally with self-emitted thermal radiation and reflected radiation of solar origin. The latter, called active radiometry, relies on artificial illumination. Figure 1 illustrates these different types of radiometer. Active radiometers are sometimes called scatterometers.

Since all radiometers depend for their operation on the measurement of one or more parameters of electromagnetic radiation, a brief review of such radiation follows.

ELECTROMAGNETIC RADIATION

Whenever charges accelerate (other than those carried by electrons in stable orbits around the nuclei of atoms), or a subatomic particle in an atom makes a transition to a lower energy level,

Reading List

To prepare this article, extensive use was made of the material of Chapters 9 and 10 of the text by D. K. Schroder entitled *Semiconductor Material and Device Characterization*, New York: Wiley, 1990. The writer gratefully acknowledges the support and initial review of the manuscript by Dr. Schroder.

In addition to this text, as well as texts dealing with various specialized topics as listed in the Bibliography, material dealing with the analysis of thin films will be found in the following:

Figure 1. Passive and active radiometry. (a) Passive measurements of self-emitted thermal radiation. (b) Passive measurements of scattered solar radiation. (c) Active (scatterometer) measurements employing monostatic geometry. (d) Active (scatterometer) measurements employing bistatic geometry.

electromagnetic energy is radiated. This energy propagates as a disturbance of the electric and magnetic fields existing in space. An electromagnetic wave propagating in an isotropic, homogeneous, medium has, sufficiently far from its source, an electric field vector, $\mathbf{E}$, magnetic field vector, $\mathbf{B}$, and unit vector pointing in the direction of wave propagation, $\mathbf{u}$, which are mutually perpendicular. Furthermore, the wave front has a curvature that is sufficiently small for it to be considered locally plane. (In a truly plane wave $\mathbf{E}$ and $\mathbf{B}$ would be constant with respect to position in any plane normal to the direction of propagation.)

For radiation of a single frequency (said to be monochromatic), $\mathbf{E}$ and $\mathbf{B}$ will vary sinusoidally with time and space. The amplitude (V/m) of such a wave is the peak value of its electric field strength, and its cyclical frequency, f (Hz), is the number of oscillations (or cycles) that the electric field completes, at a given point in space, in one second. [The radian frequency, ω (rad/s), is the phase advance in radians, at a given point in space, that the wave makes in one second and is related to cyclical frequency by $\omega = 2\pi f$.] The phase constant, β (rad/m), is the phase advance in radians that the wave makes, at a given instant of time, over one meter of space in the direction of propagation and is related to wavelength, λ , by $\beta = 2\pi/\lambda$. ($1/\lambda$ and β are therefore the spatial equivalent of cyclical and radian frequency, respectively.)

Radiation of nonzero bandwidth has an amplitude at a point in space that fluctuates over time as the phase relationships between the constituent (and elemental) monochromatic waves change. The time scale over which this amplitude fluctuation occurs is related to the bandwidth, Δf , of the radiation and is characterized by a coherence time, Δt . Coherence time is defined as the maximum time shift for which the field of the original and time-shifted waves (at a given point in space) are correlated. An equivalent quantity, coherence length, Δl , is defined (for a given instant in time) as the maximum spatial shift for which the fields of original and shifted waves are correlated. For quantitative work the term *correlated* must be interpreted as a correlation value greater than some specified fraction of its maximum. For consistent definitions of bandwidth, coherence length, and coherence time, these quantities are related by

$$\Delta l = c \Delta t = \frac{c}{\Delta f} \quad (1)$$

If the tip of the $\mathbf{E}$ vector, representing a wave at a single point in space, traces out an elliptical curve, the wave is said to be (fully) polarized. If the curve traced out is random, the wave is said to be unpolarized. A wave with an $\mathbf{E}$ vector locus that can be resolved into a deterministic component and a random component is said to be partially polarized. A fully polarized wave having a polarization ellipse with an axial ratio of 1.0, or ∞ is said to be circularly, or linearly, polarized, respectively. A linearly polarized wave therefore has an $\mathbf{E}$ vector that traces out a straight line and that, in an isotropic medium, remains in a fixed plane as the wave propagates forward.

The concepts of coherence and polarization are not entirely unrelated since a wave observed on a time scale that is short with respect to its coherence time is always fully polarized. As the observation time increases, the polarization of the wave may gradually change; however, the changes appear random on a time scale large with respect to the wave's coherence time. A wave will remain fully polarized even when observed on a time scale much longer than its coherence time if energy is radiated in one polarization only.

In passive radiometry the received electromagnetic radiation is usually incoherent, spread across a wide band of frequencies, and unpolarized. The useful measurable quantities in this case are power density (W/m^2), radiation intensity (W/sr), power spectral density (W/Hz), and angular/spatial radiation distribution. In radiometry the first three of these quantities are generally referred to as irradiance (E), radiant intensity (I), and radiant spectral flux (Φ_f), respectively. In some applications, however (microwave radiometry, for example), different terminologies are also often used (see Table 1).

DEFINITIONS OF RADIOMETRIC QUANTITIES

The commonly used radiometric quantities are as follows:

Radiant energy, Q (J)—The quantity of electromagnetic energy in a specified region of space or associated with a specified process

Radiant flux, Φ (W)—Radiant energy per unit time crossing a specified surface

Radiant density, w (J/m^3)—Radiant energy per unit volume

Radiant flux density, E or M (W/m^2)—radiant flux per unit area normal to a specified direction

Table 1. Radiometric and Photometric Quantities

Quantity	Symbol	SI Unit	Other Common Units	Defining Equation	Comments
Radiant energy	Q_e	J	erg, kWh	E	Electromagnetic energy
Radiant flux	Φ_e	W	erg/s	$\Phi_e = \frac{dQ_e}{dt}$	Electromagnetic power
Radiant density	w_e	J/m ³	erg/cm ³	$w_e = \frac{dQ_e}{dV}$	Energy density
Irradiance	E_e	W/m ²	W/cm ²	$E_e = \frac{d\Phi_e}{dA}$	Power density (also called radiant flux density)
Radiant excitance	M_e	W/m ²	W/cm ²	$M_e = \frac{d\Phi_e}{dA}$	Power density (also called emittance and radiant flux density)
Radiant intensity	I_e	W/sr		$I_e = \frac{d\Phi_e}{d\Omega}$	Angular concentration of power (also called radiation intensity)
Radiance	L_e	W sr ⁻¹ m ⁻²	W sr ⁻¹ cm ⁻²	$L_e = \frac{dI_e}{(dA \cos \psi)}$	Angular concentration of power per unit projected area of source (also called radiometric brightness, especially in microwave applications)
Luminous energy	Q_v	lm s (talbot)	lm h	$\Phi_v = K_m \int_{0.36 \mu\text{m}}^{0.83 \mu\text{m}} \Phi_{e,\lambda}(\lambda) V(\lambda) d\lambda$	Photopic definition. Scotopic definition uses primed versions of K_m and $V(\lambda)$.
Luminous flux	Φ_v	lm (lumen)		$\Phi_v = \frac{dQ_v}{dt}$	
Luminous density	w_v	lm s m ⁻³		$w_v = \frac{dQ_v}{dV}$	
Illuminance	E_v	lx (lux)	fc, ph	$E_v = \frac{d\Phi_v}{dA}$	1 lux (lx) = 1 lm/m ² 1 foot-candle (fc) = 1 lm/ft ² 1 phot (ph) = 1 lm/cm ² Also called illumination
Luminous excitance	M_v	lx		$M_v = \frac{d\Phi_v}{dA}$	Also called luminous emittance
Luminous intensity	I_v	cd (candela)		$I_v = \frac{d\Phi_v}{d\Omega}$	1 candela (cd) = 1 lm/sr
Luminance	L_v	cd/m ² (nit, nt)	sb, L, fL, asb	$L_v = \frac{dI_v}{(dA \cos \psi)}$	1 stilb (sb) = 1 cd/cm ² 1 lambert (L) = 1 cd/(π cm ²) 1 foot lambert (fL) = 1 cd/(π ft ²) 1 apostilb (asb) = 1 cd/(π m ²) Also called photometric brightness

Irradiance, E (W/m²)—radiant flux density arriving at a specified surface

Radiant excitance (or emittance), M (W/m²)—Radiant flux density leaving a specified surface

Radiant intensity, I (W/sr)—Radiant flux per unit solid angle in a specified direction

Radiance, L (W sr⁻¹ m⁻²)—Radiant intensity in a specified direction per unit projected area of the source normal to the specified direction

Radiation consisting of electromagnetic power distributed over a continuum of frequencies has infinitesimally small

power at any single frequency. Each of the preceding quantities can be characterized at a single frequency, however, by considering the quantity to be measured within a small bandwidth Δf (centered on frequency f), dividing by Δf , and taking the limit as $\Delta f \rightarrow 0$. The result is a spectral density having those units of the original quantity per hertz. (An obvious variation on this definition uses radian frequency instead of cyclical frequency.) At optical frequencies spectral densities are usually expressed as quantities per meter of wavelength rather than per hertz of frequency. A spectral density is typically indicated by preceding the quantity with the word *spectral* and adding a subscript f , ω , or λ to the appropriate symbol. Spectral irradiance, for example, can be expressed in any of the following

ways:

$$E_f(f) = \lim_{\Delta f \rightarrow 0} \left[\frac{\text{power density contained in frequency band } f - \frac{\Delta f}{2} \text{ to } f + \frac{\Delta f}{2}}{\Delta f} \right] \quad (2)$$

$$E_\omega(\omega) = \lim_{\Delta \omega \rightarrow 0} \left[\frac{\text{power density contained in frequency band } \omega - \frac{\Delta \omega}{2} \text{ to } \omega + \frac{\Delta \omega}{2}}{\Delta \omega} \right] \quad (3)$$

$$E_\lambda(\lambda) = \lim_{\Delta \lambda \rightarrow 0} \left[\frac{\text{power density contained in wave band } \lambda - \frac{\Delta \lambda}{2} \text{ to } \lambda + \frac{\Delta \lambda}{2}}{\Delta \lambda} \right] \quad (4)$$

The relationship among these various expressions is summarized by

$$E_f(f) = E_\omega\left(\frac{\omega}{2\pi}\right) 2\pi = E_\lambda\left(\frac{c}{\lambda}\right) \frac{c}{f^2} \quad (5)$$

Spectral densities may be a function of frequency and, if so, may be measured by a spectroradiometer to yield information about the source of the radiation, material through which it has passed, or a surface from which it has been reflected. Often, however, spectral densities are constant with frequency (at least over the frequency band of interest). In this case they are referred to as white and are characterized by a single value.

Related Photometric/Luminous Quantities

Radiometric quantities relate to objective measures of energy and power carried by electromagnetic radiation of any wavelength. Photometric (or luminous) quantities relate to the subjective visual impact that these quantities have on an observer (1). In practice, photometric quantities are usually measured objectively but in such a way as to reflect the visual sensation experienced by a normal human observer. This is achieved by using detectors that mimic the response of the human eye/brain system and is called physical photometry. The definition of photometric quantities therefore involves the visual response of a (hypothetical) standard observer (2). In fact two standard responses, $V(\lambda)$ and $V'(\lambda)$, called the photopic and scotopic spectral luminous efficiencies, are defined (Fig. 2). These responses correspond closely to those of human observers under conditions of high (nominally daytime) and low (nominally nighttime) illumination, respectively. (The principal reason for the difference in these two responses is that different types of retinal receptors dominate under the two conditions; cones in the former case and rods in the latter case.)

Spectral luminous efficiencies are used to define a photometric/luminous quantity corresponding to each radiometric quantity, the same symbol usually being used for both. When con-

Figure 2. Spectral luminous efficiencies: photopic, $V(\lambda)$, and scotopic, $V'(\lambda)$.

fusion between the two is possible, the radiometric version is identified using a subscript e and the luminous version using a subscript v . For photopic vision, luminous flux, Φ_v , for example, is related to the radiometric quantity, radiant spectral flux $\Phi_{e,\lambda}(\lambda)$, by

$$\Phi_v = K_m \int_0^\infty \Phi_{e,\lambda}(\lambda) V(\lambda) d\lambda \quad (6)$$

[Note that since $V(\lambda)$ is zero outside the range $0.36 \mu\text{m}$ to $0.83 \mu\text{m}$, the limits of the integral in Eq. (6) can be replaced with these values.] The coefficient $K_m (= 683.002 \text{ lm/W})$ in Eq. (6) is a conversion factor that changes radiometric units of watts (represented by the integral) into photometric units of lumens (lm). The scotopic version of Eq. (6) has identical form but is distinguished by primes added to Φ_v , $V(\lambda)$, and K_m . The value of K'_m is 1700.06 lm/W (rods, which are more sensitive than cones, dominate vision under conditions of poor illumination). The curves $K(\lambda) = K_m V(\lambda)$ and $K'(\lambda) = K'_m V'(\lambda)$, called the photopic and scotopic spectral luminous efficiencies, (Fig. 3), intersect at a wavelength of $0.555 \mu\text{m}$ ($540 \times 10^{12} \text{ Hz}$), for which $V(\lambda)$ is a maximum (unity). At this frequency, therefore, the luminous efficiency is 683 lm/W under all illumination conditions. At other frequencies the luminous efficiency is illumination dependent. The wavelength of maximum visual response for scotopic vision is $0.507 \mu\text{m}$.

Table 1 summarizes the radiometric and the corresponding photometric quantities.

Photon Flux

At optical and quasi-optical frequencies, the interaction of electromagnetic fields with matter cannot always be explained in terms of smoothly varying field quantities, and recourse must be made to quantum theory. In this description electromagnetic fields are made up of discrete, quantized packets of energy called photons. The energy, Q (joules), carried by each packet, or quanta, is related to the radiation's frequency by $Q = hf$ (J), where $h = 6.626 \times 10^{-34} \text{ (J}\cdot\text{s)}$, is Planck's constant.

Figure 3. Spectral luminous efficacies: photopic, $K(\lambda)$, and scotopic, $K'(\lambda)$.

The probability that the energy carried by a photon will be transferred to a material particle (in a detector, for example) at some specific time and location is proportional to the irradiance (power density) at that time and location. In applications where individual photons may be detected, electromagnetic power is often referred to as a photon flux.

BLACKBODY RADIATION AND EMISSIVITY

A body that absorbs all electromagnetic radiation falling on it (converting the incident radiant energy to thermal energy) and that would therefore appear black at optical frequencies is called a blackbody. Such a body, in thermal equilibrium with its surroundings, must supply precisely as much energy back to, as it receives from, these surroundings. In the absence of conduction and convection the energy transfer mechanism is limited to thermal radiation. The thermal radiant energy emitted by a body can never, therefore, be greater than that emitted by a blackbody of the same size, shape, and physical temperature. The degree of blackness of a body is quantified by its surface emissivity, defined as follows.

Emissivity, ϵ —Ratio of spectral radiant exitance at the surface of a body to the spectral radiant exitance at the surface of a blackbody with the same physical temperature

The maximum value of emissivity, corresponding to that of a blackbody, is therefore unity and the minimum value, corresponding to a surface that reflects all radiant energy falling on it, is zero. A body with an emissivity that is independent of frequency, but less than unity, is called a gray body. Many natural materials have emissivities that are frequency dependent, however, and this dependence, if measured radiometrically, can yield useful information about the material's composition and physical state.

The reflecting, transmitting, and absorbing properties of a material's surface, which can also be inferred from radiometric measurements, are quantified as follows:

Reflectance, ρ —ratio of reflected to incident spectral radiant flux at a surface

Transmittance, τ —ratio of transmitted to incident spectral radiant flux at a surface

Absorptance, α —Ratio of absorbed to incident spectral radiant flux at a surface

It is clear that

$$\rho + \tau + \alpha = 1 \quad (7)$$

The surface of a blackbody has an absorptance of unity and, therefore, a reflectance and transmittance of zero. More generally, for any opaque ($\tau = 0$) material, $\rho = 1 - \alpha$ and emissivity is numerically equal to absorptance (i.e., $\epsilon = \alpha$).

A good model of a blackbody is the surface represented by a small hole drilled in a hollow cavity. Provided that the reflectance of the interior surface of the cavity is not too close to unity, then any radiant energy falling on to the hole is reflected a sufficient number of times inside the cavity for it to be fully absorbed before it can reemerge.

The spectral radiant exitance, $M_f(f)$, of a blackbody (Fig. 4), is given by Planck's law (3); that is,

$$M_f(f) = \frac{2\pi h}{c^2} \frac{f^3}{\exp(hf/kT) - 1} \quad (8)$$

For optical frequencies, where it is traditional to express spectral quantities on a per meter of wavelength, rather than a per hertz of frequency, basis Eq. (8) can be written as

$$M_\lambda(\lambda) = \frac{2\pi hc^2}{\lambda^5} \frac{1}{\exp(hc/\lambda kT) - 1} \quad (9)$$

For $hf \ll kT$, which is appropriate for microwave radiometry at all commonly encountered temperatures, Eq. (8) reduces to the Rayleigh–Jeans approximation (Fig. 5). That is,

$$M_f(f) = \frac{2\pi}{c^2} kT f^2 \quad (10)$$

Figure 4. Planck's law for blackbody radiation.

Figure 5. Rayleigh-Jeans approximation for blackbody radiation.

[The Rayleigh-Jeans version of Eq. (9) is $M_\lambda(\lambda) = 2\pi ckT/\lambda^4$.] The spectral radiant exitance of a body with emissivity < 1.0 is therefore given by

$$M_f(f) = \epsilon(f) \frac{2\pi}{c^2} kT f^2 \quad (11)$$

Lambert's Law and Lambertian Radiators

Lambert's cosine law is that the radiant intensity from a blackbody surface is proportional to $\cos \psi$ where ψ is the angle between the direction of observation and the surface normal. Any surface (irrespective of its emissivity) that has this distribution of radiant intensity is said to be Lambertian. The radiance of such a surface (being radiant intensity per unit projected area) is independent of ψ . The spectral radiant exitance of an arbitrary surface is related to its spectral radiance by

$$M_f(f) = \int_0^{2\pi} \int_0^{\pi/2} L_f(\psi, f) \cos \psi \sin \psi d\psi d\gamma \quad (12)$$

which, for a Lambertian surface, reduces to

$$M_f(f) = L_f(f) \pi \quad (13)$$

The spectral radiance of a blackbody surface is therefore given by

$$L_f(f) = \frac{2h}{c^2} \frac{f^3}{\exp(hf/kT) - 1} \quad (14)$$

which for $kT \gg hf$ gives the Rayleigh-Jeans approximation

$$L_f(f) = \frac{2kT}{c^2} f^2 = \frac{2kT}{\lambda^2} \quad (15)$$

Radiometric Brightness and Antenna Temperatures

Consider a lossless antenna (i.e., one having an ohmic efficiency of 100%) with effective aperture area $A_e(\theta, \phi)$ receiving radiant energy from a surface S (Fig. 6). If a surface element of area dS (m²) lies at a distance R (m) from the antenna in the direction (θ, ϕ) , then the spectral radiant flux density arriving at the

Figure 6. Spectral irradiance at radiometer antenna aperture due to radiating surface element dS .

antenna due to this element is

$$dE_f = \frac{I_f(\theta, \phi)}{R^2} = \frac{L_f(\theta, \phi) dS \cos \psi}{R^2} \quad (16)$$

The power spectral density (or spectral radiant flux) received by the antenna is therefore

$$d\Phi_f = 0.5 A_e(\theta, \phi) dE_f = \frac{0.5 A_e(\theta, \phi) L_f(\theta, \phi) dS \cos \psi}{R^2} \quad (17)$$

(The factor of 0.5 accounts for the fact that the antenna will be polarization matched to only half of the randomly polarized incident energy.) The quantity $dS (\cos \psi)/R^2$ in Eq. (17) can be identified as the solid angle, $d\Omega$, subtended by the surface element at the antenna (Fig. 7). The power spectral density available at the antenna output terminals can therefore be expressed as either a surface, or a solid angle, integral; that is,

$$\begin{aligned} \Phi_f &= 0.5 \iint_S \frac{A_e(\theta, \phi) L_f(\theta, \phi) \cos \psi dS}{R^2} \\ &= 0.5 \iint_{\Omega} A_e(\theta, \phi) L_f(\theta, \phi) d\Omega \end{aligned} \quad (18)$$

The power, or radiant flux, received within a band of frequencies $f_{\min}$ to $f_{\max}$ is then given by

$$\Phi = \int_{f_{\min}}^{f_{\max}} \Phi_f(f) df \quad (19)$$

Since Eq. (18) is a power spectral density, an antenna aperture temperature, T_a , may be defined such that the noise power measured by a noiseless radiometer (i.e., one that has a noise figure of 0 dB), with a lossless antenna, is $kT_a B_N$ (where B_N is the radiometer noise bandwidth and k is Boltzmann's constant). For small B_N , such that $\Phi_f(f)$ can be considered white,

Figure 7. Solid angle subtended at radiometer antenna aperture by radiating surface element dS .

$T_a = \Phi/kB_N = \Phi_f/k$ and

$$T_a = \frac{0.5}{k} \iint_{\Omega} A_e(\theta, \phi) L_f(\theta, \phi) d\Omega \quad (20)$$

In a lossless antenna, effective area is related to antenna directivity by $A_e(\theta, \phi) = D(\theta, \phi) \lambda^2 / 4\pi$ (4), where $D(\theta, \phi)$ is the antenna directivity pattern. Equation (20) may therefore be written as

$$T_a = \frac{0.5}{k} \frac{\lambda^2}{4\pi} \iint_{\Omega} D(\theta, \phi) L_f(\theta, \phi) d\Omega \quad (21)$$

The quantity $(0.5 \lambda^2/k) L_f(\theta, \phi)$ is usually referred to as a radiometric brightness temperature, $T_B(\theta, \phi)$, allowing Eq. (21) to be written as

$$T_a = \frac{1}{4\pi} \iint_{\Omega} D(\theta, \phi) T_B(\theta, \phi) d\Omega \quad (22)$$

(In microwave radiometry the term *brightness* is often used as a synonym for spectral radiance.) The radiometric brightness temperature of a body is related to the body's physical temperature, T , by the body's emissivity; that is,

$$T_B(\theta, \phi) = \epsilon(\theta, \phi) T(\theta, \phi) \quad (23)$$

[The emissivity's dependence on ψ is not shown explicitly in Eq. (23) but is implied in its θ, ϕ dependence. The frequency dependence is suppressed only for clarity.] The first step in conventional radiometer data analysis usually requires that the radiometric brightness temperature of a particular region be estimated from a measurement of an antenna noise temperature, T_A , defined by

$$T_A = \frac{\Phi_R}{kB_N} \quad (24)$$

where Φ_R is the power supplied to the radiometer by the antenna. If the antenna has nonzero ohmic loss, the measured antenna noise temperature will comprise an attenuated aperture temperature (the aperture temperature being the temperature measured by a lossless antenna) and a thermal contribution from the physical antenna structure itself. For an antenna with ohmic (or radiation) efficiency, η_{Ω} (expressed as a per unit, not percent, quantity), and physical structure temperature, T_s , the measured antenna noise temperature will be

$$T_A = \eta_{\Omega} T_a + (1 - \eta_{\Omega}) T_s \quad (25)$$

If the antenna loss is sufficiently small, then $T_a \cong T_A$. Equation (22) shows, however, that the antenna aperture temperature is a weighted average of the observed brightness temperature in which the weighting function is the antenna directivity pattern. If the antenna has a radiation pattern with low side lobes and a beamwidth that is narrow with respect to the angular rate of change of brightness temperature, then T_a gives the required brightness temperature, in the direction of the main lobe, directly. For an imaging radiometer (which scans a beam over

some solid angle, for example, to form an image), with a beam that is not sufficiently narrow, deconvolution of the antenna pattern from the resulting image may be necessary.

Since antenna directivity and gain are related (4) by $G(\theta, \phi) = \eta_\Omega D(\theta, \phi)$, then Eqs. (22) and (25) can be combined and written as

$$T_A = \frac{1}{4\pi} \iint_{\Omega} G(\theta, \phi) T_B(\theta, \phi) d\Omega + (1 - \eta_\Omega) T_s \quad (26)$$

In the absence of significant atmospheric effects (losses and scattering), Eq. (26) shows that an adequate knowledge of antenna ohmic efficiency and antenna gain pattern will allow the brightness temperature of a surface (with a spatial resolution determined by the antenna beamwidth) to be found from a measurement of antenna noise temperature. [The noise figure of the radiometer must be considered, of course, when making this measurement (5).]

Atmospheric Loss and Scattering

If atmospheric effects cannot be neglected, then the brightness temperature inferred from Eq. (26) must be interpreted as an apparent brightness temperature since it will comprise a contribution from the target surface plus a contribution from the thermal emission of the atmosphere itself. Furthermore, the thermal radiation from each source (i.e., each surface element of the target and each volume element of the atmosphere) will be attenuated by the loss associated with the intervening atmosphere. Since atmospheric thermal emission is essentially isotropic, half of the thermal energy from each element is radiated upward (called upwelling radiation) and half is radiated downward (called downwelling radiation). For a downward-pointing radiometer (such as might be used in planetary-surface remote sensing applications), downwelling radiation may be reflected by the ground back into the antenna's main lobe. The contribution of this ground-scattered radiation will depend on the ground-reflectance and the integrated specific attenuation along the ground-reflected path to the radiometer. An upward-pointing radiometer (such as might be used in terrestrial atmospheric remote sensing applications) observes downwelling radiation from the atmosphere directly. The contribution from ground-scattered downwelling radiation, and ground thermal emission, will now be coupled into the antenna through its downward-pointing side or back lobes. The significance of this radiation will depend on the gain of these lower hemisphere lobes and the brightness temperature of the region within the antenna's main lobe. (If a microwave radiometer with high antenna gain is pointed at high elevation angle into a clear sky, well away from any discrete sources of radiation, then the brightness temperature observed by its main lobe may be as low as a few degrees kelvin. Radiation emitted by, or reflected from, the ground may, under these conditions, be a very significant source of measurement error.)

The preceding description assumes that the atmosphere is an absorbing, but nonscattering, medium. For an atmosphere filled with scattering particles, or more general scattering inhomogeneities, this simplified description is inadequate. [The operating wavelength, and the physical size and composition of inhomogeneities, will determine whether they act as significant scatterers or not (6).] In this case more rigorous theories

must be used to account for, and interpret, observed radiometric measurements (7).

APPLICATIONS

The most important application of radiometry lies in remote sensing of the earth's surface and its atmosphere (8). Polar ice mapping, for example, is possible using passive microwave radiometers located on earth-orbiting platforms. Microwave radiometry is especially useful for ice mapping because the contrast in emissivity between ice and water is particularly large at microwave frequencies. Furthermore, since passive microwave radiometry depends on self-emitted thermal radiation, and since the earth's atmosphere is essentially transparent at the microwave frequencies used, then data collection does not rely on solar illumination or the absence of cloud cover. (A requirement for solar illumination is particularly problematic in the polar regions, of course, due to the absence of the sun in winter.) Knowledge of annual, and longer term, changes in the extent of the polar ice shelves is important in the field of climatology generally and to recent concerns about possible climate change in particular.

Other surface materials (e.g., water/rock/sand) can be discriminated using microwave radiometers, and soil moisture mapping is also possible (9). Radiometer measurements applied in this area are of obvious interest in climatology, agriculture, and environmental science. Processes of desertification, like changes in the polar ice cover, are of concern in the context of global warming.

A rather different application of microwave radiometry concerns the development of the worldwide satellite communications network. Since a material's thermal emission and absorption are directly related, a brightness temperature measured at a given frequency can be used to infer the attenuation that an electromagnetic wave of that frequency would experience when propagating along the path observed. Ground-based, upward-pointing microwave radiometers can therefore be used to estimate the expected statistics of earth-space signal attenuation for use in the design of microwave satellite communication systems (10). The dominant mechanism resulting in large attenuation is the presence of precipitation along the path. Measurements of this type can, therefore, also be used in conjunction with appropriate signal attenuation/rain rate models to estimate rainfall intensity statistics for hydrological applications. (In recent years, however, the use of meteorological radar has probably become the preferred rainfall remote sensing tool.)

Active microwave radiometry can, like its passive variant, operate independent of solar illumination and is immune to cloud cover (and, depending on frequency, other meteorological phenomena that may make the atmosphere opaque). Downward-pointing scatterometers, for example, can be used to map surface wind velocities by measuring the effective reflectance of the ocean surface. The technique used in this application depends on the fact that the received signal for a nadir pointing, monostatic scatterometer decreases as the wind speed increases and the water surface becomes rough. This is due to the tendency of the reflected energy to be scattered in many directions by the rough surface, rather than reflected, specularly, back along the illuminating path. The apparent reflectance of the ocean surface can therefore be used as a measure of wind

speed. Other reflectance measurements, using forward- and side-looking radiometer beams, allow wind velocity to be inferred since the reflecting facets of the waves have a preferred orientation that depends on wind direction.

Downward-pointing, millimeterwave, spectroradiometer observations of brightness temperature around the absorption/emission lines of a homogeneously mixed atmospheric constituent can be used to estimate the vertical temperature profile of the atmosphere. Oxygen, which has a cluster of closely spaced resonance lines around 60 GHz, is often used for this purpose (11). The basic principle of such temperature measurements is as follows. The brightness temperature observed at any given frequency represents a weighted mean taken over the observed path. The weighting factor at a particular altitude depends on the density of the oxygen at that altitude and on the attenuation of the intervening atmosphere. Thus at high altitudes (near the radiometer) the contribution to total brightness will be small because the density of the gas is low. At low altitudes (far from the radiometer) the contribution to total brightness will also be low because the intervening atmosphere will greatly attenuate this contribution. The observed brightness temperature will therefore be dominated by a region of the atmosphere at some intermediate height. If measurements are made across a band of frequencies coincident with the skirt of an atmospheric constituent's absorption band where atmospheric attenuation changes rapidly with frequency, then the height from which the dominant contribution arises also changes with frequency. In this way a brightness temperature versus frequency profile can be transformed to a brightness temperature versus altitude profile.

In a related area, microwave radiometry has been applied in the estimation, using zenith pointing radiometers, of integrated atmospheric water content (both liquid and gaseous phases). The large specific, and latent, heats of water mean that mapping of this quantity is important in understanding the global energy balance. If spectroradiometer measurements are made across a significant band of frequencies close to the water vapor absorption line at 22 GHz, then the water vapor's density profile can be inferred. The technique here is essentially the same as that described previously in the context of temperature profiling using the 60 GHz oxygen absorption line(s). The temperature profile is first estimated (using the oxygen line, for example), and the brightness temperature versus frequency profile in the skirt region of the water vapor's absorption line is transformed to a brightness temperature versus altitude profile. The water vapor's density at a given altitude is then inferred from the brightness at that altitude. Similar measurement can be used to find vertical profiles of many other atmospheric constituents with applications to environmental monitoring and pollution control.

Infrared radiometry (especially at 4 μm and 11 μm) can be used for ocean surface temperature mapping with obvious applications to meteorology and climatology. In practice, both these frequencies, and at least one other intermediate frequency, are usually required in order to correct for errors introduced by atmospheric water vapor and scattering by atmospheric aerosols. Multifrequency measurements can yield data with accuracies of 1 K.

Chlorophyll, the dominant pigmentation in most species of plants, has absorption lines close to 440 nm and 650 nm corresponding to the blue and red parts of the visible spectrum, thus giving vegetation its predominantly green color. [In fact,

there are two distinct varieties of chlorophyll, blue-green and yellow-green, which both have absorption lines located about 10 nm either side of these frequencies (11).] In the near infrared region, however, absorption by chlorophyll is very low and reflectance correspondingly high. Infrared and visible reflectance measurements can, together, yield information about the photosynthetic capacity of selected areas of the biosphere (12). The presence of pigmentation other than chlorophyll can also be detected by spectroradiometric measurements and used to discriminate between different plant species. Furthermore, water absorption lines at 1.45 μm and 1.95 μm allow the water content of plant material to be estimated from infrared measurements. High-resolution, multiband, visible and infrared radiance measurements can thus be used to assess the quantity, variety, health, and photosynthetic vigour of much of the earth's surface vegetation.

Visible multiband measurements of radiance can also be used to gather information about the phytoplankton of the oceans' surface layers. A particular problem associated with these measurements is that upwelling radiation originating in the intervening atmosphere must generally be accounted for. One solution relies on the fact that the oceans do not contribute to upwelling radiance in the red part of the spectrum. Measurements in the red region of the spectrum over the oceans can therefore be used to estimate atmospheric upwelling radiance, which in turn can be used to infer atmospheric contributions at other wavelengths.

INTERFEROMETERS AND SPECTROMETERS

INTERFEROMETERS

Interferometers are instruments that measure the phase difference of waves. They allow waves to propagate and interfere inside them and yield interference fringe patterns. From the fringe patterns that the interferometer gives one can determine the phase difference of waves and perhaps other parameters such as length, thickness, displacement, angular velocity, pressure, sound, temperature, magnetic field, and so on. This article concerns only optical interferometers. They are operated over the light (ultraviolet, visible, and infrared) wavelength range from several hundred nanometers to ten micrometers. Other interferometers such as microwave interferometers, radio interferometers, and x-ray interferometers also use electromagnetic waves. Their principles are similar to those of optical interferometers.

There are many kinds of interferometers, such as the Michelson–Mach, Zehnder, Fabry–Perot, and Sagnac interferometers. The widely used Michelson interferometer has two separate optical paths, as shown in Fig. 1(a). The light beam from the optical source S is split into two beams at the semireflecting semitransmitting mirror SM and propagate along paths 1 and 2, respectively. After being reflected by two mirrors M_1 and M_2 , the two beams recombine at the semireflecting mirror SM to yield interference patterns. By moving the mirror in one path, one can change the phase difference of lightwaves in two paths and therefore find fringes shifting. The Michelson

interferometer is often used to measure length, displacement, and many other parameters.

The Mach–Zehnder is another useful interferometer in numerous measurement fields. It can transmit more optical power emerging from the light source to the receiver than the Michelson interferometer. The Mach–Zehnder interferometer also has two separate light paths (more often called *arms*) as shown in Fig. 1(b). A light beam from the optical source S is split at the first semireflecting mirror into two beams. After propagating along the two arms, respectively, the two beams are recombined at the second semireflecting mirror to yield interference. The fringes will shift as the difference of the optical path lengths between arm 1 and arm 2 varies. Because the two arms are separate, various bulk modulators, e.g., electrooptic modulators, Bragg cells, and Faraday magneto-optic modulators, can be inserted in the optical paths. Modulators provide modulations in phase, frequency, and/or polarization states of light waves. They have played important roles in various detection systems.

The Fabry–Perot interferometer belongs to the multiple-beam category of interferometers and comprises two parallel partially transparent plates, as shown in Fig. 1(c). The light beam from the optical source passes through one plate at an angle and enters the cavity between the two plates. The beams are reflected between the two plates repeatedly, and when they emerge gradually from both sides of this cavity, called the Fabry–Perot cavity, they form, respectively, two types of multiple-beam interference fringe patterns. This kind of interferometer produces sharp fringes owing to the multiple reflection. The half-width of the bright fringe is related to the reflectivity of the inner surface of the plate. The higher the reflectivity, the narrower the half-width. The Fabry–Perot interferometer is useful for temperature measurement, optical filtering, and the study of the fine structure of spectrum lines.

Fiber-optic interferometers have formed a rather large and important category among the various interferometers. In fiber-optic interferometers, the lightwave propagates in the optical fiber rather than in the air. As the fiber is flexible, the direction of the light propagation can vary continuously, which is impossible for air-path interferometers. Environmental factors can influence the fiber by changing its dimensions and the refractive indices of its materials, and therefore result in the variations in the phase difference and the polarized state of lightwaves. These influences cause noises and errors in measurements, but on the other hand, they offer the fundamentals of various sensing schemes (1). The relation between the light phase shift and the external factor is quite complicated in practical situations. It depends on the nature of the measurand and the material and structure of the fiber used. The fiber-optic interferometer generally uses a single-mode optical fiber, permitting only one mode to propagate inside it. There is birefringence in the practical fiber that produces the two orthogonal polarization waves that propagate with different phase velocities. Perturbations couple the two polarization modes and thus give noise at the output. The use of the high-birefringence fiber can prevent coupling between the two modes.

Much effort has been spent to apply fiber-optic interferometers to pressure, strain, temperature, acoustic wave,

magnetic field, and rotation rate measurements (2). Figure 2 shows schematically several useful fiber-optic interferometers. In these arrangements, bulk devices such as semireflecting mirrors and modulators are replaced by their waveguide counterparts. The measurands induce the phase shift of the signal arm. Fiber-optic interferometers usually use the phase modulators to improve their performance. The phase modulator changes the optical path length of the reference arm and leads to the phase shift of the light wave. As the length of the fiber in the measurand field can be increased readily, the fiber-optic interferometer is apt to reach higher measurement sensitivity than the air path interferometer.

The principle of the fiber-optic interferometer is similar to that of its air path counterpart. Fig. 2(a) shows the fiber-optic Michelson interferometer. The optical beam from a laser launches to the coupler and divides into two beams there. After being modulated in each arm by measurand and modulator, respectively, the two beams recombine at the same coupler and give rise to interference. Compared with the fiber-optic Michelson interferometer, the fiber-optic Mach-Zehnder interferometer has two couplers, as shown in Fig. 2(b). The coupler at which the two light beams are recombined is different from the one at which the light beam is split. Obviously, as the phase difference varies, the output of the photodetector varies.

Figure 2(c) shows the basic configuration of the fiber-optic Fabry-Perot interferometer. There are two reflecting faces inside the optical fiber. In many cases, one reflecting face is just the surface end of the fiber. The fiber portion between the two reflecting faces constitutes a Fabry-Perot cavity. When the measurand changes the optical path length of the cavity, the phase difference of light beams proceeding to the photodetector is changed.

The fiber-optic Sagnac interferometer has a common ring path for two optical beams propagating in opposite directions. Nonreciprocal factors such as rotation rate generate a nonzero phase difference between the two light waves. As shown in Fig. 2(d), light from the optical source is split at the coupler into two beams, which then counterpropagate in the fiber coil. When the fiber coil rotates clockwise about its axis, the clockwise light beam takes a longer time to travel between two fixed points in the fiber coil than the anticlockwise light beam. So there exists a nonzero phase difference between the two counterpropagating lightwaves. This interferometer can be used for inertial navigation as a gyroscope.

The properties of light sources and photodetectors play important roles to interferometer performances (1-3). In most cases, interferometers use lasers as their optical sources because the laser light has a good spatial coherence and a good temporal coherence. Both light sources and photodetectors can introduce noises. There are many noises in interferometers, such as shot noise, thermal noise, $1/f$ noise, mode-mode interfering noise, and so on, which produce errors in output. Perturbations due to the fluctuation in the optical source intensity and the variation in the polarized state of lightwaves also result in errors. A well-designed setup and an appropriate detection scheme can reduce the influences of noises. There are numerous detection schemes, and many of them suit more than one interferometer.

BASIC FORMULAE FOR INTERFERENCE

The interference of two light waves gives a superposed optical field as follows

$$\mathbf{E}(t) = \mathbf{E}_1(t) + \mathbf{E}_2(t)$$

where $\mathbf{E}_1(t)$ and $\mathbf{E}_2(t)$ represent the optical vectors of the two light waves to be superposed. The fringe intensity as well as the output of the photodetector depends on the optical power of the light wave rather than the instantaneous value of the amplitude of the light wave. Thus the fringe intensity can be written as (4)

$$I = I_0 + I_0 \mathcal{V} \cos \phi$$

Here ϕ denotes the phase difference of the two light waves, I_0 is a constant proportional to the light source intensity, and $\mathcal{V}$ gives the interference term that is related to the mixing efficiency. The fringe intensity depends on the phase difference ϕ . When $\phi = m\pi$, $|m| = 0, 1, 2, \dots$, I reaches its maximum I_a , and when $\phi = m\pi$, $|m| = \frac{1}{2}, 3/2, 5/2, \dots$, I equals minimum I_i . The distinctness of the fringe pattern can be specified by the visibility of fringe or the fringe contrast that is defined as $(I_a - I_i)/(I_a + I_i)$.

The visibility of fringe is related to the spatial coherence, the temporal coherence, and the polarized direction of the light waves used. *Spatial coherence* describes how close a practical light source approaches a point optical source. When a practical light source is an extended one, the different points in the source will produce different light waves with different phases at the observing point. Thus the interference effect due to one emitting point of the light source may be counteracted partially by another point of the light source, which results in the

decrease of the visibility of fringe. On the other hand, when the light wave from the optical source is not a strictly monochromatic one, the visibility of fringe will decrease even if the light source is a point source in the case that the phase difference of light waves is large. *Temporal coherence* describes how near a practical light source approaches a monochromatic optical source. According to quantum mechanics, the light wave emerging from an atom is a wave train with a finite length in the time axis. This temporal finite length is called *coherence time*. The interference will occur when light wave trains are overlapped partially, that is, when the time difference of the light wave trains is less than the coherence time. There is a relation between the coherence time $\Delta\tau$ and the spectral width $\Delta\omega$ of the light which can be written as

$$\Delta\tau\Delta\omega \geq 1$$

which means that the wave train is not infinitely long unless the light is a strictly monochromatic one. Another important parameter specifying the temporal coherence is the *coherence length* l_c , which is defined as

$$l_c = c\Delta\tau$$

where c is the velocity of light. Generally speaking, the visibility of the fringe will be reduced as the difference between the optical paths increases, and will approach zero as such difference becomes much greater than the coherence length. However, practical experiments show that even if the path difference is several times longer than the coherence length, the interference effects can still be seen (2).

The polarized directions of the light waves can also affect the visibility. For the linearly polarized situation, when the polarized planes of the two superposed light waves are parallel, $\mathcal{V}$ has a maximum value; whereas when they are orthogonal, $\mathcal{V}$ becomes zero.

CONFIGURATIONS, PRINCIPLES, AND APPLICATIONS OF INTERFEROMETERS

Michelson Interferometer

The Michelson interferometer is shown schematically in Fig. 3. Light waves propagating along paths one and two are recombined at the semireflecting mirror or the coupler to give rise to interference fringe. Under illumination by an extended source, the interference produces fringes of equal inclination localized at infinity if the mirror M_2 and the image of the other mirror M_1 are parallel, and fringes of equal thickness localized near M_2 if they are mutually inclined at a small angle. When the interferometer is illuminated by a white-light source, one can see only zeroth-order fringe and some low-order fringes. High-order fringes are invisible because of the short coherence length of the white light. The fringe pattern can be converted into current or voltage by use of the photodetector. The output of the photodetector that responds to the optical intensity of the fringe will vary as the mirror moves. Obviously the output of the photodetector has a one-cycle variation as the mirror moves a distance equal to half an optical wavelength $\lambda/2$. When the difference of the optical path length between paths 1 and 2 equals $m\lambda$ where $|m| = 0, 1, 2, \dots$, the output of the photodetector reaches its maximum, and when such difference

Figure 3. (a) The air-path Michelson interferometer that measures displacement of the plate M_1 . (b) The fiber-optic Michelson interferometer that is used as the interferometric sensor. L , laser; SM , semireflecting, semitransmitting mirror; M_1 , M_2 , mirrors; C , coupler; D , photodetector.

equals $m\lambda$ where $|m| = 1/2, 3/2, \dots$, the output of the photodetector reaches its minimum (4). Measuring these electric signals, one can obtain at least $\lambda/2$ or 300 nm of displacement resolution.

For the fiber-optic Michelson interferometric sensor, the variation measurand alters the length, diameter, and refractive index of the sensing fiber and thus results in the phase shift of the light wave. Take the temperature measurement as an example. In this case, the sensing fiber is attached to the thermal-sensitive material, whereas the reference fiber is attached to the thermal nonactive material. The variation in temperature makes the sensing material as well as the sensing fiber spread and contract so that the phase difference is changed. This kind of thermometer can attain a sensitivity of the order of 1×10^{-5} K (5).

The Michelson interferometer can be used to measure displacement, length, temperature, pressure, gas flow, spectrum distribution, and many other factors.

Mach-Zehnder Interferometer

Figure 4 shows the schematic of a typical Mach-Zehnder interferometer. The output of the photodetector reaches its maximum when the difference of the optical path lengths nl between

Figure 4. The Mach-Zehnder interferometer, which can transmit more optical power to the photodetector than the Michelson interferometer. (a) The air-path. (b) The fiber-optic. *L*, laser; *SM*, semireflecting, semitransmitting mirror; *M*₁, *M*₂, mirrors; *C*, coupler; *D*, photodetector; *PM*, phase modulator.

two arms 1 and 2 satisfies

$$nl = m\lambda, |m| = 0, 1, 2, \dots$$

and minimum when nl satisfies

$$nl = m\lambda, |m| = 1/2, 3/2, 5/2, \dots$$

where n is the refractive index and l is the path difference of the two arms (1).

For the fiber-optic Mach-Zehnder or other type of interferometers, the detectable phase shift usually has to be as small as 10^{-6} rad or less. Thus the noises caused by lasers, photodetectors, and other components cannot be ignored (2,3). For a stable and reliable readout, an appropriate detection scheme is necessary.

The detection schemes can be classified as homodyne with phase tracking, homodyne without phase tracking, and heterodyne. The homodyne (3) detection system is illustrated in Fig. 5. The output voltages (or currents) of the photodetectors are of

the form for this case

$$\begin{aligned} V_1 &= V_0[1 + \mathcal{V}\cos(\phi_s - \phi_r + \phi_n)] \\ V_2 &= V_0[1 - \mathcal{V}\cos(\phi_s - \phi_r + \phi_n)] \end{aligned} \quad (1)$$

where ϕ_s is the phase shift in the signal arm induced by the measurand, ϕ_r is the phase shift in the reference arm produced by modulation, and ϕ_n is the phase difference between the two arms that is due to noise and other disturbance. In this case, V_0 is the constant proportional to the optical power of the laser. $\mathcal{V}$ is the parameter related to fringe contrast. To obtain the maximum sensitivity, the system should satisfy the quadrature condition, that is, $\phi_s - \phi_r + \phi_n = 2m\pi \pm \pi/2$. The phase-tracking homodyne scheme uses the feedback control technique to maintain the quadrature condition. The electronic circuit transforms V_1 and V_2 into the feedback voltage V_m that applies to the piezoelectric transducer (PZT) device to stretch the reference arm to change ϕ_r . Under the quadrature condition, V_1 and V_2 are proportional to the phase shift induced by the measurand, approximately if this phase shift is small.

Besides the above dc modulation manner, the interferometer can be operated in the dc-ac hybrid modulation way. In this case, V_m is the sum of dc and ac voltages. The dc voltage produces a dc phase bias to maintain quadrature condition, and the ac voltage induces a phase variation with the modulation frequency to facilitate phase detection. The output V_1 can be achieved by $J_1(\max)$ method (6). One advantage of this ac modulation is the attainable high SNR because of the possible use of the lock-in amplifier in the system. Both the dc modulation scheme and the dc-ac hybrid scheme have drawbacks. They have resetting noise and are complicated in structure. However, in practice, the phase-tracking schemes can work quite well.

The no-phase-tracking homodyne system does not need feedback control. In contrast to the phase-tracking homodyne arrangement, the no-phase-tracking homodyne arrangement has a rather simple structure. It avoids the reset problem involved in the phase tracking operation. There are many no-phase-tracking homodyne schemes. Figure 6(a) shows schematically the system using a 3×3 coupler. The beams along the two arms recombine together at the 3×3 coupler instead of at a 2×2 coupler and give rise to outputs different from those given by Eq. (1). Through signal processing with appropriate electronic circuits, a result proportional to the phase difference is achieved. It has been reported that a minimum detectable phase shift of 3×10^{-6} rad at 1 kHz and a dynamic range of 10^7 were attainable for this detection scheme (7).

Figure 6(b) shows another no-phase-tracking homodyne scheme, called homodyne demodulation. The output of the photodetector V_1 in this case has the same form as that in Eq. (1). Because of the ac modulation, V_1 can be written as

$$\begin{aligned} V_1 &= V_0 + V_0 \mathcal{V} \{ [J_0(M) - 2J_2(M) \cos 2\omega_m t + \dots] \cos(\phi_s + \phi_n) \\ &\quad + [2J_1(M) \cos \omega_m t - \dots] \sin(\phi_s + \phi_n) \} \end{aligned} \quad (2)$$

where J_i denotes the Bessel function of order i , and M is modulation depth. Multiplying the first harmonic (ω_m) by the derivative of the second harmonic ($2\omega_m$), then subtracting the product of the second harmonic and the derivative of the first harmonic, and finally integrating this difference, one can obtain a result varying directly with $(\phi_s + \phi_n)$. As the signal ϕ_s and the noise ϕ_n are usually within different bands, it is not difficult to

Figure 5. The basic form of the phase-tracking homodyne system. *L*, laser; *C*, couplers; *D*₁, *D*₂, photodetectors.

remove ϕ_n by filtering. Dandridge et al. have shown that the detectable phase shift of 10^{-6} rad at 1 kHz was attainable with this scheme (8).

The $J_1 \dots J_4$ method is also a useful no-phase-tracking homodyne scheme, as shown in Fig. 6(b). The ac phase modulation is not necessary here where the interferometer is used to measure dynamic phase changes. The output of the photodetector *D* has a form similar to that of Eq. (2). According to the recurrence relation of the Bessel functions, the following expression can be obtained

$$X^2 = \frac{4i(i+1)V(i)V(i+1)}{[V(i) + V(i+2)][V(i-1) + V(i+1)]}$$

Here X is the modulation depth induced by the measurand and $V(i)$ is the voltage amplitude of the i th frequency component of the output voltage of the photodetector. This approach has removed the need of stabilizing the source intensity and polarization control, which is welcome in practical applications (9).

The heterodyne detection system uses frequency modulators to produce a frequency shift. The output of the photodetector is an FM signal in this case. It has the form of

$$V_o = 2V_0 \mathcal{V} \cos[(\omega_s - \omega_r)t + \phi_s(t) + \phi_n]$$

where ω_s and ω_r are two angular frequencies of light waves in the signal arm and the reference arm, respectively.

Another heterodyne system is called synthetic heterodyne system. This system uses the PZT element as the frequency modulator. The output signal of the interferometer is calculated or "synthesized" before entering the FM discriminator. The processed signal has the form of

$$V_s = 2V_0 \mathcal{V} J_1(M) \cos(3\omega_m t + \phi_s + \phi_n)$$

The advantage of the heterodyne scheme is that neither feedback circuit nor resetting arrangement is required. The drawback of this method is that the oscillator phase noise and the laser amplitude noise can affect the detection result (10).

The frequency of the laser diode can be modulated by its driving current or the temperature around it. This characteristic provides another heterodyne detection possibility. Interferometers using FM laser diodes have been demonstrated for measuring the impurity inside the fiber and the length of the fiber as distributed sensors (11). They are also useful for multiplexed systems.

Other schemes such as that using two or more light beams with different wavelengths, that using an amplitude modulator rather than a phase modulator, and that using passive compensation with quarter-wave plate are also found in some interferometers.

Fabry-Perot Interferometer

The Fabry-Perot interferometer consists of two parallel plates whose inner surfaces are coated with partially transparent

Figure 6. (a) The no-phase-tracking homodyne system using 3×3 coupler. (b) The passive homodyne system using demodulation or $J_1 \dots J_4$ method. L , laser; C , 2×2 couplers; D , D_1 , D_2 , photodetectors; PM, phase modulator.

high-reflectivity films, as shown in Fig. 7(a). Light beams entering the Fabry–Perot cavity will reflect many times between the two plates before going out of the cavity. To generate multiple reflection in the cavity, the plate surface must have high reflectivity, often >0.9 . This can be implemented by coating the surface with multilayer dielectric films.

Because of the multiple reflection in the Fabry–Perot cavity, the Fabry–Perot interferometer gives rise to sharp bright fringes for transmitted beams and sharp dark fringes for reflected beams. The relations between the output light intensities and the reflectivities are specified by Airy's formulae, which are written as follows:

$$I^{(t)}/I^{(i)} = T^2 / [(1 - R)^2 + 4R \sin^2(\phi/2)]$$

$$I^{(r)}/I^{(i)} = 4R \sin^2(\phi/2) / [(1 - R)^2 + 4R \sin^2(\phi/2)]$$

where $I^{(i)}$ denotes the incident optical intensity, $I^{(t)}$ the transmitted optical intensity, $I^{(r)}$ the reflected optical intensity, R and T are the reflectivity and the transmissivity of the plate surface, respectively, and ϕ is the phase difference of multiple light waves. The finesse is a parameter for specifying the sharpness of the fringes. It is defined as the ratio of the separation distance of adjacent fringes and the half-width of the fringe. The greater the finesse, the smaller the half-width and the narrower the fringes.

Figure 7. (a) The Fabry–Perot interferometer. (b) The basic configuration of fiber-optic Fabry–Perot interferometric sensor. L , laser; C , coupler; D , photodetector.

For the transmitted rays, the difference of multiple light waves is of the form (4)

$$\phi = (4\pi/\lambda)nL \cos \theta + 2\phi_d$$

where L is the separation distance between the two plates, θ is the incident angle, and ϕ_d is the additional phase change on internal reflection. Conventionally, the Fabry–Perot interferometer with fixed L is referred to as the *Fabry–Perot etalon*.

One application of the Fabry–Perot interferometer is the study of the fine structure of spectral lines. The Fabry–Perot interferometer is suitable for this work because it can give very narrow fringes. In this situation, another parameter, called the free spectral range, is used to specify the upper limit of the wavelength difference between the two light waves. When the wavelength difference approaches this upper limit, the displacement between the two fringe patterns will approach the separation distance of two adjacent fringes of any fringe pattern. Introduction of some auxiliary device, for example, a prism, into the instrument can eliminate this problem.

Another application of the Fabry–Perot interferometer is optical filtering. The Fabry–Perot interferometer only transmits the specific wavelengths that fall into the narrow pass-band corresponding to the sharp bright fringes. Therefore the

Figure 8. The arrangement of the extrinsic fiber-optic Fabry-Perot interferometer. There are two Fabry-Perot cavities in this system; one is a sensor and one is a modulator. *L*, laser; *C*, coupler; *D*, photodetector.

Fabry-Perot interferometer can serve as bandpass filter. Use of the PZT element can make this optical filter electrically tunable. In this case, applied voltage makes PZT elements stretch or contract so that the length of the Fabry-Perot cavity as well as its passband are varied.

A typical arrangement of the fiber-optic Fabry-Perot interferometric sensor is shown in Fig. 7(b). The measurand changes the optical path length of the cavity and therefore the phase difference of light beams proceeding to the photodetector. The fiber-optic Fabry-Perot interferometric sensors are suitable for measurements of temperature, pressure, and vibration. The materials of the Fabry-Perot cavity can be different from those of the optical fiber, which makes possible the application of the fiber-optic Fabry-Perot interferometric sensor to some specific measurements. Reference (12) gives an example of high temperature measurement. In this case, the sensor is a ceramic Fabry-Perot cavity connected by a multimode uncoated sapphire fiber. The report showed that it attained a resolution of 0.2°C over a range of 310° to 970°C.

Since there is no separated reference arm for the fiber-optic Fabry-Perot interferometer, a particular phase bias arrangement should be designed. Figure 8 shows an example of this. There are two Fabry-Perot cavities in this system, one is used as the remote sensor and the other as the modulator. The two Fabry-Perot cavities are modulated at two different frequencies, respectively. The output of the photodetector is the sum of the infinitely many harmonic terms. In this output the phase shift induced by the measurand can be determined by use of the Bessel recurrence relation. This detection system can eliminate the influences due to source intensity variation, fringe contrast fluctuation, and random phase drift and provide a linear readout of the phase shift (13).

FIBER-OPTIC SAGNAC INTERFEROMETER

The Sagnac interferometer is an instrument that detects the nonreciprocal phase difference of two counterpropagating lightwaves. The measurement of rotation rate as a gyro is perhaps the most important application of this interferometer. The basic configuration of the fiber-optic gyro is shown schematically in Fig. 9. The rotation of the fiber coil about its axis makes

Figure 9. The basic structure of the fiber-optic Sagnac interferometer with phase bias. It is an open-loop system. The phase modulator is placed close to one end of the fiber coil to produce effective phase modulation. *S*, optical source; *C*, coupler; *D*, photodetector.

the two optical paths unequal for the two counterpropagating beams so that a nonzero phase difference is produced between the two light waves. It can be verified that this Sagnac phase difference is

$$\phi = 8\pi NA\Omega/\lambda c$$

where Ω is the rotation rate, and N and A are the number of turns and the area of the fiber coil, respectively (14). This phase difference is nonreciprocal. Its magnitude and sign depend on the rotation rate and direction. Nevertheless, since the interference intensity varies with $\cos \phi$, the sensitivity fades completely as the rotation rate approaches zero. Moreover, the rotation direction cannot be discriminated in terms of the output of the photodetector in this situation. To solve this problem, several methods have been devised to introduce a nonreciprocal 90° phase bias into the system.

The detection schemes for the fiber-optic gyro are classified as open-loop scheme and closed loop scheme. Figure 9 shows an open-loop system. It is an all-fiber phase-bias gyroscope. An ac phase modulator PZT is inserted into the fiber loop to introduce 90° phase bias. It seems that this modulator cannot produce the nonreciprocal phase bias because the changes in paths would be identical for the two light waves. However, in practice, as the two counterpropagating light waves pass through the PZT device at different moments, the path lengths for the two lightwaves are different. The relation between the output and the phase difference is similar to that shown in Eq. (2). In this case, fiber polarizers and polarization controllers may be required to maintain the identical polarization paths. The main feature of this arrangement is that all its components are constructed on a continuous optical fiber. This helps to remove

Figure 10. The typical arrangement of the phase-nulling fiber-optical gyro, where the frequency modulator rather than the phase modulator is used. S, optical source; D, photodetector; FM, frequency modulator.

the noise caused by reflections at the joints of components. The experiment shows that this interferometer has a phase error of 2×10^{-6} rad, corresponding to $0.2^\circ/\text{h}$ of long-term stability (15).

Figure 10 shows a phase-nulling fiber-optic gyroscope. A frequency modulator rather than the phase modulator is used in this closed-loop system. The two light waves counterpropagate along the fiber coil before and after passing through the frequency modulator, and produce a beat-frequency signal that reflects Sagnac phase shift. Through the feedback system, this beat-frequency signal makes the frequency change in such a way that the phase shift due to this frequency change just nulls out the Sagnac phase shift. There are two difficulties involved in this scheme: one is the need for a low frequency modulator and the other is about the dispersion of fiber. Some methods are available for eliminating these problems (3).

The heterodyne scheme can also be used to detect the Sagnac phase shift. In this system, a frequency modulator such as the Bragg cell is employed to modulate the frequency. The FM signal with an intermediate frequency includes the information of the Sagnac phase shift. The electronic circuit discriminates this FM signal. To prevent the influence of backscattering light waves, a coding technique by which the modulation frequency varies in a triangular fashion is used. The heterodyne system can eliminate the influence of the $1/f$ noise and avoid the AM effect (16).

A special problem for the Sagnac interferometer is the influence of coherent backscattering light waves that result in unwanted interference. One method to eliminate this influence is the use of incoherent sources such as the superluminescent diode, which emits short-coherence-length light.

Besides rotation rate, other factors such as current can produce nonreciprocal phase difference in the fiber-optic Sagnac interferometer. The current passing across the fiber coil generates a magnetic field. The Faraday effect induces a nonreciprocal phase shift between the two circularly polarized light waves counterpropagating through the fiber coil. It is verified that this nonreciprocal phase shift is proportional to the current. Many practical disturbances to the measurement can influence the measurement accuracy. P-A. Nicati et al. have analyzed disturbances to the Sagnac interferometer (17).

Figure 11. The basic form of the Twyman-Green interferometer, which is used to test the deformation of the plate. S, light source; SM, semireflecting, semitransmitting mirror.

The Twyman-Green interferometer is the variant of the Michelson interferometer. Figure 11 shows the basic form of the Twyman-Green interferometer. It uses broad beams, and it can be used to test the parallelism of the wave fronts of two light waves. The observer will see a uniform illumination if the two wave fronts are parallel and distinct fringes if there is some distortion between them. The fringes will shift as the mirror moves. The shifting direction is related to the distortion direction. The feature of this interferometer makes it possible to test the surface flatness of large objects.

Heterodyne detection scheme and image sensors such as the CCD linear array and area array are usually employed to receive the spatially distributed fringes produced by the Twyman-Green interferometer. The heterodyne detection system transforms the sign of the phase difference, which depends on the distortion direction of the tested surface, to the sign of the time difference of the zero crossing of the sensing signal and that of the reference signal. Thus the spatial distortion of the surface can be determined by measuring the temporal phase difference between the sensing signal and the reference signal (18).

The fiber-optic dual-mode interferometer is a one-fiber interferometer, that is, there are two modes propagating in only one fiber rather than one mode propagating in two separate fibers. This kind of interferometer is useful in temperature and pressure measurements. The variation of the temperature leads to the variation of the phase difference between the two modes and therefore makes a fringes shift. W. Eickhoff has demonstrated a scheme for measuring temperature which used the highly and linearly birefringent fiber with internal lateral stress and had a sensitivity of $1.66 \text{ rad} \cdot \text{K}^{-1} \cdot \text{m}^{-1}$. The advantage of such an interferometer is that variation of source intensity does not influence the readout (19).

In the resonant ring interferometer the output beam reenters the interferometer to produce resonance. Because there is multiple-beam interference in the ring, this interferometer, like the Fabry-Perot, can give rise to sharp fringes. It can measure various parameters with high sensitivities and resolutions. Figure 12 shows two basic forms of the resonant ring interferometer (20).

Figure 12. Two forms of resonant ring interferometers, in which a portion of output light is fed back into the interferometer. *C*, couplers.

Other interferometers such as Young's interferometer and the Jamin interferometer are also useful in practical applications (1).

RECENT DEVELOPMENTS

Many effective interferometric schemes have been advanced during the past decade. White-light interferometers utilize wideband light sources. With white light it is possible to discriminate the zeroth-order fringe readily and thereby make absolute measurements. T. Li et al. have given an example of a white-light Michelson interferometer for absolute distance measurement (21). An interferometer combination has also been used for absolute measurement (22). Recently, multiplexing of white-light fiber-optic interferometric transducers has been demonstrated for temperature and pressure measurement (23). A digital technique has been incorporated with the interferometer. A compact interferometer with PC interface has been reported for displacement measurement (24). A heterodyne double-pass differential interferometer with a PC-based control system is used to calibrate the subnanometric displacement actuator, whose uncertainty reaches 0.7 nm (25).

The measurement abilities of the interferometer have been greatly expanded. Besides displacement, length, vibration, temperature, pressure, strain, acoustic waves, current, magnetic field, and rotation rate, applications of interferometers to measurements on gravitation and gravitational waves (26, 27), energized underground electric cables (28), hydrocarbon pollutants in the bulk of a liquid (29), and dipole-orientation distributions of a polymer (30) have been reported. Recently, many specially designed Sagnac interferometers have been demonstrated for measurements (for example) of surface profiles (31), chromatic dispersion of fibers (32), and rotation rate (33). An all-optical Sagnac interferometer can largely eliminate the

influence of the source intensity noise, with a noise suppression ratio of 35 for an unmodulated system (34).

There is much interest in the interferometric spectrometer. Chern and Chao introduced an enhanced Michelson interferometer in connection with a modified forward-backward linear prediction algorithm. It eliminates the drawbacks of the conventional FFT method, which involves a large amount of calculation (35). For spectrum measurement, it has been reported that use of the correlated unbalanced interferometric method can attain a resolution 100 times better than that of the Fabry-Perot interferometer or on the order of 0.5 kHz in some special situations (36). Some research shows that the Fabry-Perot interferometer acts as a low-pass device in response to time-varying optical input (37). A longer cavity can provide higher spectral resolution, but may result in worse dynamic response. Similar conclusions can be drawn for the ring interferometer.

Another development related to spectral devices is the electrically tunable optical filter, which is useful in communication systems for wavelength-division multiplexing. In 1990 Patel reported a Fabry-Perot interferometric filter whose cavity is filled with nematic liquid-crystal material. The voltage applied to the device regulates the refractive index of the material in the cavity, rather than the length of the cavity, to change the passband. This kind of electrically tunable optical filter has a simple structure. It consumes less power than conventional devices. However, it is polarization-sensitive. An improvement has been made by using the same material but with twisted structure. In this case, when the applied voltage was sufficiently high (2 V), the device was polarization-insensitive. The experiment showed that the linewidth of the transmission peak of this device is about 0.5 nm. Its response time is of the order of millisecond. Further research results have shown that the substitution of a ferroelectric liquid crystal for the nematic liquid crystal can increase the response speed of this kind of optical filter (38).

Similarly to the interference in the time domain, interference between two light waves can occur in the frequency domain. One can see this phenomenon even if two light-wave trains are separated by a time interval longer than the wave-train duration. Figure 13 schematically shows a frequency-domain interferometer useful for the study of femtosecond phase spectroscopy. There are three pulses propagating in this interferometer: probe, excitation, and reference. They pass

Figure 13. The frequency-domain interferometer for study of femtosecond phase spectroscopy. *S*, optical source; *M*, mirror.

through the same sample at different moments. The reference pulse passes through the sample first, followed by the excitation pulse and finally the probe pulse. The reference pulse does not experience the change in the complex refractive index caused by the excitation pulse, but the probe pulse does. One can determine the femtosecond phase spectrum in terms of the interference between the probe and the reference pulses with and without excitation. The advantage of this method is that there is no need for accurate temporal overlapping of the femtosecond pulses (39).

Misawa and Kobayashi constructed a femtosecond interferometer. They designed a Sagnac interferometer for measurement of continuous phase spectra with white light. The zeroth-order fringe of white light can be found readily in the Sagnac interferometer because of its reciprocal structure. The sample is inserted into the optical loop. The reference pulse arrives at the sample earlier than both the excitation and the probe pulse. The probe and reference pulses propagate in opposite directions, and the probe pulse reaches the sample after the excitation pulse passes through it. According to the interference results between the probe pulse and the reference pulse, one can estimate the nature of the sample (40).

Besides the measurement of femtosecond phase spectra, the interferometer finds application in the generation and detection of ultrafast optical signals. A mode-locked ring laser was reported to have a pulse output with 0.4 ps width (41). A simple common-path-designed Sagnac interferometer was demonstrated for detection of ultrafast optical signals; it is operated at normal incidence with an objective for pumping as well as probing (42). An interferometer can also be used in the study of soliton collisions (43).

Nonlinear or digital use of the interferometer is an attractive research area. Figure 14 shows the block diagram of a hybrid bistable and multistable interferometer (44). With the help of electronic feedback, the interferometer can be

operated in a bistable or multistable state. In this case, the external light input minus the output of the interferometer controls the injection current of the laser diode. The bistable and multistable states are observed in the output from the laser diode. Besides this hybrid arrangement, all-optical devices such as the twin-core fiber nonlinear Mach-Zehnder interferometer (45) and the bistable fiber-optic unbalanced Michelson interferometer (46) are available for bistable operation. Jinno and Matsumoto reported a nonlinear Sagnac interferometer. Highly stable logic operations, including Inversion, AND, OR, and XOR, were achieved at multigigabit-per-second rates (47).

Some new bistable schemes have been discussed recently. Figure 15 shows a fiber-reflection Mach-Zehnder interferometer. It is able to switch the light from reflection to transmission or vice versa by changing the phase difference of light waves when couplers have splitting ratios in a range ($0.146 < \kappa < 0.854$). Beyond this range the interferometer transmits most of the light and reflects only a small portion of it—a feature that will make this interferometer useful for optical switching (48).

ACOUSTIC WAVE INTERFEROMETERS

Propagation of sound in a medium is a wave phenomenon and thus exhibits interference. In fact, interference is observed when two coherent waves are allowed to be superimposed in space. It is possible to obtain two coherent waves by splitting a single wave either at its wavefront, by passing through two or more apertures, or in its amplitude, by reflection and transmission at the interface of media of different phase velocity and/or density. The interference pattern at any point depends on the phase difference (relative time delay) caused by the propagation of these initially coherent waves through different acoustic paths.

When two sound waves interact with a particle of the propagation medium, the resultant displacement, velocity, and pressure are the vector sum of the effects due to the separate waves. If the final distribution of energy for this particle is different from what it would have been for each separate wave, interference has occurred. This phenomenon may be used to determine the relative physical properties of the media through which these waves have traveled prior to their superimposition. If two or more coherent waves propagate along a different acoustic path with respect to the reference material or to each other, their superimposition produces fringes (i.e., alternating regions of constructive and destructive interference, with a maximum or minimum of intensity, respectively). The shape of these regions depends on the geometry of the media causing the path difference. Thus a properly designed acoustic interferometer (or an interferometer, in general) behaves as a differential device since it transforms the phase difference of the initially coherent wave into intensity modulation.

A variety of experimental acoustic (and ultrasonic) techniques for material characterization have been developed in recent decades: for example, time-of-flight methods, photoelastic and acoustoelastic techniques, pulse-echo overlap methods, and phase detection methods (1). Among all these techniques, the interferometric ones, based on the aforementioned phenomenon of interference, present several advantages as far as accuracy and reproducibility of the measurements are concerned. In fact, they are not based on the measurement of absolute values, like other techniques, but rather on the determination of differences between reference signals and perturbed ones (e.g., phase shifts, frequency shifts) (2). Such differences are responsible for destructive or constructive interference between signals, which can be measured with high precision by using simple experimental setups. Other advantages of acoustic interferometry are as follows:

1. Its applicability to very small samples
2. Its ability to measure simultaneously both velocity and attenuation
3. The possibility of using noncontact detectors
4. The higher precision that may be obtained from the direct measurement of the difference between unperturbed and perturbed quantities

A proper logical control device is connected to the detector in order to trigger, both in amplitude and frequency, the signal generator of the acoustic wave until a specific interferometric pattern is achieved. This capability is exploited when the interferometric device is used to measure the triggering required for reproducing the same pattern under different external conditions. In this case the precision and sensitivity of the instrument can be highly enhanced.

Although all interferometers are based on the same simple general principle, several different realizations may be designed. First, acoustic waves may interfere directly or can be used to produce an electric signal or to modify the path of an optical wave, and then be used for interference. Second, different techniques may be used for generating the path difference. The simplest way is to let the wave experience multiple reflections at the interfaces of the propagation medium. Alternatively, the input and output signals may be correlated or two different input signals injected in different locations may be used.

Acoustic interferometers are used both for measuring the actual phase velocity and attenuation factor of the propagation medium and for evaluating their variation in the presence of a perturbation (e.g., pressure variation, presence of impurities) with respect to a reference case (ambient pressure, homogeneous specimen, etc.). In the first case, the physical properties are directly correlated to the position and intensity of the maxima and minima of the interference pattern. In the second case, higher accuracy may be obtained if some device characteristics (e.g., position, frequency) are properly modified in order to reproduce the same interference pattern as in the unperturbed case (in particular, the conditions for destructive interference).

To obtain constructive and/or destructive interference fringes, the acoustic path difference between the two interfering beams must be at least one-half of a wavelength. This puts constraints on the specimen thickness (or allowed variation of

it) and the frequency of the acoustic wave employed. For low frequencies, one may need a thicker specimen in order to obtain several fringes, whereas for higher frequencies the required variation in an acoustic path may be smaller, provided that the attenuation is low enough to have a signal-to-noise ratio greater than one.

Acoustic interferometric techniques may be realized by means of a proper experimental setup or a specific interferometric device. In the next section, we discuss the first case, in which interference of acoustic waves is realized and the interference pattern is directly sensed by a transducer. The following section is devoted to the description of indirect interferometric techniques, which analyze the interference in an electronic device (e.g., an oscilloscope) between the electric signal feeding the transducer and the one induced by the acoustic wave at the receiver. Then the operational principles of quadrature detector systems, which may be used to improve the performance of interferometers, are briefly described. Since in recent years great effort has been devoted to developing techniques based on optical sensors and interferometers, in the last section a brief comparison is made between acoustic and other interferometric techniques.

DIRECT ACOUSTIC INTERFEROMETRIC TECHNIQUES

In direct interferometric techniques the interference occurs among acoustic waves and the interference pattern is sensed by a transducer. One of the earliest demonstrations of acoustic interference was carried out by Quincke in 1866 (3) by using an apparatus suggested by J. Herschel. It consisted of a tube, which branched into two tubes differing in length by an odd number of half wavelengths of sound in air and joining again at the other end into a single tube. Stewart (3) modified this interferometer by using equal-length branches but varying the frequency in order to obtain interference. A more sophisticated tool for measuring the velocity in gases consisted of a column formed by an ultrasonic transducer and an adjustable reflecting piston (4).

In more recent times, a simple setup, called a standing wave acoustic interferometer, has been used for the characterization of molten materials, such as metals or alloys, and dense fluids (5,6). A continuous wave (cw) is injected from the left side of a sandwich, composed of two external layers (A) of known properties and an intermediate layer (B) of the molten or fluid material, whose acoustic properties need to be determined (Fig. 1). The output signal is detected by a receiver (R) at the right side of the setup. The impedance mismatch at the interfaces between the materials A and B generates multiple reflections that interfere with each other. A resonant constructive standing wave is formed when the thickness x of the layer B is equal to integer multiples of half wavelengths, while antiresonant conditions

Figure 1. Scheme of a standing wave acoustic interferometer for the determination of the acoustic properties of the material B.

Figure 2. Interference pattern obtained with the standing wave acoustic interferometer.

occur when

$$x = (n + 1/2) \frac{\lambda}{2} \quad (1)$$

By varying the thickness x (and the geometry) of B, the transmitted ultrasonic signal traces out an interference pattern with alternating maxima and minima (Fig. 2). By fitting the curve amplitude versus thickness, according to simple theoretical expressions, the phase velocity and attenuation factor may be easily calculated.

A particularly suitable setup consists of two movable metal rods partially submerged in a tank containing the molten material. Thus the thickness of B can be easily varied with continuity. In this case, the analytical expression for the wave amplitude at the receiver is given by (5)

$$\frac{1}{|A|} = \frac{1}{4} \sqrt{\frac{2(4 + H) \cosh\left(\frac{\beta x}{Q}\right) + 8F \sinh\left(\frac{\beta x}{Q}\right)}{+ 2(4 - H) \cos(2\beta x) - 8G \sin(2\beta x)}} \quad (2)$$

where F , G , and H are functions of the acoustic impedances of the rod and the molten material and β and Q are the real part of the wave number in the molten material and the quality factor, respectively. Both may be evaluated through a least-squares fitting of the experimental data (Fig. 2) with Eq. (2). Thus, the same measurement allows one to compute the phase velocity v_B and the specific attenuation factor α for the medium B:

$$v_B = \frac{\omega}{\beta}; \quad \alpha = \frac{\beta}{2Q} \quad (3)$$

where ω is the known carrier-wave frequency.

Several effects may affect the accuracy of the standing wave acoustic interferometric technique (e.g., beam spreading in layer B or lack of parallelism and flatness of the A faces). However, the technique is rather accurate as far as the measurement of the velocity is concerned.

A similar approach has been used (7) for determining the speed of sound in gases by evaluating the resonant frequencies in a cylindrical interferometer. A transducer is used for generating an acoustic wave in a gas inside an acoustical cavity. Longitudinal modes are formed, due to interference between multiple reflecting waves, with resonance frequencies

$$f_n = \frac{u}{2L}(n + \delta) \quad (4)$$

where L is the length of the cavity, u the sound speed, n the order of the resonance, and δ a phase shift correction due to the finite diameter of the cavity. The resonant frequencies are measured through an oscilloscope, and a fitting with Eq. (4) yields optimal values for the parameters u and δ .

INDIRECT ACOUSTIC INTERFEROMETRIC TECHNIQUES

In indirect acoustic interferometric techniques the interference occurs between the electric signal feeding the transducer and the one induced by the acoustic wave at the receiver. The simplified circuit diagram (neglecting almost all electronic components) of a typical interferometric device (8) is reported in Fig. 3. A generator feeds a signal into a doubler (not reported in Fig. 3), which splits the signal into two components, called reference and testing signals. The latter is amplified by a power amplifier and converted into an ultrasonic pulse by a piezoelectric (or other) transducer. The signal detected by the receiver passes through a low-noise amplifier and is recombined in the region H with the unperturbed reference signal, thus producing interference. In Fig. 3(b), a zooming of the region H is reported for a two-channel quadrature detection system (described later) (9). Before interference the reference signal is split in A into two arms in quadrature. Then each one is combined in C with the testing signal split in B into two arms in phase. The two channels are usually named cosine and sine channels.

This technique is particularly efficient for evaluating the variations of a physical parameter of the specimen due to external perturbations. For such a purpose, the frequency of the reference signal is modulated in order to maintain quadrature (i.e., a destructive interference) when the intensity of the

Figure 3. (a) Simplified circuit diagram for an indirect acoustic interferometric setup. (b) Scheme of the quadrature detection system.

perturbation is changed. The fractional change in the interferometer frequency with respect to the nonperturbed case gives, through simple relationships, the variation of the physical parameter.

To clarify the method, we discuss its use (10) for the determination of the acoustic nonlinearity parameter B/A , defined as

$$\frac{B}{A} = 2\rho_0 c_0 \frac{\Delta c}{\Delta p} \quad (5)$$

where ρ_0 is the medium density, c_0 the sound velocity, and Δc the velocity variation resulting from a pressure change Δp for an isentropic transformation. A sample material maintained at a constant temperature is pressurized with different values of p . For each pressure, the effective path length between the transducers changes due to a variation of the sound velocity in the propagation medium. An adjustment of the transmitted frequency is necessary in order to maintain quadrature. Then the parameter B/A can be easily evaluated from the fractional change in the interferometer frequency $\Delta f/f_0$ necessary to maintain quadrature:

$$\frac{B}{A} = 2\rho_0 c_0^2 \frac{\Delta f}{f_0 \Delta p} \quad (6)$$

where f_0 is the reference frequency. In this situation the velocity variation is measured with a very high accuracy (up to 1%).

A similar approach is based on the measurement of the cross-correlation function between the signals from the receiver (R) and the transmitter (T) (8,11–19). For example (11,12), continuous waves of suitable frequency (1 MHz to 20 MHz) are split into two parts. One portion of these waves excites an immersion transducer, while the other (reference signal) is fed into a phase-sensitive detector. The specimen is submerged in water and oriented in such a way that the incident beam scans its surface at a fixed angle. Receiver and transmitter are mounted on the same bridge and initially located and oriented so that the received signal (testing signal) is maximum. The amplitude of the signal resulting from the crosscorrelation between the reference and testing signals is measured for different positions of the transducer. It depends, of course, on the length of the effective acoustical path of the testing wave from T to R , leading to plots similar to the one reported in Fig. 2.

When the geometry of the specimen is properly defined, this crosscorrelation technique leads to results that can be easily interpreted in terms of the relevant physical variables. A particularly interesting case occurs when the material specimen is cut in the shape of a wedge (11) (Fig. 4). In fact, if the material

is homogeneous, the only difference between waves entering the wedge at different locations (e.g., T and T' in Fig. 4) is their length y of propagation path within the material, since all other factors, such as boundary conditions, remain identical. Therefore, the results depend only on the interference effects and are not affected by the angular dependence of reflection, refraction, and mode conversion, which in general greatly complicate the physical picture.

Assuming that the wedge angle is small, the ultrasonic signal S_T , sent by the transmitter, and S_R , received by the transducer R , are given by

$$\begin{aligned} S_T &= F_T A_0 \cos(\omega t + \Phi_0) \\ S_R &= T_{12} T_{21} F_R A_0 \exp[-\alpha_1(l-y) - \alpha_2 y] \\ &\quad \cos\left(\omega\left\{t - \left[\frac{l-y}{v_1}\right] - \frac{y}{v_2}\right\} + \Phi_0\right) \end{aligned} \quad (7)$$

where F_T and F_R are the response factors of the transmitter and of the receiver and associated electronics; T_{12} and T_{21} are the transmission factors between water and the specimen material and vice versa; α_1 , α_2 , v_1 , and v_2 are the attenuation coefficients and phase velocities in water and in the material, respectively; A_0 is the initial amplitude of the cw; and l is the fixed distance between the transducers T and R .

After some algebraic manipulation, one finds that the cross-correlation factor between the two signals S_T and S_R is given by (11)

$$\Psi = \Psi_0 + C \exp(-\alpha y) \cos(by + \Phi) \quad (8)$$

where Ψ_0 , C , α , b and Φ are parameters that can be found by least-squares fitting the experimental curves (see, e.g., Fig. 5a). Since

$$\alpha = \alpha_2 - \alpha_1 \quad (9)$$

$$\beta = \omega \left(\frac{1}{v_2} - \frac{1}{v_1} \right) \quad (10)$$

one immediately obtains the attenuation coefficient and phase velocity for the material, since the values of the corresponding quantities for water are well known. It is worthwhile to remark that Fig. 5(a) yields α_2 and v_2 by simple inspection, since α_2 is given by the coefficient of the envelope curve $\exp(-\alpha y)$ and v_2 by the distance between successive maxima and minima.

This technique may also be used for the detection of flaws in the material specimen. In fact, in the presence of defects the crosscorrelation plot is locally modified [see Fig. 5(b)] and from the difference between the two plots (the so-called signature of the defect) the main features of the flaw may be evaluated.

Since for practical purposes material plates are much more important than wedges, the method has been extended to the treatment of plates (12). The main ingredient (i.e., the continuous variation of the acoustic path in the material specimen y) is obtained by slowly varying the angle of incidence. Also in this case it is possible to obtain the attenuation coefficient and phase velocity of the material through a best fitting of the theoretical formula. The fitting formulas are, however, more

Figure 4. Experimental setup for indirect interferometric measurements of the acoustic slowness and attenuation in a wedge-shaped material specimen.

Figure 5. Typical experimental crosscorrelation curves obtained using the wedge-shaped specimen shown in Fig. 4. (a) Specimen without defects. (b) Specimen with a hole drilled into it. The frequency is in both cases $f = 11$ MHz.

complicated and the measured attenuation is no longer absolute, since there are boundary effects depending on the incidence angle.

QUADRATURE DETECTOR SYSTEMS

A quadrature detector system is an interferometer based on comparison between the correlations of the testing signal with two reference signals in quadrature in two different channels (cosine and sine channels). To illustrate the operation of an ideal quadrature detector system (see Fig. 3), let us consider a wave train of angular frequency ω and wavelength λ crossing a path length L in a medium with propagation velocity c . If $w = \cos(\omega t)$ is the transmitted signal, the received signal is

in the form

$$s = A \cos\left(\omega t - \frac{2\pi L}{\lambda}\right) \quad (11)$$

where A is its amplitude. The testing signal is then demodulated in the two channels of the quadrature detector with two reference signals $u = 2 \cos(\omega t)$ and $v = -2 \sin(\omega t)$. Neglecting high-frequency contributions (filtered out by a low-pass filter), the two detected signals are $u_1 = A \cos(2\pi L/\lambda)$ and $u_2 = A \sin(2\pi L/\lambda)$. The pair (u_1, u_2) are components of a vector $\mathbf{u}$ with constant modulus, which rotates when L varies. The number of fringes η crossed by the vector $\mathbf{u}$ can be easily counted by recording the zeroes of u_1 and u_2 . The change in path length is then given by

$$\Delta L = (\eta + F) \frac{\lambda}{4} \quad (12)$$

where F is the fractional number of fringes, obtained by interpolation between the counts.

All interferometers with quadrature detector systems are affected by a set of errors (9), which in many cases severely limit the precision and accuracy of the measurements. These errors are due to a lack of quadrature between the reference signals (the phase shift is not exactly $\lambda/4$), to an unequal gain in the detector channels, and to an error in the zero offsets of the device. Moreover, in real systems, due to electronic and mechanical overtones (nonlinearity), higher-harmonics effects are always present and will severely affect the evaluation of transient times. Therefore, while for an ideal quadrature detector system the precision is limited only by the system noise, in real cases the endpoint of the vector $\mathbf{u}$, is no longer on a circle and F is affected by an error, causing errors in ΔL up to a few percent of λ , which is very large compared to the accuracy of a good interferometer. If r is the channel gain ratio, p and q are the offsets in the cosine and sine channels, and α is the reference signal quadrature error, the output signal from the detector becomes

$$u_1^D = u_1 + p \quad (13)$$

$$u_2^D = \frac{1}{r}(u_2 \cos \alpha - u_1 \sin \alpha) + q \quad (14)$$

describing an ellipse. The real signals can, however, be easily reconstructed from the ones used in Eqs. (13) and (14), since we are considering systematic errors and therefore the corrections p , q , r , and α must be calculated only once. By several measurements of u_1^D and u_2^D for a few sets of known values of ΔL , the parameters p , q , r , and α can be obtained by least-squares fitting the distorted ellipse equation to the experimental data. Such an approach allows one to reach a resolution on the order of 10^{-8} m, 100 times higher than the one obtained with uncorrected data.

By using a similar approach, it is possible to introduce corrections taking into account the transformation of the ellipse into a deformed ellipse due to the presence of higher-order harmonics. Such corrections are obtained by using the least-squares method iteratively (20).

OTHER INTERFEROMETRIC TECHNIQUES

There are many other types of devices, e.g., acoustic spectrometers (21) and acoustic microscopes (22) which use the underlying principles of interferometry for their operation but have not been labeled as interferometers. Acoustic spectrometers are used to measure frequencies of mechanical resonances (standing waves in the thickness of the specimen) caused by interference between the normal incident acoustic waves and the ones reflected from the back surface of a parallel plate. These resonances are obtained by varying the frequency of the incident plane wave or by varying the thickness (e.g., corroded steel plates) for a broadband incident pulse. The resonant frequencies and Q -factor of these resonances are used to compute phase velocity and attenuation. Both of these quantities can be used to characterize the material.

The acoustic microscope is also an example of a device based on interference phenomena. It can be designed for various applications to materials and tissue characterization. For example, a specially designed acoustic lens (with aperture angle larger than Rayleigh critical angle) facilitates the oscillations in a quantity $V(z)$ which is the record of the modulus of the measured voltage as a function of the z distance between the focal point of the acoustic lens and the specimen surface. These oscillations are due to interference between the normal specular reflection from the fluid-loaded surface of a solid specimen and a ray passing through the Rayleigh critical angle. The velocities and attenuation of elastic wave propagation mode can be obtained from the periodicity and decay of $V(z)$. Theoretical fit of the velocities with those obtained from $V(z)$ determines elastic constants which are useful for characterization of thin films deposited on an elastic substrate (see Achenbach et al., Ref. 23).

Different types of interferometers based on optics have also been developed (e.g., the Mach interferometer) for the purpose of detecting the gas flow in supersonic wind tunnels. Displacements of the interference fringes in the optical wavefront, traveling normal to the gas flow and the reference beam, can be used to determine the density change in the gas flow. A coupling of the light beam to the specimen (gas flow) does not perturb its initial phase. Conversely, ultrasonic nondestructive evaluation may require the use of contact transducers, which perturb the system and therefore the accuracy of specific measurements. For instance, wave attenuation measurements are severely limited by the mode conversion of the wave at the interface between the medium and the transducer. In fact, such an effect becomes, in many cases, the dominant contribution to the measured attenuation factor. To overcome this difficulty, considerable effort has been devoted to the development of optical techniques for the generation and detection of ultrasonic waves. Such techniques are based on the so-called photoacoustic effect; for example, the generation of an ultrasonic pulse through a laser beam incident on an elastic specimen (24) and the evaluation of the acoustic wave amplitudes through modulations of the optical phase of a light beam (25–31). In the latter, the phase shift may be demodulated to a change in optical intensity through an optical fiber interferometer. The acoustic wave amplitude and/or the acoustic properties of the medium can be easily obtained from these measurements. Optical methods are particularly suitable for determination of the dispersion law of the medium, since optical interferometers measure directly the phase shift for any given frequency of the induced wave.

Figure 6. Simple scheme for a fiber optics sensor.

Without going into details, which are beyond the scope of this article, we illustrate the photoacoustic effect in Fig. 6, based on a Michelson-type interferometer (25–27). Let us consider an elastic medium with surfaces polished or coated with a reflective tape M [e.g., Mylar (32) tape] in order to increase its reflectivity. A transducer T driving a continuous plane wave produces standing waves at discrete frequencies. A light beam generated by a polarized laser L is launched into a fiber optic system through a beam splitter B . One arm (reference arm) is launched into a fixed-length light guide F . The other (signal) arm is sent to the sensor S , where it is collimated through a cylindrical lens and reflected off the vibrating surface. The reflected back reference and signal arms are then brought to interfere with each other and an intensity-varying output signal is created. A photodiode P connected to electronic devices can then measure the changes in light intensity.

If the specimen is enclosed in a rigid tube (e.g., water in a Plexiglas tube; Ref. 33), since the external surface is not sensitive to vibrations, a membrane must be inserted in a hole of the tube in order to sense the pressure variations in the enclosed medium. The standard setup shown in Fig. 6 may be used to implement different techniques by means of fiber optics or laser interferometers. They may achieve a very high sensitivity for displacements, of the order of $1 \text{ \AA}$ for the Michelson interferometer, and a flat bandwidth response, from 1 kHz to 20 MHz in the case of the Mach-Zender interferometer.

The Mach-Zender interferometer may be either bonded to the surface (29) or embedded in the specimen (30,31). In both cases, the acoustic wave displacement induces a pressure on the light guides (31), leading to axial compression/tension and, therefore, to a phase shift of the propagating light beam. It is sensitive to both in-plane and out-of-plane displacements, but in the case of composites, it has been found to be insensitive to small angular misalignments of fibers with respect to the incoming wave front. The embedded configuration is shown to be several times more sensitive to the wave motion (up to 12 Pa per 1 m length of lightguide in the measuring channel) (e.g., in the case of Lamb waves) than the surface-bonded one. However, the latter configuration may be more practical.

A dual-probe interferometer (34) is based on the interference of two signals received from two fiberoptic receivers located in different positions on the surface of the specimen. A similar approach has been used by Clark, Delsanto, and Mignogna (35,36) using piezoelectric transducers for the determination of times of flight of ultrasonic Rayleigh waves in acoustoelasticity applications (texture and stress measurements in polycrystalline aggregates). However, this technique could be problematic since the signal is affected by the contact transducer it must pass. A different approach, based on the Doppler effect, is at the basis

of the Fabry–Perot interferometer (37). If an elastic specimen is subject to vibrations, the reflected light is Doppler shifted and the wavelength shift is related to the surface velocity of the target.

Two major problems lead to signal fading in optical fiber interferometers. The first is represented by a fluctuation in the state of optical polarization within the optical fiber and can be removed by using polarization control or polarization-maintaining fibers. The second concerns changes in the optical phase difference between the interfering channels due, for example, to thermal effects. As a consequence, the device sensitivity can drop to zero when the measurement is performed. To avoid variations in sensitivity, several stabilization schemes have been developed. In the case of homodyne systems, feedback is used in order to lock the interferometer at quadrature; heterodyne techniques allow the environmental noise to be effectively cancelled, but lead to a rise in the demodulation circuitry complexity. Passive stabilization schemes are very efficient but require complex signal processing.

In general, photoacoustic transducers and sensors present several disadvantages compared with piezoelectric transducers. The efficiency of sound generation by thermal sources is rather low and the sensitivity of ultrasonic detection is poorer. However, since these are noncontact devices, they can scan curved surfaces conveniently and measure displacement. Since the optical wavelength is several orders of magnitude smaller than the wavelength of acoustic pulses, the resulting accuracy in the determination of the displacement amplitudes becomes correspondingly better.

SUMMARY

Acoustic interference is due to the superposition of two or more initially coherent sound waves, which are superimposed after they have traveled different acoustic paths. Acoustic interferometry has been used for determining material properties and their dependence on parameters such as temperature or pressure; or the presence of impurities or defects by determining the phase velocity and/or attenuation as a function of these variables. When the geometry of the specimen is properly defined, the phase velocity and attenuation in the specimen can be determined accurately as a function of the physical parameters by using a suitable acoustic interferometer. We have shown various examples of configurations of different interferometers and discussed their usefulness in studying the properties of fluids as well as of solids.

MASS SPECTROMETERS

APPLICATIONS OF MASS SPECTROMETRY

Mass spectrometers precisely determine the masses of ionized atoms or molecules with extreme sensitivity (1,2). Such investigations allow the following measurements.

The Identification of Atoms or Molecules

From a reasonably resolved mass spectrum, the original atoms or molecules (see Fig. 1) are identified by determining their atomic or molecular weight precisely. From such a mass spectrum the binding energies of different isotopes of one or of several elements are also determined (3,4) if the mass-resolving power $m/\Delta m$ of the mass analyzer is large enough (see also the section "The Magnetic Ion Trap Mass Spectrometer").

The Investigation of Macromolecules

The mass analysis of macromolecules is helpful for investigating very large biomolecules (see Fig. 2) and also atomic or molecular clusters. The goal of such investigations is to precisely determine the molecular weight.

Figure 1. Mass spectrum of β -chain insulin of mass $m \approx 3494.9$ u, recorded as $(m + H)^{3+}$, that is, with one proton attached. This mass spectrum was recorded in a time-of-flight mass spectrometer (see Fig. 9) of mass resolving power $m/\Delta m = 17000$ (FWHM), that is, measured as the full line width at half maximum. Since carbohydrate molecules all contain about one ^{13}C -atom for every one hundred ^{12}C -atoms there is a mass multiplet of ions for every molecule. When the molecule is large, the probability is high that it contains one or several ^{13}C -atoms. Thus, the most abundant molecule is usually not the one that contains only ^{12}C -atoms.

The Determination of the Structure of Molecules

To understand the structure of complex organic molecules one can isolate ions of one specific mass in a first-stage mass analyzer, fragment this ion by gas collisions in some intermediate gas cell, and analyze the mass spectrum of the molecule fragments in a second-stage mass analyzer. This (MS/MS) technique (5) is used, for instance, in the amino acid sequencing of proteins (6).

Figure 2. The mass spectrum of ≈ 30 to ≈ 55 times charged ions of albumin. This molecule has a molecular weight of about $(66,439 \pm 0.6)$ u. The time-of-flight mass spectrometer used for this investigation had only a mass resolving power $m/\Delta m \approx 12,000$ so that individual ion masses could not be separated from each other. Also shown is the mathematical combination of all of these mass distributions, from which one determines the molecular mass of albumin with certain adducts with a precision of only 10 ppm. The main adducts here had a mass of $m_1 = 119.2$ u.

Figure 3. Mass cross-contamination caused by the tails of an intense neighboring mass line. The shown spectrum was recorded by a rather good sector field mass analyzer that had a (FWHM) mass-resolving power of $m/\Delta m \approx 5000$ and was operated at a pressure of only a few times 10^{-8} mbar.

The Measurement of Isotopic Distributions

When some isotopes of a certain element decay radioactively, the isotopic intensity distribution reveals the age of the sample. Some of the isotopes exist only in very small quantities while others are abundantly available. For this reason it is very important to use a mass analyzer that provides for a rather small mass cross-contamination from one mass to the next. The system must be designed properly for this purpose, and it must have a very good vacuum to reduce residual gas scattering of the most abundant ion species (see Fig. 3). Especially low mass cross-contamination is achieved by using high-energy ions accelerated in tandem accelerators (7). In such systems, for instance, the isotopic ratio $^{14}\text{C}/^{12}\text{C}$ can be investigated. This is important because ^{14}C , which has a half-life of 5730 years, is constantly produced in the earth's atmosphere by the sun, so that the $^{14}\text{C}/^{12}\text{C}$ ratio is a good measure for the age of old natural products, such as wood or bones.

The Detection of Small Amounts of Specific Atoms or Molecules

To investigate the pollution, for instance, of water or air samples one can use the high sensitivity and specificity of mass spectrometers and combine them with the selectivity of gas chromatographs (GC/MS), liquid chromatographs (LC/MS), or of complex but powerful capillary zone electrophoresis (CZE) systems. In such chromatographs the molecules are separated according to their chemical adsorption properties (8), that is, simultaneously injected chemically different molecules leave the chromatograph successively. A specific substance is identified in such a system by the mass spectrum of the chromatograph's effluent recorded at a specific time (see Fig. 4).

FUNDAMENTALS OF MASS SPECTROMETRY

The very diverse applications described are all united by the use of the same instrumentation. Thus it is neces-

Figure 4. The record of a GC/MS investigation of traces of about 10^{-12} g of (1) toluene, (2) chlorobenzene, (3) nonane, (4) chloroheptane, and (5) *t* butylbenzene. For such a measurement several thousand or 10,000 mass spectra are recorded of the chromatograph effluent, and each mass spectrum is characteristic of the effluent at a specific time. For clarity, however, here only one mass spectrum is shown for each GC peak. A typical record, as shown here, requires several hundred seconds and in some cases up to a few thousand seconds because one must wait until the substance with the longest retention time leaves the gas chromatograph.

sary to describe the mass spectrometric techniques in some detail.

An atomic or a molecular ion to be mass analyzed is characterized by

1. its mass m measured in *mass units* u , that is, the mass of one-twelfth of a ^{12}C -atom;
2. its charge q measured in *charge units*, that is, the negative value of the charge of one electron or $\approx 1.6022 \times 10^{-19}$ C;
3. its kinetic energy $K = qV$ measured in electron volts where V is the potential difference by which the ion has been accelerated; and
4. its velocity v measured in kilometers per second or in millimeters per microsecond (9) is given by

$$v \approx 9.82269 \sqrt{\frac{2K}{m}} \quad (1)$$

The numerical multiplier is found from $c/\sqrt{m_u} \approx 299,792,458/\sqrt{931,494,300}$ where c is the velocity of light in millimeters per microsecond and m_u is the energy equivalent of one mass unit in electron volts.

MASS ANALYZERS

To distinguish ions of different masses, the electromagnetic fields used can either provide a lateral dispersion, that is, a mass-dependent beam deflection or a longitudinal dispersion, that is, a mass-dependent flight-time difference. In the second case one must use a chopped and bunched ion beam, whereas in the first case bunched ion beams and dc beams can be used.

Laterally Dispersive Mass Analyzers

Laterally dispersive mass analyzers consist mainly of a magnetic deflecting field of flux density B measured in Tesla (T). In

a magnetic flux density B , nonrelativistically fast ions ($v \ll c$) of mass m , energy K , and charge q move along radii ρ measured in millimeters according to the expression

$$B\rho \approx \frac{\sqrt{2Km}}{9.82269q} \quad (2)$$

Usually the ions produced are all accelerated by the same potential difference V_0 so that their kinetic energies are all $K_0 = qV_0$. Thus their velocities $v_0 \approx 10\sqrt{2K_0/m}$ are also the same. However, because of the ionization process, the ions always have an energy spread $\pm\Delta K$ which is usually smaller than 1 eV.

When ions of different masses $m = m_0 \pm \Delta m$ and of a range of energies $K = K_0 \pm \Delta K$ enter into a magnetic sector field, the ions are finally separated from the beam axis by $\pm[(x_B|m)(\Delta m/m_0) + (x_B|K)(\Delta K/K_0)]$ with $(x_B|m) = (x_B|K)$ for a given magnetic field. Here $\pm(x_B|m)(\Delta m/m_0)$ determines the desired mass separation between ions of masses $m_0 + \Delta m$ and $m_0 - \Delta m$, and $(x_B|K)(\Delta K/K_0)$ causes a detrimental beam widening because of the continuous distribution of ion energies from $K_0 - \Delta K$ to $K_0 + \Delta K$. This energy spread also causes the ions to diverge from the ion source at angles of divergence given by

$$\gamma_0 = \pm \frac{v_i}{v_0} = \pm \sqrt{\frac{\Delta K}{K_0}} \quad (3)$$

because the velocity distribution of the unaccelerated ions is isotropic.

For a given magnetic field this widening of a mass line caused by the ions' energy distribution is unavoidable. However, for a combination of two or more sector fields, one can arrange the fields such that the energy dispersions compensate for each other, and the overall mass dispersion is $(\bar{x}|m)\Delta m \neq 0$. For a two-sector field system there are two possible arrangements (see Fig. 5):

1. The first solution uses an electrostatic sector field in addition to the magnetic sector which is dimensioned so that the forwardly calculated energy dispersion $(\bar{x}_E|K)(\Delta K/K_0)$ of the electrostatic sector field is equal to the backward calculated energy dispersion $(\bar{x}_B|K)(\Delta K/K_0)$ of the magnetic sector field (9,10), as indicated in Fig. 5(a). Because the electrostatic sector field has no mass dispersion, the mass dispersion of the magnetic sector field is also the mass dispersion of the full system.
2. The second solution uses a small magnetic sector field to compensate for the energy dispersion of the main magnetic sector (11), as indicated in Fig. 5(b). When the two sector magnets operate at different potentials and the energies K_1 and K_2 denote the ion energies in the two fields, one must postulate that the forwardly calculated energy dispersion $(\bar{x}_{B1}|K)(\Delta K/K_1)$ of the first magnetic sector field equals the backward calculated energy dispersion $(\bar{x}_{B2}|K)(\Delta K/K_2)$ of the second sector field (11). However, such a combination of two sector fields is useful only for $K_1 \neq K_2$ because only in this case the mass dispersions of the two sector magnets do not cancel each other for the case of a vanishing energy dispersion.

Figure 5. Ion trajectories are shown in two types of angle and energy focusing mass spectrometers which in the example shown both use the same geometry for the final magnetic sector-field mass analyzer. In Fig. 5(a) this magnetic sector field is preceded by (9,10) an electrostatic sector field and in Fig. 5(b) by a magnetic sector field placed at a different potential (10). It is assumed here that the ions are accelerated in a dipole sheet between the two stages. Note that in both systems 18 ion trajectories are shown characterized by two energies and three masses which leave the ion source at three different angles of inclination. For both systems there are also only three beams at the end (characterized by the three ion masses) independent of the angles at which the ions left the ion source and independent of the energy of these ions.

Comparing the two solutions, one sees that the overall mass dispersion is a little larger for the first case than for the second. The mass cross-contamination, however, is lower for the second solution (11) because the two momentum analyzers are used in series whereas only one momentum analyzer exists for the first solution (10).

Longitudinally Dispersive Mass Analyzers

Laterally dispersive mass analyzers have proven to be effective and powerful tools exhibiting the lowest mass cross-contamination of all known mass analyzers. However, longitudinally dispersive systems are becoming more and more popular because they are mechanically simpler. There are three types of such systems:

1. high-frequency mass analyzers (12,13,14) in which low mass ions pick up higher speeds than high mass ions within one frequency cycle. Thus, low mass ions swing in this field with larger amplitudes that can become larger than the electrode separation.

Figure 6. In the ion trap shown the ions can swing in the rotationally symmetrical quadrupolar ac field. If the dc power supply is left off, only ions above a certain mass move along stable orbits. The addition of a dc power supply also provides a limit for the high mass ions. In all cases the ion motion is mainly up and down in the figure shown here.

2. mass spectrometers in which ions circulate in a homogeneous magnetic field (15–17) or in race tracks (3,9).
3. time-of-flight mass analyzers (18–23) in which the mass-dependent flight times are observed directly for ions that have started simultaneously.

High-Frequency Mass Analyzers. High-frequency mass analyzers cause ions of energies of a few electron volts to swing in electric ac fields of some 100 V/mm and frequencies of $\nu \approx 1$ MHz. Because low mass ions swing with larger amplitudes than high mass ions, ions of too low mass are intercepted by the electrodes and only high mass ions survive. Adding a dc potential to the electrodes (see Figs. 6 and 7) also eliminates the heaviest ions (12,13) so that only ions within a small range of masses move along stable trajectories. There are two basic configurations of such mass analyzers.

The Quadrupole Ion Trap. The *quadrupole ion trap* uses rotationally symmetrical, hyperbolically shaped electrodes (see Fig. 6). Into such a *trap* ≈ 10 eV ions are introduced which then under the action of the high-frequency field mainly swing up and down between the two electrodes of the two-surface hyperboloids of Fig. 6. If the ac voltage is increased over time, the amplitudes of these swings also increase, and ions of higher and higher masses impinge on the electrodes or if appropriate holes are provided (14), leave the trap and can be recorded on some sensitive ion detector. By varying the voltages on these electrodes appropriately over time or during different time intervals, ions over a wide mass range or over a deliberately narrowed one can be made to move along stable orbits. One very useful MS/MS sequence requires that during the time interval Δt_1 the voltages are chosen so that stable ion motion is guaranteed only for ions of one particular molecule mass m_0 , whereas during the time interval Δt_2 the voltages are chosen so that ions of a range of masses all perform stable motions. Though, at the beginning of this time interval Δt_2 , only ions of mass m_0 are in the trap, these ions fragment because of collisions with residual gas atoms. With properly chosen ac and dc voltages,

these fragments are all stored in the trap. Then during the time interval Δt_3 , the voltages are scanned so that the mass range for the ions that perform stable motion is constantly decreased. Thus a mass spectrum is recorded of the fragment ions which become unstable successively according to their mass values.

The Quadrupole Mass Filter. A second well-established high-frequency mass analyzer consists of four rod-like electrodes (see Fig. 7) with ≈ 10 eV ions injected along the quadrupole axis. For appropriate ac and AD voltages of several 100 V, only ions within a very small mass range pass this *mass filter* (12,13), that is, move in the z -direction about 0.1 mm in each high-frequency period and at the same time swing transversally between the electrodes with amplitudes of about 5 mm. At the end, a mass spectrum is recorded in an ion detector if the ac and dc amplitudes are scanned appropriately over time.

The Magnetic Ion Trap Mass Spectrometer. A mass spectrometer of very high mass-resolving power $R = m/\Delta m$ is a system in which ions move in a magnetic flux density B along radii ρ according to Eq. (2) with a velocity v according to Eq. (1). Thus the flight time per turn in microseconds is given by

$$\bar{t} \approx 2\pi \frac{\rho}{v} \approx 0.0651212 \frac{m}{B} \quad (4)$$

where B is in Tesla and m is in mass units. This flight time is independent of the ion energy K . There are several ways to determine this flight time per turn.

1. If the radius ρ is large enough, one can determine the time $\bar{t}$ directly for one turn by small pulsed beam deflectors (15). In principle, this method is also applicable for many turns (9).

Figure 7. The quadrupole mass filter. Under the action of ac and dc fields, low energy ions swing laterally between the electrodes shown, and they move with constant velocity in the direction of the z -axis. Analogously to the ion motion in an ion trap, here also a pure ac field would allow only ions above a certain mass to move along stable orbits, whereas an added dc field would make the trajectories of the heavier ones unstable.

Figure 8. A Fourier transform mass analyzer that uses a high field magnetic solenoid (14). The mass-resolving power increases with an increased magnetic flux density B .

2. One can amplify the potentials induced on electrodes close to the ion path (see Fig. 8). After a Fourier analysis these induced voltages reveal mass specific frequencies $\nu = 1/\bar{t}t$ and thus the desired mass spectrum (3,16).
3. If the radius ρ is small enough, one can superimpose a high frequency electrostatic field to the magnetic one and register the finally left ions in the system by accelerating them axially out of the magnetic field. In this case the ions' azimuthal velocities are transformed into axial velocities that can be measured by a time-of-flight technique (17) which identifies the ions in resonance.

All these systems deliver rather high mass resolving powers of $m/\Delta m \geq 100,000$ or more which can be used for molecule mass analysis (16) or for the determination of nuclear mass defects (24) and other basic information like the CPT invariance (25). Note here that the mass resolving power of such systems is proportional to the number of rotations of the ion cloud and that the mass resolving power per turn can be rather small (16,17). Thus for a given experimental time it is advantageous to increase the magnetic flux density as much as possible. Note also that for $B = 7$ T, singly charged 100 eV ions of 100 u would move along circles of radius $\rho \approx 2.057$ mm with $\bar{t}t \approx 0.930$ μ s.

Instead of having ions move along circles in a homogeneous magnetic field, one can also arrange a number of magnetic and/or electrostatic sector fields into a *race track* with intermediate field-free regions (3,9,18) and then determine the flight time $\bar{t}t$ per turn via Fourier transform techniques. In principle this flight time $\bar{t}t$ depends on the ion mass and also on the ion energy. However, there are still two ways to achieve high mass-resolving power:

1. reduce the energy spread in the ion beam either by an electron cooler (3) for high energy ions or by gas collisions (26) for low energy ions.
2. introduce magnetic and/or electrostatic quadrupole lenses into the ring and excite them so that the overall system is energetically isochronous (9,18), that is, faster ions are sent around the ring along properly elongated trajectories.

Both race track systems have been used successfully for mass measurements of stable (14) and of short-lived nuclei (4).

Figure 9. A time-of-flight mass analyzer for heavy molecules. Note the folded flight path in the z -direction and the large ion mirror used (23). Also note the orthogonal ion injection in the x -direction and the pulsed ion acceleration in the z -direction (21). The electrospray ion source (31) forms charged droplets and sends them into the vacuum system where in flight they evaporate all the solvent, so that highly charged ions remain. Then these ions are passed through three quadrupoles the last of which is powered in a dc mode and focuses the 10 eV ions into the extraction region. The other two are two gas-filled ac only quadrupoles the first of which *heats* the ions to boil off any molecule adducts or to fragment the main molecule (6), and the second of which because of its different gas pressure *cools* the ions by gas collisions. This procedure works continuously so that finally the ions all have more or less the same velocity in the x -direction before being pulse accelerated orthogonally in the z -direction.

Time-of-Flight Mass Analyzers

A different approach is a time-of-flight (TOF) mass spectrometer (MS) into which a bunch of ions of different masses is injected and the ion arrival is recorded at some downstream ion detector (see Fig. 9). Differing from all scanning mass analyzers, there is no limit in a TOF-MS on the mass values of the ions under investigation. Therefore TOF-MS systems are powerful tools for the investigation of large biomolecules or cluster ions.

The ion source for a TOF system requires that all ions of equal mass start from some point at the same time. This is guaranteed by

1. a pulsed ion acceleration in which a pulsed electric field acts on some cloud of ions. If all of these ions are stationary initially and then are accelerated in the z -direction, they all reach a properly placed ion detector simultaneously if their masses are the same. In other words, *they will be bunched* because the ions that start from $z_0 + \Delta z$ receive a little less energy than those that start from

$z_0 - \Delta z$, but the first ones must also travel a little further (18,19). There are three ways to implement this method:

- (a) introduce ions at a specific z_0 , and wait until they move apart to different z -values because of their thermal energies (19). In this case the final ion positions z are correlated to their initial energies which improves the bunching properties considerably.
- (b) store (20) the ions in the potential well caused by a beam of electrons of energy K_0 . Depending on the electron beam current I_e , the potential in the middle of the beam is $V_e \approx 15200(I/\sqrt{U_0})$. For $U_0 = 70$ eV and $I = 0.0005$ A, one thus finds that $V_e \approx 0.75$ V. In this case the final bunch length is usually determined by the "turnaround time," that is the time in which an ion that moved initially in the $-z$ -direction has reversed its velocity.
- (c) introduce a low energy ion beam perpendicularly to the z -direction, that is, the direction of the pulsed ion acceleration (21). In this arrangement some "ion storage" is also achieved because it takes a relatively long time for the ions to perpendicularly traverse the region from which they are then accelerated. Most importantly, however, there is almost no ion motion in the z -direction initially. Thus the "turnaround time" is reduced compared to 1(b).

For such a pulsed ion acceleration, the final energy distribution in the bunched ion beam is large, for instance, $\Delta K \approx 100$ eV.

2. a pulsed ion generation which is, for instance, the case for the laser ionization of a sample. A very good method is (20) to embed some organic material into a matrix, for instance one of glycerol, so that each molecule to be investigated is surrounded only by matrix molecules. Irradiating this sample by a short intense laser pulse releases such molecules as ions. This method is called *matrix-assisted laser desorption and ionization* (MALDI). The performance of this technique is improved by accelerating these ions in an electrostatic field that is switched on shortly after the laser pulse (19).

The time focus (19,21) achieved by pulsed ion acceleration is a good technique for achieving reasonable mass-resolving powers for a so-called *linear TOF-MS*. One can improve the simultaneous arrival of ions of equal mass by using this time focus as the source for a folded-flight-path TOF-MS (18,20). In such a system the ions are reflected by some *electrostatic ion mirror* in an energy isochronous manner, that is, so that the more energetic and thus faster ions reach the final ion detector only via a properly dimensioned detour (18,23) achieved by their deeper penetration into the reflector field. One can also say: *to first order the overall flight time becomes independent of the ions' energy spread ΔK* . Investigating q -times charged ions of energy $(K_0 \pm \Delta K)$ that enter a homogeneous repeller field E this condition of isochronicity postulates that

$$L_1 + L_2 = \frac{4qE}{K_0} \quad (5)$$

where L_1 and L_2 denote the lengths of the field-free regions between the ion source and the repeller field and between the

repeller field and the final ion detector, respectively. In this case the overall flight time is $t + \Delta t$ with $\Delta t/t = (\Delta K/K_0)^2/8 + \dots$. Using an ion reflector composed of two regions (23) of properly dimensioned field strengths or a grid-free ion reflector (18,20) that produces a properly dimensioned field region, the performance of such a TOF-MS can even be improved, so that finally only much smaller effects proportional to $(\Delta K/K_0)^3$ remain.

ION SOURCES

Many different ion sources have been developed for different mass spectrometers and different applications. Only in a few cases this ion formation can occur inside a mass analyzer, as for instance inside of an "ion trap." In most cases an external ion source is used that consists of two parts: the ionization device and the ion accelerating and beam-forming device.

Electron Impact Ion Sources

Energetic electrons ionize vaporized atoms or molecules by collisional impact. The electron energy here must be large enough that at least one electron in the shell of the atom or molecule in question is removed. Optimally, (2,27) beams of electrons of 70 eV or 80 eV are used with currents of usually a few 100 μ A. In many cases these beams are held together by magnetic fields of perhaps 0.01 T produced easily by permanent magnets. This magnetic field usually confines the electron beam to diameters ≤ 2 mm and at the same time elongates the electron path thus increasing the overall ionization probability for a given electron current. Usually the ions are pulled from the ionization region through some narrow orifice by an accelerating electrode at a potential of some 100 V or even 1000 V. However, the ions often are also pushed toward this orifice by some relatively large pusher electrode at a potential of a few volts.

Plasma Ion Sources

In a plasma ions already exist and only need to be extracted. However, electrostatic fields cannot penetrate deeply into a conductive plasma and thus ions can be extracted only from the plasma surface which consequently is depleted of ions to some depth after a very short time. Thus a pulsed ion acceleration that extracts ions from a replenished *plasma surface* is especially effective (28). As one should expect, the extracting field strength shapes the plasma surface and thus greatly influences the ion optical properties of the extracted ion beam.

Thermal Ion Sources

If the ionization energy I_p for some atom under consideration is smaller than the work function W of a substrate, the atoms leave this substrate partially as ions. The ratio between ionized and neutral atoms evaporating from a filament heated to a temperature T is given by

$$\frac{N^+}{N^0} = \exp \frac{W - I_p}{kT} \quad (6)$$

where $k = 8.62 \times 10^{-5}$ is the Boltzmann constant measured in electron volts per K. Re and also W or Ta substrates have large work functions which cause them to efficiently remove one electron from evaporating alkali atoms, that is Li, Na, K, Rb, Cs, Fr and from some earth alkali atoms during evaporation. With

Rb or Sr on 2500 K hot Re, and $I_p(\text{Rb}) = 4.18 \text{ eV}$ or $I_p(\text{Sr}) = 5.7 \text{ eV}$ one finds that $N^+/(N^0 + N^+)$ equals 100% or 85% if the work function of the Re surface is assumed to be 6.1 eV. However, other atoms, for instance, U are also ionized with some efficiency (2,27). Similarly, one can also attach one electron to atoms with large electron affinities (for instance, Br) if they are evaporated from a substrate that has a very low work function, for instance, LaB_6 .

This simple ionization technique is improved considerably if the substrate forms the inner surface of a hot cavity (29). In this case most elements are ionized with efficiencies of about 1%. The reason for this enhancement is that the ions are extracted through a small hole in this cavity whereas the atoms stay in the cavity and thus get another chance to be ionized.

Laser Ion Sources

As one might expect, one can directly ionize specific isotopes by high-power lasers of some resonant frequencies. However, often one uses only lasers of broader frequency bands and thus ionizes all isotopes of a specific element simultaneously (30). In some cases one also uses the property of a finely focused laser beam to produce a small plasma at some surface as, for instance, for the previously mentioned MALDI sources (22).

Electrospray Ion Sources

A very interesting ion source for high mass biomolecules uses the electrospray technique (31). In one of these ion sources a very dilute solution of the molecules of interest is sprayed in fine droplets into some gas at about 1 bar. Then the gas and these droplets are sucked through a small orifice into a vacuum vessel where the droplets will evaporate most of the solvent and thus rapidly decrease in size. If there were only one molecule in the droplet there is only one molecule left at the end when all the solvent has evaporated. Because the droplets were multiply charged from the beginning, as is the case in the spray from any waterfall, the final molecule is multiply charged (see Figs. 1 and 4).

CONCLUSION

Mass spectrometry began as a special technique to determine the isotopic distribution of all elements (9), but it has grown into a very general, sensitive, and specific analytical technique for ionized atoms or molecules. For this reason mass spectrometers have been used in very diverse applications from nuclear physics to pharmacology. The fastest growing application certainly is the analysis of biomolecules and the trace detection of organic molecules.

MICROSCOPY

ELECTRON MICROSCOPES

In 1873, it was proven by Ernst Abbe that the resolving power of a light microscope will always be limited by the wavelength of the light, which is of the order of $1\text{ }\mu\text{m}$, so that there could be no hope to visualize much smaller objects such as atomic scale structures. (In the 1980s, near-field optical scanning techniques were developed that can bring the resolution down by two orders of magnitude.) Fifty years later, a new impulse was given to the problem by the hypothesis of Louis De Broglie about the wave nature of particles so that other particles could also serve as "light." In 1931 Ernst Ruska developed the first transmission microscope TEM that uses electrons instead of photons. In 1986 Ernst Ruska was awarded the Nobel Prize for his pioneering work. Electrons are the best candidates since they can easily be generated by a heated filament or extracted from a point by an electric field and they are easily deflected by electric and magnetic fields. When accelerated to, say, 100 keV, their wavelength is much smaller ($3\text{ pm} = 3 \times 10^{-12}\text{ m}$) than that of visible light. They can also be detected on a photoplate, a fluorescent screen, or an electronic camera. On the other hand, they can only propagate in vacuum and they can only penetrate through very thin objects ($<10^3\text{ nm}$), so that vacuum and specimen preparation techniques are crucial.

In past decades, electron microscopy has matured to an indispensable tool for materials and biomedical research. Numerous are the Nobel Prizes for research work in which electron microscopy revealed crucial evidence. Despite the very small wavelength of the electrons, it has only recently been possible to visualize individual atoms. The reason for this is that magnetic lenses inevitably suffer from aberrations that, contrary to glass lenses in a light microscope, cannot easily be corrected. Recently the problem of compensating the spherical aberration has become solved on the research level.

When individual atoms, the building blocks of nature, can be revealed, electron microscopy enters into a new era. Indeed, then it becomes possible to determine the atomic structure of matter quantitatively and accurately, even for objects for which only limited prior knowledge is available. Although the goal is not yet achieved, the progress is very encouraging. In the future, as materials science evolves into materials design, and mesostructures into nanostructures, the role of electron microscopy will become even more important.

In recent years we have also seen the development of related techniques such as scanning transmission electron microscopy (STEM), electron holography, ptychography, and add-on techniques that use complementary information such as X-ray analysis (EDX), and energy filtering. There is now a growing tendency to incorporate all these techniques into one versatile instrument under full computer control, where they are all considered as different ways to obtain complementary information, mainly of chemical nature.

The development of scanning electron microscopy (SEM) has taken place parallel to that of TEM. The first SEM was constructed by Manfred von Ardenne in the 1930s. The SEM is conceptually simpler than the TEM. With the aid of magnetic lenses, the electron beam is focused into a small point that is scanned over the surface of the object. The backscattered

electrons, or other secondary signals, can then be detected and synchronously displayed on a cathode-ray-tube (CRT) screen. The SEM is relatively easy to use and does not require extensive specimen preparation and is also less expensive than the TEM. On the other hand, it can only be used to study the surface area and, because of the beam spread in the object, its resolution is rather limited and quantitative interpretation of the images is more difficult.

TRANSMISSION ELECTRON MICROSCOPY

The Instrument

A transmission electron microscope is very similar to a light microscope (Fig. 1) in which the light bulb is replaced by an electron source and the glass lenses by magnetic (or electric) lenses. The focusing of the lenses can be varied by changing the lens currents so that the setting of the microscope (focusing, magnification, etc.) can easily be altered. The condenser lens shapes the electron flow into a parallel beam. The specimen is a very thin object mounted in a holder that, through an airlock system, can be brought into the electron beam. Holders exist with a variety of degrees of freedom (translation, rotation,

Figure 1. Comparison between an electron microscope (right) and a light microscope (left). All the components of the light microscope have their analog in the electron microscope. The acceleration electrons have a wave character and act as light.

tilt, temperature, stress). The objective lens produces an enlarged and rotated image, which in its turn, through a system of intermediate and projector lenses, is further magnified and projected onto a fluorescent screen, a photoplate, or an electronic camera.

Another mode of operation is not to image the object but to image the focal plane of the objective lens. In this way one can observe the electron-diffraction pattern directly onto the fluorescent screen.

The resolving power of the electron microscope is mainly determined by the quality of the objective lens. With modern instruments, a resolution of about 0.15 nm can be reached.

In modern electron microscopes the microscope is operated under computer control and the alignment can be done automatically. The visual electron source, which is a thermal filament, is increasingly replaced by a field-emission source, from which the electrons are extracted by an electric field and which yields a much higher brightness.

Image Formation

Intuitive Description. The imaging process in the electron microscope can be sketched in a very simple way as follows (Fig. 2). The object is illuminated by a plane wave. Due to the interaction of the electrons with the atoms of the object, the electron wave is modulated by the structure of the object. By propagating this object exit wave through the electron microscope to the image plane this electron wave is blurred, that is, each point of the wave is spread into the so-called point-spread function or impulse response function. The wave as well as the point-spread function is a complex valued function with an amplitude and a phase component. Finally, however, in the image plane only the intensity is recorded so that the phase information is lost. Full recording of this phase information can be done using holographic techniques (discussed later).

Wave Optical Description. As in the light microscope, the formation of the image must be described by wave optics (Fig. 3).

Figure 2. Schematic representation of the imaging process. The electron wave is modulated by the object and then blurred by the electron microscope.

Figure 3. Wave optical representation of the image formation by the objective lens in a transmission electron microscope. The corresponding mathematical operations are indicated [see text with $\mathbf{R} = (x, y)$ and $\mathbf{G} = (u, v)$].

The electron wave is diffracted by the object, and each diffracted beam is focused by the objective lens into one point in the focal plane. The electron wave in the focal plane can be considered as the Fourier transform of the exit wave of the object. The high spatial frequencies (small details) correspond to beams far from the optical axis and the small spatial frequencies (large details) are located close to the optical axis. In case the object is periodical, such as is the case of a perfect crystal, the Fourier transform is discrete, that is, the diffraction pattern in the back focal plane consists of discrete spots. These are the different diffracted beams. In case the object is aperiodic, the image in the focal plane shows diffuse intensity. In the second step of the imaging process, the points in the focal plane act again as sources of waves, which interfere in the image plane. The image wave found in the image plane is the reverse Fourier transform of the wave found in the focal plane; therefore, under ideal imaging conditions with no imaging aberrations or apertures, the image wave should be identical to the object exit wave. In short, the whole imaging process is wave optically considered as a sequence of two Fourier transforms, the first one leading from the object plane to the back focal plane of the objective lens, and the second one from the focal plane to the image plane. In practice, however, the objective lens has intrinsic aberrations. The most important ones are the spherical aberration and the defocus. As a consequence, the Fourier components of the electron wave in Fourier space suffer from hampering phase shifts arising from these aberrations that are more important for the high spatial frequencies and that blur the image.

Usually the Fourier components, falsified by more than a tolerable threshold, are masked out to minimize the blurring

Figure 4. Different imaging modes. (a) Bright-field imaging: only the transmitted beam contributes to the image. (b) Dark field: only one diffracted beam contributes to the image. (c) High-resolution imaging: the image is formed by interference of many diffracted beams.

effect. On the other hand, one has to find a compromise because, for high-resolution imaging, as many Fourier components as possible should be admitted to the image. In a sense, one can then consider the image wave as a truncated Fourier reconstruction of the object exit wave with only a limited number of Fourier components, which may be falsified by the aberrative phase shift. The image formed by interference of the residual waves cannot be interpreted easily.

The resolution, in a sense the smallest detail present in the image, is then determined by the highest spatial frequency that is allowed to contribute to the image formation. One distinguishes between the point resolution, which is the highest spatial frequency that contributes without extra phase shift and which gives rise to directly interpretable details, and the information limit, which is the highest spatial frequency in the image formation but with a phase shift that complicates a direct interpretation of the details.

For special investigations of crystalline objects, it is useful to include only one diffracted beam for imaging (Fig. 4). If the central beam is used, one obtains a so-called bright field image (BF); if only a diffracted beam is included, a so-called dark field image results. In these cases, since there is no interference between diffracted beams, the image contrast can more easily be interpreted in terms of the number of electrons scattered in the corresponding particular direction. However, high resolution cannot be obtained with these techniques.

In any case, for the interpretation of the images, it is equally important to understand the interaction between the electrons and the object.

Mathematical Formulation

Transfer Function. By interaction with the object, the object exit wave $\psi(\mathbf{R})$ is modulated both in amplitude and phase. Hence $\psi(\mathbf{R})$ is complex. $\mathbf{R}$ is the position vector in the object exit plane. According to Fraunhofer's diffraction theory the diffracted wave in the direction given by the reciprocal vector $\mathbf{g}$ (or spatial frequency) is given by the Fourier transform of the object function, that is,

$$\phi(\mathbf{g}) = F_{\mathbf{g}}\psi(\mathbf{R}) \quad (1)$$

The wave in the back focal plane of the objective lens is then the Fourier transform of the object wave. If one directly images the focal plane, one can see the diffraction pattern, given by $|\phi(\mathbf{g})|^2$. If the object is periodic, such as a crystal, the diffraction pattern will consist of sharp spots. A continuous object will give rise to a continuous diffraction pattern. The second stage of the imaging process is described by an inverse Fourier transform that reconstructs the object function $\psi(\mathbf{R})$ (usually enlarged) in the image plane (Fig. 3). The intensity in the image plane is then given by $|\psi(\mathbf{R})|^2$.

In practice, by inserting an aperture in the focal plane of the objective lens, it is possible to obtain an image in which only selected beams contribute. On passing through the objective lens, each electron beam $\mathbf{g}$ undergoes a phase shift and an amplitude reduction (damping). Hence the transfer function takes the form

$$T(\mathbf{g}) = A(\mathbf{g}) \exp[-i\chi(\mathbf{g})]D(\mathbf{g}) \quad (2)$$

$A(\mathbf{g})$ describes the effect of the beam-selecting aperture and the damping caused by incoherent effects (such as fluctuations in voltage and lens currents). $\chi(\mathbf{g})$ is the phase shift, given by

$$\chi(\mathbf{g}) = \frac{\pi}{2}(C_s\lambda^3g^4 + 2\epsilon\lambda g^2) \quad (3)$$

with C_s the spherical aberration constant of the objective lens, ϵ the focus distance, and λ the electron wavelength. The wave function at the image plane is now given by the inverse Fourier transform

$$\psi_{\text{im}}(\mathbf{R}) = F_{\mathbf{R}}^{-1}T(\mathbf{g})\phi(\mathbf{g}) \quad (4)$$

and the image intensity by

$$I_{\text{im}}(\mathbf{R}) = \|\psi_{\text{im}}(\mathbf{R})\|^2 \quad (5)$$

Equation (4) is called the coherent approximation; it is valid for thin objects. In general, the expressions are more complicated. One then has to consider the image as an incoherent superposition of images that are slightly different, due to fluctuations

in the conditions of the electron microscope. For a more general description we refer the reader to Ref. 1.

The total image formation process is illustrated in Fig. 2.

Impulse Response Function. As intuitively described earlier the image transfer can also be described in real space as a blurring effect, and as also follows from Eq. (4) using the convolution theorem,

$$\Phi(\mathbf{R}) = \psi(\mathbf{R}) * t(\mathbf{R}) \quad (6)$$

where $\psi(\mathbf{R})$ is the object wave in real space and $t(\mathbf{R})$ is the Fourier transform of the transfer function. For an hypothetical ideal pointlike object, the object wave $\psi_{\text{im}}(\mathbf{R})$ would be a δ function or “impulse” [$\psi(\mathbf{R}) = \delta(\mathbf{R})$] so that $\Phi_{\text{im}}(\mathbf{R}) = t(\mathbf{R})$, that is, the microscope would reveal $t(\mathbf{R})$, which therefore is called impulse response function. If the transfer function would be constant (i.e., perfectly flat) in the whole spatial frequency range, the impulse response function would be a δ function so that $\psi_{\text{im}}(\mathbf{R}) = \psi(\mathbf{R})$, that is, the wave function in the image plane represents exactly the wave function of the object. In a sense the microscope is perfect. However, in practice the transfer function cannot be made constant as is shown in Fig. 5. The impulse response function is still peaked as shown in Fig. 6.

Figure 5. Transfer function (imaginary part) of a 300 keV electron microscope at optimum defocus.

Figure 6. Impulse response function (imaginary part) corresponding to the transfer function of Fig. 5.

Hence, as follows from Eq. (6), the object wave $\psi(\mathbf{R})$ is smeared out (blurred) over the width of the peak. This width can then be considered as a measure for the resolution in the sense as originally defined by Rayleigh. The width of this peak is the inverse of the width of the constant plateau of the transfer function in Fig. 5. From another point of view one can argue that if all the spatial frequencies have the same phase shift, the information is transferred forward and keeps a point to point relation to the object.

However, the information beyond this plateau is still contributing to the image but with a wrong phase. It is scattered outside the peak of the impulse response function and it is thus redistributed over a larger area in the image plane.

Phase-Contrast Microscopy. In an ideal microscope, the image wave function would exactly represent the object wave function and the image of a pure phase object function would show no contrast. This can be compared with imaging a glass plate with variable thickness in an ideal light microscope.

If the phases of the diffracted beam (Fourier components) are shifted over $\pi/2$ with respect to the central beam the image contrast would directly reveal the phase of the object. In light microscopy, phase contrast can be obtained by inserting an annular quarter-wavelength plate in the focal plane of the objective lens.

In electron microscopy, phase-contrast imaging can be achieved by making the transfer function as constant as possible. From Eq. (3) it is clear that phase shifts occur due to spherical aberration and defocus. However, the effect of spherical aberration, which, in a sense, makes the objective lens too strong for the most inclined beams, can be compensated somewhat by slightly underfocussing the lens.

The focus setting is called the optimum focus or Scherzer focus and its value can be calculated as

$$\epsilon = -1.2 C_s^{1/2} \lambda^{1/2} \quad (7)$$

The transfer function for this situation is depicted in Fig. 5. The phase shift $\chi(\mathbf{g})$ is nearly equal to $-\pi/2$ with respect to the central beam for a large range of spatial coordinates, up to the value

$$|\mathbf{g}| = 1.5 C_s^{-1/4} \lambda^{-3/4} \quad (8)$$

The image then reveals directly the phase of the object. Now a thin material object acts as a phase object in which the phase is proportional to the electrostatic potential of the atoms projected along the viewing direction. Hence, if the object would be very thin, optimum focus imaging would directly reveal atom columns as dark dots and empty spaces as light areas. However, this argument only holds for spatial frequencies that are within the range given by Eq. (8). Furthermore the thickness up to which an object can be considered as a weak phase object is very small (e.g., 1 nm) and is rarely met in practice.

Resolution. One has to distinguish between point resolution (or structural resolution) as the finest detail that can be interpreted in terms of the structure and the information limit, which is the finest detail that can be resolved by the instrument, irrespective of a possible interpretation.

The point resolution can be obtained from the inverse of the maximal spatial frequency equation (8) as

$$\rho_s = 0.65 C_s^{1/4} \lambda^{3/4} \quad (9)$$

The point resolution is also equal to the “width” of the impulse response function (Fig. 6). The information beyond ρ_s is transferred with a nonconstant phase and, as a consequence, is redistributed over a larger image area.

The information limit ρ_I can be defined as the finest detail that can be resolved by the instrument. This limit is mainly determined by incoherent effects (fluctuations on the energy of the electrons and on the lens currents, divergences of the illuminating beams). The information limit is usually smaller than the point resolution. Typical values are $\lambda = 2$ pm (300 keV), $C_s = 1$ mm, $\rho_s = 0.2$ nm, $\rho_I = 0.13$ nm. The point resolution can be improved by reducing the incoherent effects (e.g., energy and current fluctuations), for instance, by using a field emission source and a stable voltage supply.

The Specimen

Specimens for high-resolution electron microscopy are prepared using the same techniques as for usual transmission electron microscopy, that is, ion beam milling, chemical and electrolytical thinning, cleavage, crushing, and so on. The only requirements are that the specimen should be sufficiently thin, that is, less than about 10 nm. Furthermore, the specimen should be sufficiently clean and free of contamination. Depending on the type of specimen one can use different thinning methods such as ion beam milling, electrochemical etching, crushing, and dimpling.

For details of specimen preparation we refer the reader to Ref. 2.

Figure 7. Formation of the diffraction pattern. The simultaneously excited electron beams can be used for image formation.

Crystalline specimens are oriented with a zone axis parallel to the incident beam so that all the diffracted beams of that zone are excited simultaneously and maximal information is present in the image. This is shown in Fig. 7. In this situation, the electrons propagate parallel to a zone axis, that is, parallel to the atom rows, which makes a possible interpretation of the images in terms of the projected structure meaningful. As an example, Fig. 8 shows a drawing of a model of a dislocation viewed along a zone axis.

It is also possible, using an aperture placed in the focal plane of the objective lens, to select a particular set of beams so that the images contain specific information. If the central beam is not included, these images are called dark-field images.

After finding a suitably thin part with the proper orientation, one has to adjust the focus. When the specimen is very thin, the zero focus corresponds to minimal contrast.

In practice, one takes a series of images at gradually different focus settings, recorded approximately around the optimum defocus. This is called a through-focus series. When dealing with a specimen that is unstable in the electron beam, the specimen can be completely destroyed within a period of seconds. Here a minimal exposure technique has to be used.

Figure 8. Structure model of a crystal containing a dislocation viewed along the atomic columns.

Electron Diffraction

Diffraction Mode. When the focal length of the intermediate lens is increased, by weakening its excitation, so as to make the back focal plane of the objective lens coincide with the object plane of the projector lens, a magnified image of the diffraction pattern is projected on the screen. Neither specimen orientation nor selected area are hereby changed; the diffraction pattern is thus representative of the selected area. It should be noted that the area selected in the diffraction mode is much larger than the field of view for imaging.

Geometry of the Diffraction Pattern. The diffraction conditions can be formulated in two different ways: either emphasizing direct space or reciprocal space. In direct space the diffraction conditions are known as *Bragg's law* (3). Attention is focused on sets of parallel lattice planes with interplanar spacing d_H , where H represents the three Miller indices of the considered family of lattice planes. "Reflection" will occur for certain "glancing" angles θ_H satisfying Bragg's law; $2d_H \sin \theta_H = n\lambda$, where λ is the wavelength of the radiation used and n is an integer. This relation expresses the condition that the difference in path length between waves scattered by two successive lattice planes is an integer number of wavelengths (Fig. 9). For 100 kV

Figure 9. "Reflection" of electron waves by successive lattice planes leading to the Bragg condition.

Figure 10. Ewald construction of diffracted wave. A diffracted wave is formed if Ewald's sphere ($\approx$ plane) intersects a reciprocal-lattice node H . k_0 is the wave vector of the incident wave, k_H is the wave vector of diffracted wave, and B_H is the reciprocal-lattice vector belonging to node H .

electrons $\lambda \sim 0.004$ nm and hence the Bragg angles are very small, of the order of a few degrees at most.

In terms of reciprocal space the *Ewald diffraction condition* (4) can be formulated as $k_H = k_0 + B_H$, where k_0 is the wave vector of the incident wave and k_H that of the scattered wave and B_H is a reciprocal-lattice vector $B_H = h_1 b_1 + h_2 b_2 + h_3 b_3$. The b_j are the base vectors of the reciprocal lattice, defined in terms of the base vectors a_i of the direct lattice by the relations $a_i \cdot b_j = \delta_{ij}$ (Kronecker δ) ($i, j = 1, 2, 3$). The Ewald condition expresses the conservation of energy and linear momentum on elastic scattering; its physical content is the same as that of Bragg's law. Geometrically it expresses the condition that a sphere with radius $|k| = 1/\lambda$ and center C in $-k_0$ (Ewald's sphere) must pass through a point H of the reciprocal lattice for diffraction to occur. The scattered wave direction is then obtained by joining the center of Ewald's sphere with the excited reciprocal-lattice point H (Figs. 7 and 10).

In electron microscopy the specimen has to be a thin foil since electrons are strongly "absorbed" in solids. This causes an anisotropic relaxation of the Bragg condition along the foil normal. Diffraction now occurs also for conditions deviating somewhat from the exact Bragg angles. This is represented in reciprocal space as a change of the sharp spots into infinitely thin rods, called "relrods" perpendicular to the foil surfaces. These relrods have an intensity profile represented in Fig. 11 according to the kinematical theory of electron diffraction (see the Appendix).

Figure 11. Intensity profile along a "relrod" for a foil with thickness $> t$.

Figure 12. Illustration of the diffraction geometry in reciprocal space, defining the excitation error s_H . (a) $s_H = 0$. (b) $s_H < 0$.

Since the radius of Ewald's sphere ($1/\lambda$) is large as compared to the mesh size of the reciprocal lattice ($1/d_H$), the sphere can be approximated by a plane. The diffraction pattern can thus be considered as the projection of an undeformed planar section of the reciprocal lattice.

The distance s_H by which Ewald's sphere misses the reciprocal-lattice node H is called the *excitation error*. It is a vector parallel to the foil normal that connects the reciprocal-lattice node and the intersection point with Ewald's sphere. It is by convention called positive when pointing in the sense of the propagating electrons, that is, when the node is inside Ewald's sphere. In Fig. 12(b), s_H is negative.

Convergent Beam Electron Diffraction. By converging the incident beam into a cone, the diffraction spots become disks with a fine structure of intensity variations. This way of diffraction is highly sensitive to small changes in the crystal structure. It can be used very efficiently to determine the space group symmetry of a crystal, to measure very accurately the unit cell dimensions, thermal expansion coefficients, local strain, and crystal potentials. For more detail, we refer to Ref. 5.

Imaging

Diffraction-Contrast Imaging

Principles. Diffraction-contrast images are preferably obtained under two-beam conditions since this allows an easier interpretation. The specimen is oriented such that apart from the direct beam only one scattered beam is strong. The selector aperture allows us to select either the direct beam or the intense scattered beam. The selected diffraction spot is then highly magnified by the lenses. The image obtained in this way is a highly magnified map of the intensity distribution in the corresponding diffraction spot. If the direct beam is magnified this is called a *bright-field image* [Fig. 13(a)]; if the diffracted beam is selected, the image is a *dark-field image* [Fig. 13(b)]. Since the electrons propagate within a narrow column by diffracting back and forth, such columns can be considered as picture elements forming the image (Fig. 14). This is the so-called column approximation (6,7).

The amplitude of either the scattered or the transmitted beam emerging in a point on the exit surface of the foil is the sum of the contributions of all volume elements along a column parallel to the incident beam. This amplitude depends on the variation of the excitation error s_H along the column, which itself depends on the local orientation of the diffracting planes.

In a perfect foil s is constant and it is the same along all the columns; the image is an area of uniform intensity. If a strain pattern is present in the foil s will vary differently along different columns and as a result an image is formed. Diffraction-contrast images are thus very sensitive to strain patterns but they do not reveal the crystal structure.

Interface Contrast

Examples. Interfaces situated in planes inclined with respect to the foil surfaces divide the foil into two wedge-shaped parts. These two parts are related by a translation if the interface is a stacking fault or an antiphase boundary with $\mathbf{R} = \mathbf{R}_0$; they differ in orientation, that is, in s when the interface is a domain boundary (Fig. 15).

In both cases sets of parallel fringes are formed, which are parallel to the closest intersection line of the interface and the surface. Their intensity profiles are different, however. Planar interfaces parallel to the foil surfaces only cause a brightness difference in the faulted area.

In Fig. 16 the two types of fringes are compared. The most important feature is the nature, bright (B) or dark (D), of the edge fringes (i.e., the first and the last fringe). Bright-field

Figure 13. Ray paths for the (a) bright-field mode and (b) dark-field mode.

Figure 14. Repeated reflection of electron waves in a column of crystal. According to the (a) kinematical theory and (b) dynamical theory.

fringe patterns produced at stacking faults have edge fringes of the same nature, whereas in the dark-field fringe pattern the edge fringes have opposite nature. The reverse is true for domain boundary fringes; the edge fringes are of opposite nature in the bright-field image, whereas in the dark-field image the nature of the two edge fringes is the same.

From the nature of the first and last fringes one can conclude, for instance, whether a stacking fault in a face-centered cubic crystal is either *intrinsic* (i.e., of the type ...*abcababc*...) (8) or *extrinsic* (i.e., of the type ...*abcbacabc*...). Figure 16, right refers to a domain boundary whereas Fig. 19, left is due to a stacking fault.

Dislocation Contrast (9,10). The contrast produced at dislocation lines can be understood by noting that the reflecting lattice planes in the regions on two opposite sides of the dislocation line are tilted in the opposite sense. Hence the Bragg condition for reflection is differently affected on the two sides of the line. On one side, the diffracted intensity may be enhanced because the Bragg condition is better satisfied (s is smaller), whereas it is decreased on the other side because s is larger, leading to a black-white line contrast shown schematically in Fig. 17 for the case of an edge dislocation. In this schematic representation the line thickness is proportional to the local beam intensity. In bright-field images dislocation lines are thus

imaged as dark lines, slightly displaced from the actual position of the dislocation line towards the “image side.”

This model implies that imaging in reflections associated with families of lattice planes that are not deformed by the presence of the dislocation will not produce a visible line image; the image is then said to be *extinct* (Fig. 18). The extinction condition can to a good approximation be formulated as $\mathbf{H} \cdot \mathbf{b} = 0$, where $\mathbf{b}$ is the Burgers vector of the dislocation. If extinction occurs for two different sets of lattice planes with normals $\mathbf{H}_1$ and $\mathbf{H}_2$, the direction of the Burgers vector $\mathbf{b}$ is parallel to $\mathbf{H}_1 \times \mathbf{H}_2$.

Images of dislocations can be simulated accurately by numerically solving the equations that describe the dynamical scattering of the electrons in the object (see the Appendix).

Fast computer programs (10) have been developed to calculate such images for various strain fields and various diffraction conditions. An example of the agreement between the observed and the computed image that can be achieved is shown in Fig. 19 after Ref. 10.

Weak-Beam Images (11). The width of the bright peak that images a dislocation in the dark-field imaging mode decreases with increasing s . This effect is exploited systematically in the weak-beam method, which allows one to image the dislocations as very fine bright lines on a dark background, using a reflection that is only weakly excited, that is, for which s is large. Unfortunately the contrast is weak and long exposure times are required (Fig. 20).

High-Resolution Imaging

Images of Thin Objects. A very thin object acts as a phase object, in which the phase is proportional to the projected potential along the electron path. The reason is that, in an electrostatic potential, the electron changes speed, which results in a phase shift. Then the exit wave of the object can be written as

$$\psi(\mathbf{R}) \approx 1 + i\sigma V_p(\mathbf{R}) \quad (10)$$

$V_p(\mathbf{R})$ is the projected potential of the object.

In the phase-contrast mode [Appendix A1, Eq. (18)], the phase shift of $\pi/2$ changes i into -1 so that the image intensity is

$$I(\mathbf{R}) \approx 1 - 2\sigma V_p(\mathbf{R}) \quad (11)$$

The image contrast of a thin object is proportional to its electrostatic potential $V_p(\mathbf{R})$ projected along the direction of incidence.

Building-Block Structures. It often happens that a family of crystal structures exists, of which all members consist of a stacking of the simple building blocks but with a different stacking sequence. This is, for instance, the case in mixed-layer compounds, polytypes, and periodical twins, but also periodic interfaces such as antiphase boundaries and crystallographic shear planes can be considered as mixed-layer systems. If the blocks are larger than the resolution of the microscope, each

block will show its characteristic contrast. In this way, stacking of the blocks can be directly “read” from the image. The relation between image and structure is called the image code.

An example is shown in Fig. 21 for the case of the binary alloy Au_4Mn in which Au or Mn atoms are located on two sublattices of a single fcc lattice. In this image the Mn atoms are visualized as bright dots. The Au atoms are not visible. This kind of image can be interpreted unambiguously.

Figure 17. Image formation at an edge dislocation according to the kinematical approximation. The thickness of the lines is a measure for the intensity of the beams. I_T is the intensity of the transmitted beam and I_S of the scattered beam.

Figure 18. Three images of the same area made under two-beam conditions using three different diffraction vectors $H_1 = 020$, $H_2 = 1\bar{1}0$, $H_3 = \bar{2}10$. Note the extinctions.

Interpretation using Image Simulation. In most cases, however, the image cannot easily be decoded in terms of the object structure, making interpretation difficult, especially at very high resolution, where the image contrast can vary drastically with the focus distance. As a typical and historical example, structure images obtained by Iijima for the complex oxide

Figure 19. Comparison of observed (left) and computer simulated (right) images of dislocations. Note the excellent correspondence (after Ref. 9).

Figure 20. Weak beam image of dislocations in RuSe_2 .

$\text{Ti}_2\text{Nb}_{10}\text{O}_{25}$ with a point resolution of approximately 0.35 nm are shown in Fig. 22 (upper parts). The structure as reproduced schematically in Fig. 23 consists of a stacking of corner- or face-sharing NbO_6 octahedra with the titanium atoms in tetrahedral positions. High-resolution images are taken at different focus values, causing the contrast to change drastically. The best resemblance with the X-ray structure can be obtained near the optimum Scherzer defocus, which is -90 nm in this particular case. However, the interpretation of such high-resolution images never appears to be trivial. The only solution remains in the comparison of the experimental images with those calculated for various trial structures. The results of such a calculation using the model of Fig. 23 are also shown in Fig. 22 (lower parts) and show a close resemblance with the experimental

images. Image simulation, however, is a very tedious technique that has to deal with a number of unknown parameters (specimen thickness, exact focus, beam convergence, etc.). Furthermore, the comparison is often done visually. As a consequence, the technique can only be used if the number of plausible models is very limited.

Holographic Reconstruction Methods. Due to the complexity of the imaging process, the information about the structure of the object is scrambled in the image. The structural information can be extracted directly from the images using holographic reconstruction methods. These methods aim at undoing the image process, that is, going back from image to object. Such a procedure consists of three steps. First one has to reconstruct the electron wave in the image plane. Then one has to reconstruct the exit wave at the object and from this one has to deduce the projected structure of the object. In a recorded image, which shows only intensities, the phase information is lost. Hence, the reconstruction of the whole image wave is a typical phase problem that can only be solved using holographic methods.

Figure 23. Comparison of experimental images (upper parts) and computer simulated images (lower parts) for $\text{Ti}_2\text{Nb}_{10}\text{O}_{29}$ as a function of defocus. (Courtesy S. Iijima.)

Figure 24. Experimentally reconstructed exit wave for $\text{YBa}_2\text{Cu}_4\text{O}_8$. Top, reconstructed phase; center: structure model; bottom: experimental image.

Basically two methods are workable. One method is *off-axis holography* (12). Here the electron beam is split in two waves by means of a biprism, which essentially is an electrostatically charged wire. One wave crosses the object so as to produce an enlarged image. The other wave (reference wave) passes by the object through the vacuum and interferes with the image wave in the image plane. In this way the high-resolution image is modulated by the interference fringes. From the position of the fringes one can then determine the phase of the electron wave. The other method is the *focus variation* method (1). The image wave is calculated by computer processing a series of images taken at different focus settings. Figure 24 shows an experimentally reconstructed exit wave for $\text{YBa}_2\text{Cu}_4\text{O}_8$. From this the structure of the object can be deduced.

Quantitative Structure Determination. Ideally quantitative extraction of information should be done as follows. One has a model for the object, for the electron object interaction, for the microscope transfer and for the detection, that is, all the ingredients needed to perform a computer simulation of the experiment. The object model that describes the interaction with electrons consists of the assembly of the electrostatic potentials of the constituting atoms. Also the imaging process is characterized by a number of parameters such as defocus, spherical aberration, and voltage. These parameters can either be known a priori with sufficient accuracy or not, in which case they have to be determined from the experiment. The model parameters can be estimated from the fit between the theoretical images and the experimental images. What one really wants is not only the best estimate for the model parameters but also their standard deviation (error bars), a criterion for the goodness of fit, and a suggestion for the best experimental setting. This requires a correct statistical analysis of the experimental data. The goodness of the fit between model and experiment has to

Figure 25. Scheme for the refinement procedure.

be evaluated using a criterion such as likelihood, mean square difference, or R factor (as with X-ray crystallography). For each set of parameters of the model, one can calculate this goodness of fit, so as to yield a fitness function in parameter space.

In principle, the search for the best parameter set is then reduced to the search for optimal fitness in parameter space. This search can only be done in an iterative way as given in the schematic in Fig. 25. First one has a starting model, that is, a starting value for the object and imaging parameters $\{a_n\}$. From these one can calculate the experimental images. This is a classical image simulation. (Note that the experimental data can also be a series of images and/or diffraction patterns.) From the mismatch between experimental and simulated images one can obtain a new estimate for the model parameters (for instance, using a gradient method), which can then be used for the next iteration. This procedure is repeated until the optimal fitness (i.e., optimal match) is reached.

The refinement procedure needs a good starting model to guarantee convergence. Such a model can be derived from holographic reconstruction. The refinement can also be done using experimental electron diffraction patterns.

An application of such refinement is shown in Figs. 26 and 27. Figure 26 (left) shows an HREM image of a Mg/Si precipitate in an Al matrix (13). Figure 26 (right) shows the phase of the exit wave, which is reconstructed experimentally using the focus variation method. From this an approximate structure model can be deduced. From different precipitates and different zones, electron diffraction patterns could be obtained, which were used simultaneously for a final fitting.

For each diffraction pattern the crystal thickness as well as the local orientation was also treated as a fittable parameter. An overview of the results is shown in Table 1. The obtained R factors are of the order of 5%, which is well below the R factors using kinematical refinement that do not account for the dynamical electron scattering. Figure 27 shows the structure obtained after refinement. Details of this study have been published by Zandbergen et al. (14).

SCANNING ELECTRON MICROSCOPY

The SEM is a mapping, rather than an imaging device (Fig. 28) and so is a member of the same class of instruments as the facsimile machine, the scanning probe microscope, and the confocal optical microscope (19). The sample is probed by a

Figure 26. HREM image (a) and phase of the experimentally reconstructed exit wave (b) of an Mg/Si precipitate in an Al matrix. [Courtesy H. Zandbergen (14).]

beam of electrons scanned across the surface. Radiations from the specimen stimulated by the incident beam are detected, amplified, and used to modulate the brightness of a second beam of electrons scanned, synchronously with the first beam, across a cathode-ray-tube display. If the area scanned on the display tube is $A \times A$ and the corresponding area scanned on the sample is $B \times B$, then the linear magnification $M = A/B$. The magnification is therefore geometric in origin and may be changed by varying the area scanned on the sample. The arrangement makes it possible for a wide range of magnifications

Figure 27. Structure model with MSLS from the fitting procedure described in the text. [Courtesy H. Zandbergen (14).]

to be obtained and allows rapid changes of magnification since no alterations to the electron-optical system are required. There is no rotation between object and image planes, and once the instrument has been focused on a given area the focus need not be changed when the magnification is varied. To a first approximation the size of the finest detail visible in the image will be set by the size of the probe scanning the specimen. Multiple detectors can be used to collect several signals simultaneously that can then be displayed individually or combined in perfect register with each other. It is this probability in particular that makes the SEM so useful a tool since multiple views of a sample, in different imaging modes, can be collected and compared in a single pass of the beam.

Figure 29 shows the basic components of a SEM. These can be divided into two main categories: the electron-optical and detector systems and the scanning processing and display systems. The electron-optical components are often described as being the “column” of the instrument while the other items are the “console” of the machine. The source of electrons is the gun, which produces electrons either by thermal emission, from tungsten or lanthanum hexaboride cathodes, or from a field-emission source. These electrons are then accelerated to an energy in the range from 500 eV to 30 keV. The beam of electrons leaving the gun is then focused onto the specimen by one or more condenser lenses. Although either electrostatic or electromagnetic lenses could be employed all modern SEMs use electromagnetic lenses. Typically, the final objective lens

has been of the pinhole design with the sample sitting outside the field of the lens since this arrangement gives good physical access to the specimen. However, in this arrangement the specimen is 10 mm to 20 mm away from the lens, which must therefore be of long focal length and correspondingly high aberration coefficients. In modern, high-performance instruments it is now common to use an immersion lens (15), in which the sample sits inside the lens at the center of the lens field, or a “snorkel” lens (16) in which the magnetic field extends outside of the lens to envelop the sample. Although the immersion lens gives very good performance and, by making the sample part of the lens structure, ensures mechanical stability, the amount of access to the specimen is limited. The snorkel lens, on the other hand, combines both good electron-optical characteristics with excellent access for detectors and stage mechanisms.

The coils that scan the beam are usually incorporated within the objective lens. A double-scan arrangement is often employed in which one sets of coils scans the beam through some angle θ from the axis of the microscope while a second set scans the beam through an angle 2θ in the opposite direction. In this way all scanned beams pass through a single point on the optic axis allowing for the placement of a defining aperture without any constriction of the scanned area. The scan pattern, produced on the specimen, is usually square in shape and is made up of 1000 horizontal lines, each containing 1000 individual scanned points or *pixels*. The final image frame thus contains 10^6 pixels, although for special activities such as focusing or alignment frames containing only 256×256 pixels may be used.

Increasingly the detector output is passed through an analog-to-digital convertor (ADC) and then handled digitally rather than as an analog video signal. This permits images to be stored, enhanced, combined, and analyzed using either an internal or an external computer. While the majority of the images are still recorded onto photographic film, digital images can be stored directly to magnetic or magneto-optic disks, and hard-copy output of the images can then be obtained using laser or dye sublimation printers. Typically scan repetition rates ranging from 15 or 20 frames/s (“TV rate”) to one frame in 30 s to 60 s (“photographic rate”) are provided. In addition individual pixels or arrays of pixels within an image field may be accessed if required.

In the case of the SEM the attainable resolution is determined by a number of factors, including the diameter of the electron-beam probe that can be generated, the current I_b contained in that probe, the magnification of the image, and the type of imaging mode that is being used. Over most of the

Table 1. Results of Structure Refinement Using Electron Diffraction Data

Other Imaging Modes. With a SEM it is possible to measure the current through the object as induced by the imaging electron beam [electron-beam-induced current (EBIC)]. This signal gives information about the electron-hole pair carriers in a semiconductor such as those at p - n junctions. In cathode luminescence, one detects the fluorescence radiation that is due to irradiation by the incident beam. This is a very sensitive technique that gives information about the impurities in semiconductors.

For more information we refer the reader to Ref. 19.

SCANNING TRANSMISSION ELECTRON MICROSCOPY

In principle a STEM can be considered as a SEM in which the object is transparent for the high energy electrons and in which the detector is placed behind the object. As in a STEM, a fine electron probe, formed by using a strong objective electron lens to demagnify a small source, is scanned over the specimen in a two-dimensional raster [Fig. 33(a)]. The electron probe is necessarily convergent: the convergence angle is, ideally, inversely proportional to the minimum probe size that determines the microscope resolution. On any plane after the specimen, a

Figure 32. Voltage contrast from an integrated circuit. Recorded at 5 keV in a Hitachi S-800 field-emission SEM. [Courtesy D. Joy (19).]

convergent beam electron-diffraction pattern is formed. Some part of this diffraction pattern is collected in a detector, creating a signal, which is displayed on a cathode-ray-tube screen to form the image using a raster scan matched to that which deflects the incident electron beam (20,21).

Dark-field images, obtained with an annular detector in a STEM instrument, showed the first clear electron microscopy images of individual heavy atoms (22). From that time, STEM has developed as an important alternative to conventional, fixed-beam transmission electron microscopy (CTEM), with special advantages for many purposes.

The use of a field emission gun (FEG) for high-resolution STEM is necessary to provide sufficient signal strength for viewing or recording images in a convenient time period. Because the FEG source has a brightness that is a factor of 10^4 or 10^3 greater than that of a W hairpin filament, the total current in the electron beam is greater when beam diameters of less than about 10 nm are produced. The current in a beam of 1 nm diameter is typically about 1 nA. As suggested by Fig. 33(b), the essential components of a STEM imaging system are the same as those for a CTEM instrument, with the electrons traveling in the opposite direction. In this diagram condensor and projector lenses have been omitted, and only the essential objective lens, which determines the imaging characteristics, is included. The STEM detector replaces the CTEM electron source. The STEM gun is placed in the detector plane of the CTEM, and the scanning system effectively translates the STEM source to cover the CTEM recording plate. When one uses a detector with a hole to eliminate the unscattered electron beam, the imaging is effectively incoherent so that the image contrast can be interpreted directly in terms of the atomic number of the constituting atoms. This imaging mode is therefore called Z contrast imaging (20). Figure 34 shows a STEM image of a tilt boundary in silicon in which the local atomic configuration can be seen directly in the images.

The strength of STEM as compared to TEM is that a variety of signals may be obtained in addition to the bright-field or dark-field signals derived from the elastic scattering of electrons in the specimen. STEM instruments are visually fitted with an energy-loss spectrometer. Energy filtered images reveal compositional information. For more information we refer to Refs. 20 and 24.

APPENDIX A. ELECTRON-DIFFRACTION THEORIES

Phase Object Approximation

We will now follow a classical approach. The nonrelativistic expression for the wavelength of an electron accelerated by an electrostatic potential E is given by

$$\lambda = \frac{h}{\sqrt{2meE}} \quad (\text{A1})$$

with h the Planck constant, m the electron mass and e the electron charge.

During the motion through an object with local potential $V(x, y, z)$ the wavelength will vary with the position of the electron as

$$\lambda'(x, y, z) = \frac{h}{\sqrt{2me[E + V(x, y, z)]}} \quad (\text{A2})$$

For thin phase objects and large accelerating potentials the assumption can be made that the electron keeps traveling along the z direction so that by propagation through a slice dz the electron suffers a phase shift.

$$\begin{aligned} d_\phi(x, y, z) &= 2\pi \frac{dz}{\lambda'} - 2\pi \frac{dz}{\lambda} \\ &= 2\pi \frac{dz}{\lambda} \left(\frac{\sqrt{E + V(x, y, z)}}{\sqrt{E}} - 1 \right) \\ &\simeq \sigma V(x, y, z) dz \end{aligned}$$

with

$$\sigma = \pi/\lambda E \quad (\text{A3})$$

Therefore the total phase shift is given by

$$\phi(x, y) = \sigma \int V(x, y, z) dz = \sigma V_p(x, y) \quad (\text{A4})$$

where $V_p(x, y)$ represents the potential of the specimen projected along the z direction.

Under this assumption the specimen acts as a pure phase object with transmission function

$$\psi(x, y) = \exp[i\sigma V_p(x, y)] \quad (\text{A5})$$

In case the object is very thin, one has

$$\psi(x, y) \approx 1 + i\sigma V_p(x, y) \quad (\text{A6})$$

This is the weak-phase approximation.

The effect of all processes prohibiting the electrons from contributing to the image contrast, including the use of a finite aperture, can in a first approximation be represented by a projected absorption function in the exponent of Eq. (A.5) so that

$$\psi(x, y) = \exp[i\sigma V_p(x, y) - \mu(x, y)] \quad (\text{A7})$$

or

$$\psi(\mathbf{R}) = \exp[i\sigma V_p(\mathbf{R}) - \mu(\mathbf{R})] \quad (\text{A8})$$

with $\mathbf{R} = (x, y)$ the vector in the plane perpendicular to z .

Figure 34. $\Sigma = 9, [221](100)$ symmetric tilt boundary in silicon viewed along the $[110]$ direction showing its five- and seven-membered ring structure. ADF = annular dark field; EELS = electron energy loss spectroscopy. [Courtesy S. Pennycook (21).]

Kinematical Theory

As follows from Eq. (1) a diffraction pattern can be calculated from the Fourier transforms of the exit wave $\psi(\mathbf{R})$. However, even for a simple approximation such as Eq. (A.8) the Fourier transform is not expressed in a simple analytical form. In order to derive a simpler, albeit approximated, expression for the diffraction pattern it is more convenient to describe the diffraction process directly in Fourier space.

According to the kinematical diffraction theory electrons are scattered in the specimen only and moreover the incident beam is not depleted by scattering. Each atom (scattering center) thus sees the same incident beam amplitude. This approximation is excellent in neutron diffraction, justified in X-ray diffraction, but it is poor in electron diffraction because the atomic scattering cross sections for electrons are relatively much larger than those for the other forms of radiation. The kinematical approximation is therefore only applicable to very thin crystals (a few nanometers for most materials) or for very large deviations from the exact Bragg condition (large s). It allows one to compute the amplitude of the diffracted beam only since the incident beam remains undepleted. Qualitative conclusions from the kinematical theory are nevertheless usually in agreement with the observations.

A crystal is made up of identical unit cells, regularly arranged at the basic lattice nodepoints given by

$$\mathbf{A}_L = l_1 \mathbf{a}_1 + l_2 \mathbf{a}_2 + l_3 \mathbf{a}_3 \quad (\text{A9})$$

Figure 35. Illustrating the path difference $OC - AB$ between waves diffracted by an atom at the origin and an atom at $\mathbf{r}_j$.

(where l_j is an integer). In each unit cell, a number N of atoms is found at the relative positions ρ_k ($k = 1, \dots, N$). Mathematically speaking, the whole crystal is made up by convolution of one unit cell with the basic crystal lattice. Atom positions are thus $\mathbf{r}_j = \mathbf{A}_L + \rho_k$ and they depend on four indices l_1, l_2, l_3 , and k .

Let $\mathbf{k}_0$ represent the wave vector of the incident wave and $\mathbf{k}$ that of the diffracted wave; then at large distance, i.e., in the Fraunhofer approximation, the phase difference between a wave diffracted by an atom at the origin and an atom at $\mathbf{r}_j$ is given by $2\pi(\mathbf{k} - \mathbf{k}_0) \cdot \mathbf{r}_j$ and the scattered amplitude $A(\mathbf{k})$ along the direction of $\mathbf{k}$ (Fig. 35)

$$A(\mathbf{k}) = \sum_j f_j \exp[2\pi i(\mathbf{k} - \mathbf{k}_0) \cdot \mathbf{r}_j] \quad (\text{A10})$$

This amplitude will exhibit maxima if all exponents are integer multiples of $2\pi i$; maxima will thus occur if $(\mathbf{k} - \mathbf{k}_0) \cdot \mathbf{r}_L$ is integer, which implies that $\mathbf{k} - \mathbf{k}_0$ must be a reciprocal-lattice vector

$$\mathbf{k} - \mathbf{k}_0 = \mathbf{B}_H \equiv h_1 \mathbf{b}_1 + h_2 \mathbf{b}_2 + h_3 \mathbf{b}_3 \quad (\text{A11})$$

(where h_j are integers and $\mathbf{b}_i$ are base vectors). This is Ewald's condition as discussed in the section on electron diffraction.

However, $A(\mathbf{k})$ will also be different from zero if the diffraction condition is not exactly satisfied, that is, if Ewald's sphere misses closely a reciprocal-lattice node by a vector $\mathbf{s}$, called the excitation error. This vector is parallel to the foil normal and connects the reciprocal-lattice node with the intersection point with Ewald's sphere; by convention s is positive when the reciprocal-lattice node is inside Ewald's sphere and negative when outside (Fig. 7). One can now set

$$\mathbf{k} - \mathbf{k}_0 = \mathbf{B}_H + \mathbf{s} \quad (\text{A12})$$

and

$$A_H = \sum_j f_j \exp[2\pi i(\mathbf{B}_H + \mathbf{s}) \cdot \mathbf{r}_j] \quad (\text{A13})$$

and with $\mathbf{r}_j = \mathbf{A}_L + \rho_k$.

$$A_H = \sum_L \sum_k f_k \exp[2\pi i(\mathbf{B}_H + \mathbf{s}) \cdot (\mathbf{A}_L + \rho_k)] \quad (\text{A14})$$

Neglecting $\mathbf{s} \cdot \boldsymbol{\rho}_k$ as compared to the other terms and noting that $\mathbf{B}_H \cdot \mathbf{A}_L$ is always an integer, this can be written as

$$A_H = F_H \sum_L \exp(2\pi i \mathbf{s} \cdot \mathbf{A}_L) \quad (\text{A15})$$

where the structure factor F_H is defined as

$$F_H = \sum_k f_k \exp[2\pi i (\mathbf{B}_H \cdot \boldsymbol{\rho}_k)] \quad (\text{A16})$$

Equation (A.15) is in fact a triple sum over the indices $\mathbf{L}(l_1, l_2, l_3)$. If $\mathbf{s}$ is written as a vector in terms of the reciprocal-space base vectors $\mathbf{b}_j$:

$$\mathbf{s} = s_1 \mathbf{b}_1 + s_2 \mathbf{b}_2 + s_3 \mathbf{b}_3 \quad (\text{A17})$$

one has

$$\mathbf{s} \cdot \mathbf{A}_L = l_1 s_1 + l_2 s_2 + l_3 s_3 \quad (\text{A18})$$

The triple sum can be expressed as the product of three single sums of geometrical progressions. Calling N_1 , N_2 , and N_3 the numbers of unit cells along the three lattice directions $\mathbf{a}_1$, $\mathbf{a}_2$, and $\mathbf{a}_3$, one obtains, neglecting an irrelevant phase factor

$$\begin{aligned} A_H &= F_H \sum_{l_1=0}^{N_1-1} \sum_{l_2=0}^{N_2-1} \sum_{l_3=0}^{N_3-1} \exp[2\pi i (l_1 s_1 + l_2 s_2 + l_3 s_3)] \\ &= F_H \frac{\sin \pi s_1 N_1}{\sin \pi s_1} \frac{\sin \pi s_2 N_2}{\sin \pi s_2} \frac{\sin \pi s_3 N_3}{\sin \pi s_3} \end{aligned} \quad (\text{A19})$$

This is the well-known *von Laue interference function* (10) (Fig. 36), which describes the dependence of the scattered amplitude on the deviation parameter s . The sine functions in the denominators can be approximated by their arguments, since these are always small. We further note that for large N one has $\sin(\pi N s)/N \pi s \sim \delta(s)$ with $\delta(s) = 0$ for $s \neq 0$ and $\delta(s) = 1$ for $s = 0$. We can then write, neglecting irrelevant phase factors,

$$A_H = F_H \delta(s_1) \delta(s_2) \delta(s_3) (\Omega / V_a) \quad (\text{A20})$$

Figure 36. von Laue interference function describing the dependence of the scattered intensity on the excitation error s_x .

where Ω is the volume of the crystal and V_a the volume of the unit cell ($\Omega = N_1 N_2 N_3 a_1 a_2 a_3$; $V_a = a_1 a_2 a_3$). For a parallelepiped-shaped crystal block one often introduces the components of $\mathbf{s}$ along the three mutually perpendicular edges of the block with unit vectors $\mathbf{e}_x$, $\mathbf{e}_y$, and $\mathbf{e}_z$:

$$\mathbf{s} = s_x \mathbf{e}_x + s_y \mathbf{e}_y + s_z \mathbf{e}_z \quad (\text{A21})$$

One can then rewrite Eq. (A.19) in terms of s_x , s_y , and s_z as

$$A_H = F_H \frac{\sin \pi s_x N_1 a_1}{\sin \pi s_x a_1} \frac{\sin \pi s_y N_2 a_2}{\sin \pi s_y a_2} \frac{\sin \pi s_z N_3 a_3}{\sin \pi s_z a_3} \quad (\text{A22})$$

Hereby use was made of the relations valid for a parallelepiped

$$s_1 = s_x a_1, \quad s_2 = s_y a_2, \quad s_3 = s_z a_3 \quad (\text{A23})$$

Equation (A.22) is only true if N_1 , N_2 , and N_3 are sufficiently large. However, the foils used in transmission electron microscopy are only large in two dimensions, that is, along x and y , the foil being only a small number N_3 of unit cells thick along z . In such a foil one thus obtains

$$A_H = F_H \frac{\Omega}{V_a} \delta(s_x) \delta(s_y) \frac{\sin \pi s_z N_3 a_3}{\pi s_z a_3} \quad (\text{A24})$$

Introducing the specimen thickness $N_3 a_3 = t$ and assuming s_x , $s_y = 0$ and calling $s_z = s$ one finds

$$A_H = \frac{\sin \pi s t}{s t_H} \quad (\text{A25})$$

per surface area where $t_H = \pi / F_H$; t_H is called the *extinction distance*. This result is interpreted as meaning that the sharp reciprocal-lattice nodes, characteristic of a large crystal, become rods in the case of a thin plate, as already mentioned before. These rods are perpendicular to the foil plane and have a weight profile given by $\sin(\pi s t) / s t_H$. The corresponding intensity is given by (Fig. 37)

$$I_H = \frac{\sin^2 \pi s t}{(s t_H)^2} \quad (\text{A26})$$

Figure 37. Rocking curve for a foil with thickness t_0 according to the kinematical theory.

it is called the *rocking curve*. An intensity can be associated with each intersection point of the Ewald sphere with this rod (called *relrod*), that is, with each s value, the intensity being given by the value of the function at the intersection point.

Another way to interpret these results is the following: In the Fraunhofer approximation, the diffracted wave is expressed by the Fourier transform of the electrostatic potential of the crystal.

A crystal can be considered as a convolution product of two factors: The convolution theorem then states that the diffracted wave is given by the product of the respective Fourier transforms of these two factors [e.g., Eq. (A.15)]. The Fourier transform of the lattice function yields delta functions at the reciprocal nodepoints, which describe the directions of the diffracted beams. The amplitudes of these beams are then given by the Fourier transforms of the potential of one unit cell, i.e., the structure factors [e.g., Eq. (A.20)]. The conservation of energy also requires that the wavevectors of the diffracted beams should all have constant length, or, that the reciprocal nodes should lie on a sphere, the Ewald sphere. In case the object is a thin crystal slab, it can be described as the product of an infinite crystal with a slab function that is equal to 1 inside the slab and 0 elsewhere. In that case, the diffraction pattern is given by the convolution product of the diffraction pattern of the infinite crystal with the Fourier transform of the slab function. Then each reciprocal node is smeared along a line perpendicular to the slab, with a factor given by a sinc function of the form in Eq. (A.26).

Note that if the Ewald sphere would be flat, the diffracted wave can be derived from the Fourier transform of Eq. (A.8) provided the phase is weak. This means that, apart from the Ewald sphere, the weak phase object theory and the kinematical theory are equivalent.

Equation (A.15) can also be understood intuitively in terms of the column approximation along the z direction. The amplitude of the wave diffracted by the volume element Δz_n at level z_n in the column (measured from the entrance face) is given by $\Delta A_H = F_H \Delta z_n \exp(2\pi i s z_n)$ or in differential form

$$dA_H = F_H \exp(2\pi i s z) dz \quad (\text{A27})$$

The amplitude at the exit face of the column is then given by the sum

$$A_H = F_H \sum_n \exp(2\pi i s z_n) \Delta z_n \quad (\text{A28})$$

which, if $s = \text{const}$, can be approximated by the integral

$$A_H = F_H \int_0^t \exp(2\pi i s z) dz \quad (\text{A29})$$

or

$$A_H = (F_H \sin 2\pi s t) / \pi s \quad (\text{A30})$$

which is consistent with Eq. (A.26), though not identical.

In the complex plane the sum equation (A.28) can be represented by an amplitude-phase diagram (7) (Fig. 38); it consists of the vector sum of elementary vectors, all of the same length, each representing the amplitude diffracted by a unit cell. Successive unit cells along a column in a perfect crystal

Figure 38. Complex plane construction of the amplitude-phase diagram for a perfect foil.

diffract with constant phase differences, that is, the corresponding vectors enclose constant angles. The diagram is a regular polygon that can be approximated by a circle with radius $F_H/2\pi s$. The length of the arc of the circle is equal to the column length. The amplitude diffracted by the column is given by the length of the segment connecting the endpoints P' and P of the arc. It is clear that the amplitude will be zero if the column length (i.e., the foil thickness t) is an integer number of complete circles long. The maximum amplitude is equal to the diameter of the circle, that is, to $F_H/\pi s$. Along deformed columns the amplitude-phase diagrams become curved (spiral shaped) since the angle between successive segments is no longer constant.

Two-Beam Dynamical Theory for Perfect Crystals

The dynamical theory takes into account that a scattered beam can act in turn as an incident beam and be scattered again in the interior of the crystal. The simplest case that can analytically be discussed and which moreover is relevant for image formation in the diffraction contrast mode is the two-beam case. Next to the incident beam only one beam is strongly excited (has small s). This scattered beam is then again an incident under the Bragg angle for the same set of lattice planes and can thus be scattered again. This interplay between incident and scattered beam tends to obliterate the destruction between incident and scattered beam in the interior of the crystal; it limits strongly the lateral spread of an incident Bragg diffracted electron beam and justifies the column approximation used in image calculations of defects according to the diffraction contrast mode. The dynamical theory is applicable to "thick" crystals provided also absorption is taken into account. It allows to compute the amplitudes of the transmitted beam as well as of the diffracted beam for a single Bragg reflection.

We will include all usual approximations in the model already from the onset. These approximations are as follows: (i) ideal two-beam situation, (ii) no absorption, and (iii) column approximation. Within a column along z , perpendicular to the

Figure 39. Schematic representation of the interfering waves during dynamical diffraction in the two-beam case. (a) Right: transmitted beam, left: scattered beam. (b) Changing $H \rightarrow -H$ changes also $s \rightarrow -s$.

foil surface, we describe the interplay between the transmitted beam represented by the plane wave $\phi_0(z) \exp(2\pi i \mathbf{k}_0 \cdot \mathbf{r})$ and the scattered beam represented by $\phi_H(z) \exp(2\pi i \mathbf{k} \cdot \mathbf{r})$ (two-beam approximation). The complex amplitudes ϕ_0 and ϕ_H depend on z only (column approximation). Within the slice dz at the level z behind the interface we express that the transmitted beam amplitude results from the interference between the twice transmitted beam with amplitude $\phi_0(z)\phi_0(dz)$ and the doubly scattered beam of which the amplitude is $\phi_H(z)\phi_{-H}(dz)$ [Fig. 39(a)]. The minus sign in $-H$ means that reflection takes place from the $-H$ side of the set of lattice planes. We thus obtain

$$\phi_0(z + dz) = \phi_0(z)\phi_0(dz) + \phi_H(z)\phi_{-H}(dz) \quad (\text{A31})$$

The slice dz being arbitrarily thin the kinematical approximation [e.g., Eq. (A.27)] can be applied rigorously to $\phi_0(dz)$ ($\equiv 1$, no beam depletion) and $\phi_{-H}(dz) = \pi i/t_H \exp(-2\pi i s z) dz$, where the factor i results from the phase change on scattering and where the structure amplitude F_H has been expressed in terms of the extinction distance t_H . Note that changing $H \rightarrow -H$ also changes the sign of s [Fig. 39(b)].

Similarly the scattered beam amplitude results from the interference between (1) the transmitted beam, which is subsequently scattered in dz , and (2) the scattered beam, which is subsequently transmitted through dz [Fig. 39(a)]. This leads to the relation

$$\phi_H(z + dz) = \phi_0(z)\phi_H(dz) + \phi_H(z)\phi_0(dz) \quad (\text{A32})$$

where again $\phi_0(dz) = 1$ and $\phi_H(dz) = (\pi i/t_H)[\exp(2\pi i s z)] dz$. The two equations (A.31) and (A.32) can be transformed into differential equations by noting that quite generally

$$\phi(z + dz) - \phi(z) = \frac{d\phi}{dz} dz \quad (\text{A33})$$

One thus obtains the following set of coupled differential

equations:

$$\begin{aligned} \frac{d\phi_0}{dz} &= [(\pi i/t_{-H}) \exp(2\pi i s z)] \phi_H(z) \\ \frac{d\phi_H}{dz} &= [(\pi i/t_H) \exp(-2\pi i s z)] \phi_0(z) \end{aligned} \quad (\text{A34})$$

in centro-symmetrical crystals $t_{-H} = t_H$. An alternative system is obtained by the substitution

$$\phi_0 = T, \quad \phi_H = S \exp(-2\pi i s z) \quad (\text{A35})$$

which only changes the phase of the amplitudes but not the resulting intensities. One obtains

$$\begin{aligned} \frac{dT}{dz} &= (\pi i/t_{-H}) S \\ \frac{dS}{dz} &= 2\pi i s S + (\pi i/t_H) T \end{aligned} \quad (\text{A36})$$

These are the *Darwin-Howie-Whelan equations* (10,11) of the two-beam dynamical diffraction theory.

The solution for a perfect crystal (i.e., s is constant) is easily obtained by the standard procedure used to solve systems of coupled first order differential equations; one finds

$$\begin{aligned} T &= [\cos(\pi \sigma_H z) - i(s_H/\sigma_H) \sin(\pi \sigma_H z)] \exp(\pi i s_H z) \\ S &= [(i/\sigma_H t_H) \sin \pi \sigma_H z] \exp(\pi i s_H z) \end{aligned} \quad (\text{A37})$$

where

$$\sigma_H^2 = (1 + s_H^2 t_H^2)/t_H^2 \quad (\text{A38})$$

The scattered intensity is thus given by the square modulus of S

$$I_S = SS^* = [\sin^2(\pi \sigma_H z)]/(\sigma_H t_H)^2 \quad (\text{A39})$$

Figure 40. Illustration of the formation of thickness extinction contours.

where S^* denotes the complex conjugate of S and $I_T = 1 - I_S$ since absorption is neglected. Formula (A.39) is the homolog of formula (A.26), found in the kinematical approximation. Note that the depth period, which is $1/s_H$ in the kinematical case, now becomes $1/\sigma_H$. There is no longer a divergence for $s_H \rightarrow 0$.

Equations (A.34) describe the periodic transfer of electrons from the transmitted beam into the scattered beam and vice versa; this effect is called the *Pendellösung* effect because of its similarity with the behavior of two coupled pendulums or two coupled oscillating circuits.

Equations (A.37) describes the periodic depth variations of the diffracted and transmitted intensity, as well as the variation as a function of the excitation error s . Equation (A.39) is called the *rocking curve*. In an undeformed wedge-shaped specimen the depth variation gives rise to *thickness extinction contours*, which are parallel to the cutting edge of the wedge (Fig. 40). In a bent plane-parallel specimen the lines of constant s give rise to equi-inclination or *bent contours* (Fig. 41).

It can be shown that taking absorption into account the shape of the rocking curve becomes asymmetric in s for the transmitted beam (Fig. 42) whereas it remains symmetric for the scattered beam. [A similar effect occurs in x-ray diffraction: the *Bormann effect* (22).] The steep slope of the transmitted intensity in the vicinity of $s = 0$ is exploited in imaging strain fields due to dislocations and other defects.

Two-Beam Dynamical Theory for Faulted Crystals

Displacement Fields of Defects. In transmission electron microscopy defects are characterized by their displacement fields $R(\mathbf{r})$. The simplest example is the stacking fault, for which $R(\mathbf{r})$ is a step function, $R = 0$ for $z < z_1$, and $R = R_0$ for $z_1 < z < z_0$, z_1 being the level of the stacking fault plane in the foil and z_0 being the foil thickness. The exit part of the foil is displaced over a vector $\mathbf{R}_0$ with respect to the entrance part (Fig. 15). At the

Figure 41. Illustration of the formation of equi-inclination (bent) contours.

level of the interface the diffracted beam undergoes a relative phase shift given by

$$\gamma = 2\pi \mathbf{H} \cdot \mathbf{R}_0 \quad (\text{A40})$$

whereas the transmitted beam is unaffected. The amplitude T_S of the transmitted beam for the foil containing a stacking fault

Figure 42. Schematic representation of the interfering waves in the case of a foil containing a planar interface. Left: transmitted amplitude; right: scattered amplitude.

Figure 43. Cross section of foil containing a stacking fault in an inclined plane: illustrating the formation of stacking-fault fringes. (a) According to the kinematical theory $s \neq 0$; (b) according to the dynamical theory $s = 0$.

parallel to the foil plane can thus be formulated as (Fig. 42, left)

$$T_S = T_1 T_2 + S_1 S_2^- e^{i\gamma} \quad (\text{A41})$$

The expressions T_1 , T_2 , S_1 , S_2 refer to the amplitudes for perfect foils. The indices 1 and 2 refer to the entrance part and the exit part, respectively; the minus sign indicates that the excitation error is $-s$ in the corresponding expression because the diffraction vector is $-\mathbf{H}$.

Similarly the diffracted beam amplitude can be expressed as (Fig. 42, right)

$$S_S = T_1 S_2 e^{-i\gamma} + S_1 T_2^- \quad (\text{A42})$$

The meaning of Eq. (A.41) is obvious; it expresses that the transmitted beam results from the interference between the doubly transmitted beam and the doubly scattered beam. The factor $\exp(i\alpha)$ takes into account the phase shift over α of the beam scattered by the exit part. Equation (A.42) has a similar meaning. In Eq. (A.42) the phase shift is $-\alpha$ because the phase shifts are opposite in sign for S_2 and S_2^- . Detailed expressions can be obtained by replacing T_1 , T_2 , S_1 , S_2 by their explicit expressions in Eq. (A.37).

If the fault plane is inclined with respect to the foil plane, the phase change α takes place at a level z_1 , which now depends on position x along the foil. For instance, in Fig. 43, z_1 becomes a linear function of x . As a result T_S and S_S become quasiperiodic functions not only of z_1 , but also of x .

For $s = 0$ the depth period is equal to t_H ; for $s \neq 0$ it becomes $1/\sigma_H$, where σ_H is given by Eq. (A.38).

Strained Crystals. Strain fields and lattice defects are characterized by their displacement fields $\mathbf{R}(\mathbf{r})$: the atom that was at $\mathbf{r}$ before deformation will be found at $\mathbf{r} + \mathbf{R}(\mathbf{r})$ after deformation. A twin boundary with a small twinning vector (domain boundary) parallel to the foil plane at the level z_1 (Fig. 15) can, for instance, be represented by the displacement field $R = 0$ for $z < z_1$ and $R = kz$ for $z > z_1$.

A pure screw dislocation can be described by the function $\mathbf{R} = \mathbf{b}(\theta/2\pi)$, where θ is the azimuth angle measured in the plane perpendicular to $\mathbf{b}$; all displacements are parallel to $\mathbf{b}$.

The Darwin-Howie-Whelan equations (A.36) can be adapted to the case of a deformed crystal by the substitution

$$s \Rightarrow s_{\text{eff}} = s + H \frac{dR}{dz} \quad (\text{A43})$$

The Multislice Method

The two-beam dynamical treatment is insufficient for the general situation in which high resolution images are taken with the incident beam along a zone axis where many diffracted beams are involved. Therefore the multislice method was developed as a numerical method to compute the exit wave of an object.

Although the multislice formula can be derived from quantum-mechanical principles, we follow a simplified version (23) of the more intuitive original optical approach (24). A more rigorous treatment is given in the next section.

Consider a plane wave, incident on a thin specimen foil and nearly perpendicular to the incident beam direction z . If the specimen is sufficiently thin, we can assume the electron to move approximately parallel to z so that the specimen acts a pure phase object with transmission function equation (A.5)

$$\psi(x, y) = \exp[i\sigma V_p(x, y)] \quad (\text{A44})$$

A thick specimen can now be subdivided into thin slices, perpendicular to the incident beam direction. The potential of each slice is projected into a plane that acts as a two-dimensional phase object. Each point (x, y) of the exit plane of the first slice can be considered as a Huyghens source for a secondary spherical wave with amplitude $\psi(x, y)$ (Fig. 44).

Now the amplitude $\psi(x', y')$ at the point (x', y') of the next slice can be found by the superposition of all spherical waves of the first slice, that is, by integration over x and y , yielding

$$\psi(x', y') = \int \exp[i\sigma V_p(x, y)] \times \frac{\exp(2\pi ikr)}{r} dx dy \quad (\text{A45})$$

When $|x - x'| < \epsilon$, $|y - y'| < \epsilon$, with ϵ the slice thickness, the

Figure 44. Schematic representation of the propagation effect of electrons between successive slices of thickness ϵ .

Fresnel approximation can be used, that is,

$$\begin{aligned} r &= \sqrt{(x - x')^2 + (y - y')^2 + \epsilon^2} \\ &\approx \epsilon \left(1 + \frac{(x - x')^2}{2\epsilon^2} + \frac{(y - y')^2}{2\epsilon^2} \right) \end{aligned} \quad (\text{A46})$$

so that

$$\begin{aligned} \psi(x', y') &\approx \frac{\exp(2\pi i k \epsilon)}{\epsilon} \int \exp[i\sigma V_p(x, y)] \\ &\times \exp\left(i \frac{\pi k}{\epsilon} [(x - x')^2 + (y - y')^2]\right) dx dy \end{aligned} \quad (\text{A47})$$

which, apart from constant factors, can be written as a convolution product:

$$\psi(x, y) = \epsilon [i\sigma V_p(x, y)] \exp\left(\frac{i\pi k(x^2 + y^2)}{\epsilon}\right) \quad (\text{A48})$$

where the convolution product of two functions is defined as (in one dimension)

$$f(x) * g(x) = \int f(x') g(x - x') dx' \quad (\text{A49})$$

If the wave function at the entrance face is $\psi(x, y, 0)$, instead of a plane wave one has for the wave function at the exit face

$$\psi(x, y, \epsilon) = \{\psi(x, y, 0) \exp[i\sigma V_p(x, y)]\} \exp\left(\frac{i\pi k(x^2 + y^2)}{\epsilon}\right) \quad (\text{A50})$$

This is the Fresnel approximation in which the emerging spherical wavefront is approximated by a paraboloidal wavefront.

The propagation through the vacuum gap from one slice to the next is thus described by a convolution product in which each point source of the previous slice contributes to the wave function in each point of the next slice. The motion of an electron through the whole specimen can now be described by an alternation of phase object transmissions (multiplications) and vacuum propagations (convolutions). In the limit of the slice thickness ϵ tending to zero, this multislice expression converges to the exact solution of the nonrelativistic Schrödinger equation in the forward-scattering approximation.

In the original multislice method one used the Fourier transform of Eq. (A.50) where the real space points (x, y) are transformed into diffracted beams $\mathbf{g}$ and where convolution and normal products are interchanged, that is,

$$\psi(\mathbf{g}, \epsilon) = [\psi(\mathbf{g}, 0) \exp(i\sigma V_g)] \exp\left(\frac{i\pi \mathbf{g}^2 \epsilon}{k}\right) \quad (\text{A51})$$

where V_g are the structure factors (Fourier transforms of the unit-cell potential).

The wave function at the exit face of the crystal can now be obtained by successive application of Eq. (A.50) or (A.51). This can either be done in real space [Eq. (A.50)] or in reciprocal space [Eq. (A.51)]. The major part of the computing time is required for the calculation of the convolution product, which is proportional to N^2 [N is the number of sampling points (real space) or beams (reciprocal space)].

Since the Fourier transform of a convolution product yields a normal product (with calculation time proportional to N) a large gain in speed can be obtained by alternately performing the propagation in reciprocal space and the phase object transmission in real space (23). In this way the computing time is devoted to the Fourier transforms and is proportional to $N \log_2 N$.

Another way of increasing the speed is in the so-called real-space method (24). Here the whole calculation is done in real space using Eq. (A.50) but the forward scattering of the electrons is exploited so as to calculate the convolution effect of the propagation only in a limited number of adjacent sampling points. In this way, the calculation time is proportional to N . This method does not require a periodic crystal and is thus suitable for calculation of crystal defects.

Electron Channeling

The multislice method is an efficient method to compute numerically the exit wave of an object. However it observes interesting physical aspects of dynamical electron scattering. The channelling theory is more approximate (1,25) (although improvements are currently being made) but it is simple and it gives much physical insight.

Electron Wave. Consider an isolated column of atoms, parallel to the electron beam. If we assume that the fast electron in the direction of propagation (z axis) behaves as a classical particle with velocity $v = \hbar k/m$ we can consider the z axis as a time axis with

$$t = \frac{mz}{\hbar k} \quad (\text{A52})$$

Hence we can start from the time-dependent Schrödinger equation

$$-\frac{\hbar}{i} \frac{\partial \psi}{\partial t}(\mathbf{R}, t) = H\psi(\mathbf{R}, t) \quad (\text{A53})$$

with

$$H = -\frac{\hbar^2}{2m} \Delta_{\mathbf{R}} - eU(\mathbf{R}, t) \quad (\text{A54})$$

with $U(\mathbf{R}, t)$ the electrostatic crystal potential, m and $\hbar$ the relativistic electron mass and wavelength, and $\Delta_{\mathbf{R}}$ the Laplacian operator acting in the plane $(\mathbf{R})$ perpendicular to z .

Using Eq. (A.52) we then have

$$\frac{\partial \psi(\mathbf{R}, z)}{\partial z} = \frac{i}{4\pi k} [\Delta_{\mathbf{R}} + V(\mathbf{R}, z)] \psi(\mathbf{R}, z) \quad (\text{A55})$$

with

$$V(\mathbf{R}, z) = \frac{2me}{\hbar^2} U(\mathbf{R}, z) \quad (\text{A56})$$

This is the well-known high-energy equation in real space, which can also be derived from the stationary Schrödinger equation in the forward-scattering approximation (22).

If we now consider the depth proportional to the time, the dynamical equation (A.55) represents the walk of an electron in the two-dimensional projected potential of the columns. The solution can be expanded in eigenfunctions (eigenstates) of the Hamiltonian

$$\psi(\mathbf{R}, z) = \sum_n C_n \phi_n(\mathbf{R}) \exp\left(-i\pi \frac{E_n}{E} \frac{z}{\lambda}\right) \quad (\text{A57})$$

where

$$H\phi_n(\mathbf{R}) = E_n \phi_n(\mathbf{R}) \quad (\text{A58})$$

with the Hamiltonian

$$H = -\frac{\hbar^2}{2m} \Delta_{\mathbf{R}} - eU(\mathbf{R}) \quad (\text{A59})$$

$U(\mathbf{R})$ is the projected potential of the column

$$E = \frac{\hbar^2 k^2}{2m} \quad (\text{A60})$$

E is the incident electron energy, and λ is the electron wavelength. For $E_n < 0$ the eigenstates are bound to the column. We now rewrite Eq. (A.57) as

$$\psi(\mathbf{R}, z) = \sum_n C_n \phi_n(\mathbf{R}) + \sum_n C_n \phi_n(\mathbf{R}) \left[\exp\left(-i\pi \frac{E_n}{E} \frac{z}{\lambda}\right) - 1 \right] \quad (\text{A61})$$

The coefficients C_n are determined from the boundary condition

$$\sum_n C_n \phi_n(\mathbf{R}) = \psi(\mathbf{R}, 0) \quad (\text{A62})$$

In case of plane-wave incidence one thus has

$$\sum_n C_n \phi_n(\mathbf{R}) = 1 \quad (\text{A63})$$

so that

$$\psi(\mathbf{R}, z) = 1 + \sum_n C_n \phi_n(\mathbf{R}) \left[\exp\left(-i\pi \frac{E_n}{E} \frac{z}{\lambda}\right) - 1 \right]$$

Only states will appear in the summation for which

$$|E_n| \geq \frac{E\lambda}{z} \quad (\text{A64})$$

These are bound states with deep energy levels that are localized near the column cores. In practice if the column does not consist of heavy atoms and the distance between columns is not too close (e.g., larger than 0.1 nm) only one eigenstate will appear, which can be compared to the 1s state of an atom.

We then have

$$\psi(\mathbf{R}, z) = 1 + C\phi(\mathbf{R}) \left[\exp\left(-i\pi \frac{E}{E_0} \frac{z}{\lambda}\right) - 1 \right] \quad (\text{A65})$$

A very interesting consequence of this description is that, since the state ϕ is very localized at the atom core, the wave function for the total object can be expressed as a superposition of the individual column functions ϕ_i so that Eq. (A.65) in that case becomes

$$\psi(\mathbf{R}, z) = 1 + \sum_i C_i \phi_i(\mathbf{R} - \mathbf{R}_i) \left[\exp\left(-i\pi \frac{E}{E_0} \frac{z}{\lambda}\right) - 1 \right] \quad (\text{A66})$$

where the summation runs over all the atomic columns of the object parallel to the electron beam.

The interpretation of Eq. (A.66) is simple. Each column i acts as a channel in which the wave function oscillates periodically with depth. The periodicity is related to the “weight” of the column, that is, proportional to the atomic number of the atoms in the column and inversely proportional to their distance along the column. The importance of these results lies in the fact that they describe the dynamical diffraction for larger thicknesses than the usual phase-grating approximation and that they require only the knowledge of one function ϕ_i per column (which can be set in tabular form similar to atom scattering factors or potentials). Furthermore, even in the presence of dynamical scattering, the wave function at the exit face still retains a one-to-one relation with the configuration of columns for perfect crystals as well as for defective crystals provided they consist of columns parallel to the electron beam. Hence this description is very useful for interpreting high-resolution images.

Diffraction Pattern. Fourier transforming the wave function equation (A.66) at the exit face of the object yields the wave function in the diffraction plane, which can be written as

$$\psi(\mathbf{g}, z) = \sum_i \sum_i \exp(-2\pi i \mathbf{g} \cdot \mathbf{R}_i) F_i(\mathbf{g}, t) \quad (\text{A67})$$

In a sense the simple kinematical expression for the diffraction amplitude holds, provided the scattering factor for the atoms is replaced by a dynamical scattering factor for the columns, which is defined by

$$F_i(\mathbf{g}, z) = \left[\exp\left(\frac{-i\pi E_i}{E} \frac{z}{\lambda}\right) - 1 \right] C_i f_i(\mathbf{g}) \quad (\text{A68})$$

with $f_i(\mathbf{g})$ the Fourier transform of $\phi_i(\mathbf{R})$. It is clear that the dynamical scattering factor varies periodically with depth. This periodicity may be different for different columns.

In case of a monatomic crystal, all F_i are identical. Hence $\psi(\mathbf{g}, z)$ varies perfectly periodically with depth. In a sense the electrons are periodically transferred from the central beam to the diffracted beams and back. The periodicity of this dynamical oscillation (which can be compared with the Pendelösung effect) is called the dynamical extinction distance. It has, for instance, been observed in Si(111). An important consequence of Eq. (A.67) is the fact that the diffraction pattern can still be described by a kinematical type of expression so that existing results and techniques (e.g., extinction rules) that have been based on the kinematical theory remain valid to some extent for thicker crystals in zone orientation.

X-RAY MICROSCOPY

X-ray microscopy is not a new field, with the first work dating back to the beginning of the twentieth century. The first instruments were simple indirect transmission microscopes. A common technique was contact microradiography and involved placing a photographic film in contact with a sample and then illuminating the sample with X rays to produce a shadowgraph. The image was then magnified using an optical microscope. This technique, when modified to allow projection of the object onto the film instead of having the film in contact with the sample, produced a 0.1 μm resolution by the 1950s. Contact microscopy, in which the film is replaced by a photosensitive material, was the next natural development. Both classical X-ray microscopy techniques continue to be used in medical and biological research and have produced some spectacular images of samples ranging from chromosomes to brain tissue (1,60,61).

The question may arise then why a 0.1 μm resolution for modern day X-ray microscopes (XRMs) should be counted as an important achievement. The reason is that today's XRMs are capable of doing many more types of experiments than the previous generation microscopes could. Although they lost ground to the high resolution scanning electron microscope (SEM) in the 1960s and later to the atomic resolution scanning tunneling microscope (STM) in the 1980s, XRMs have recaptured the interest of the scientific community because they are capable of unique experiments not possible with other microscopes. High intensity broad-band X rays generated as synchrotron radiation (62,63), improved optics and instrumentation, the ability to study radiation-sensitive and wet samples with soft X rays, and the ability to do spectroscopic imaging make today's X-ray microscopes extremely versatile (64–67). The 0.1 μm resolution record has also been broken by several X-ray microscopes.

Many interesting effects—both basic and technological—are observed in the dimensional range of approximately 50 nm to 5 μm . This region bridges the nanostructure domain with the macroscopic world and contains aspects of both. A typical

case is that of integrated circuit (IC) development, where today the critical dimension (CD) is approaching $0.1\ \mu\text{m}$. X-ray microscopes are ideally suited to the study of systems in that size range, from untreated biological samples to semiconductor heterostructures. They can yield information about local variations in chemical composition and electronic structure through spatially resolved absorption, fluorescence, and photoelectron spectra. One speaks often of *spectromicroscopes*, not just microscopes. The word *spectromicroscopy* combines aspects of spectroscopy and microscopy as does the word *microspectroscopy*. However, it is the last four syllables of either expression that describe the thrust of either technique. Thus, spectromicroscopic measurements entail taking images containing partial spectral information of small areas. Typically a larger energy band pass is selected to allow for a sufficiently high count rate to allow image acquisition in reasonable time. Microspectroscopic measurements involve acquiring spectroscopic data with partial spatial information. In this incarnation it is common to collect a high resolution spectrum from an area of the image by either counting for a longer time or using a larger area. The two techniques are frequently used in unison. Given a high X ray flux, it is even possible to use both techniques simultaneously, collecting an energy spectrum for each pixel of the image.

In 1994, Moewes catalogued the world's VUV and X-ray microscopes, listing 42 such instruments, 25 of which use synchrotron radiation (2). The extreme vacuum ultraviolet (VUV) region extends from $2\ \text{eV}$ to $1000\ \text{eV}$ ($12\ \text{eV}$ to $6200\ \text{eV}$). Of this, the range from $20\ \text{eV}$ to $500\ \text{eV}$ ($25\ \text{eV}$ to $620\ \text{eV}$) is often called the soft X-ray region. In the hard X-ray region, the wavelength ranges from $0.5\ \text{nm}$ to $2\ \text{nm}$ (the energy from $6.2\ \text{keV}$ to $25\ \text{keV}$) (3). Since then, however, more X-ray microscopes have come into existence, in particular at new third-generation synchrotrons such as the Advanced Light Source of the Lawrence Berkeley National Laboratory and the Sincrotrone Trieste in Trieste, Italy. Spectromicroscopy programs are in the genesis stage at budding synchrotrons such as the Advanced Photon Source in Illinois and the Synchrotron Radiation Research Center in Hsinchu, Taiwan. Any of these light sources is a site of choice for building a X-ray spectromicroscope because of the high brightness available. There are also efforts to use plasma X-ray sources for microscopy (4). These sources are inherently limited in light output, but they do allow experiments to be done away from synchrotrons.

Most modern X-ray microscopes, though varying widely in their optics and signal collected, can be divided into two broad categories: *imaging* and *scanning*. Both types, in their transmission and emission incarnations, will be described in this article. Indirect techniques such as Fourier-transform X-ray holography will not be discussed.

INTERACTION OF X RAYS WITH MATTER

It would not be appropriate to treat in depth here a topic on which books have been written. We will confine our discussion of the interaction of X rays with matter to the cases that directly concern the operation of X-ray spectromicroscopes, with an emphasis on photoemission in solids.

Surface Sensitivity

Nondiffractive optics for X rays only work at glancing angles. This fact follows from the calculation of the reflectivity of light

at an interface using the Fresnel equations. Only a glancing angle produces a significant reflectivity for X-ray wavelengths. X rays are not simply reflected off the top surface of the material under study. In fact, it is important to know how far the X rays penetrate into the sample in order to understand what fraction of the sample contributes to the signal collected, and thus, what part of the sample we are really studying. This can be arrived at through consideration of the absorption coefficients of the materials composing the sample. The absorption coefficient α is a function of the photon energy [small h , stroke] ω , and the intensity at a distance z inside the material can be written as

$$I = I_0 e^{-\alpha z} \quad (1)$$

where I_0 is the intensity incident on the surface. The photon attenuation length λ_{ph} (also called the photon mean free path) is $1/\alpha$ and is commonly used as a measure of how far the photons penetrate into the sample (although the intensity at that distance is about 37% of the incident intensity). λ_{ph} is a function of photon energy and varies for different substances because of differences in material characteristics. For instance, at a photon energy of $100\ \text{eV}$, λ_{ph} is $0.18\ \mu\text{m}$ for carbon and $0.11\ \mu\text{m}$ for molybdenum, yet at $1000\ \text{eV}$ it is $1.9\ \mu\text{m}$ for carbon and $0.19\ \mu\text{m}$ for molybdenum, and at $5000\ \text{eV}$ it is $234.1\ \mu\text{m}$ for carbon and $1.8\ \mu\text{m}$ for molybdenum. Clearly, for transmission X-ray microscopes rather thick samples may be used, with local differences in the absorption coefficient of the sample providing a contrast mechanism. Photoemission microscopes rely on the photoelectrons ejected from the sample for their signal. As illustrated in Fig. 1, photoelectrons (and Auger electrons) are excited everywhere the X rays can reach in the sample, but because of electron scattering, only those electrons excited within the (isotropic) electron mean free path λ_e of the sample surface can escape from the sample. This is why photoemission spectroscopy (PES) is a *surface-sensitive* technique. λ_e , a function of the electron kinetic energy (approximately proportional to the

Figure 1. Schematic showing the surface sensitivity of photoemission. Although X rays penetrate to a depth of λ_{ph} in the sample, only those photoelectrons excited within the electron escape depth λ_e are emitted from the sample.

square root of the kinetic energy) that also varies for different materials, varies from about 5 eV to 100 eV for kinetic energies from 2 eV to 130 eV , (5), a range of interest for the University of Wisconsin spectromicroscope MAXIMUM. Because of this ability to sample only the top layers of a material, PES is an ideal technique for the study of surfaces and interfaces. It is also possible to design a microscope that collects the photoelectrons emitted from the opposite side of a thin sample that is illuminated with X rays, thus combining transmission and emission X-ray microscopy (6).

Photoemission

To explain the photoemission process, it is useful to examine the band structure of a solid. A photon of energy $[h\omega]$ excites an electron in a valence band state of energy E_i into an unoccupied state of energy E_f in the conduction band and leaves behind a hole. We have

$$E_f = E_i + \hbar\omega \quad (2)$$

If E_f is sufficient to overcome the material's photoionization potential or work function ϕ , the electron energy is above the vacuum level E_{vac} given by $E_v + \phi$, where E_v is the energy of the top of the valence band (and is identical to the Fermi energy E_F in a metal), the photoelectron can escape into vacuum. This electron is said to have been *photoemitted*. Subtracting E_{vac} from Eq. (2), we obtain

$$E_f - E_{\text{vac}} = \hbar\omega - (E_v + \phi) \quad (3)$$

$$= \hbar\omega - (E_v - E_i) - \phi \quad (4)$$

Because $E_f - E_{\text{vac}}$ is the photoelectron kinetic energy E_{kin} and $E_v - E_i$ is the binding energy E_b of the electron in the solid, we may rewrite Eq. (4) as

$$E_{\text{kin}} = \hbar\omega - E_b - \phi \quad (5)$$

E_{kin} is the value measured in a photoemission experiment. In an experimental system, assuming that the electron energy analyzer and the sample are in equilibrium, ϕ in Eq. (5) will be the work function of the analyzer, which is typically higher than the sample work function. (Because the analyzer's vacuum level is not the same as the sample's (although the Fermi level is), it can only detect electrons with a kinetic energy above its own threshold). This difference also leads to the secondary electron peak being cut off at its lower energy end.

Not all transitions from E_i to E_f are allowed. In the absence of spin-orbit interaction, only those transitions that obey the dipole selection rules

$$\Delta l = \pm 1 \quad (6)$$

$$\Delta m = 0 \pm 1 \quad (7)$$

are permitted, where l is the azimuthal or orbital angular momentum quantum number and can take on the values $0, 1, 2, \dots, n-1$ (where n is the principal quantum number), and m is the magnetic quantum number and ranges from $-l$ to l . If a spin-orbit intersection exists, as it does for metals, the total angular momentum quantum number $j = l \pm 1/2$ gives rise to a splitting in the binding energy. Such a split for the

Figure 2. EDC from MAXIMUM showing spin-orbit splitting of the Al $2p$ core level.

Al $2p$ core level can be seen in the electron energy distribution curve (EDC) in Fig. 2. In EDCs there is also a large diffuse peak near 0 eV kinetic energy, which is the secondary electron background and results from electrons that have lost energy through inelastic scattering from other electrons. Core levels of low kinetic energy will be seen riding on top of this background.

See also the article Photoemission in this Encyclopedia.

Photoemission: Applications. There are various experimental techniques that use photoemission. Examples include angle-resolved photoemission spectroscopy (ARPES), extended X-ray absorption fine structure (EXAFS) and its cousins SEXAFS (S for surface) and NEXAFS (N for near edge), and, of course, electron spectroscopy for chemical analysis (ESCA) and X-ray photoelectron spectroscopy (XPS). ESCA and XPS are essentially the same physical technique, as are EXAFS and NEXAFS, with the difference in nomenclature arising from the application. We shall refer to them as *X-ray photoemission* and *X-ray absorption*, respectively. In the former, the occupied valence band and deeper states are probed by using a fixed photon energy and examining the distribution of photoelectron kinetic energies (the EDC). In the latter, unoccupied conduction band states are explored by scanning the photon energy and collecting the photoelectrons in total yield mode as a function of photon energy. In both photoemission and photoabsorption modes the aim of spectromicroscopy is to distinguish between chemical states on a microscopic scale. This can be done by studying chemical shifts of electronic levels corresponding to specific materials comprising the sample.

Chemical Shifts. Core level electrons are tightly bound to their atoms and thus serve well as a means of elemental identification. Variations in local chemistry induce local charging and hence *shifts* in the core level binding energies, which are reflected in the photoelectron spectra. This happens because of changes in the screening of the nucleus by the valence electrons. For example, if the atom of interest is in a chemical environment that results in additional valence electrons being drawn to the atom, Coulomb screening will increase and the binding

energy of the core level will be decreased. If, however, the atom is bonded to a highly electronegative material, its oxidation state will change and the number of valence electrons screening the core will be decreased, resulting in a corresponding increase in the core level binding energy. The effects on binding energy are more complicated in the case of nonionic bonding. Shifts from pure elemental values have been observed for several compound materials. The amount and sign of the shift can be quantified in a straightforward way for the chemical shift $\Delta E_n(A, B)$ for atom n in two different chemical environments A and B by the following equation (7):

$$\Delta E_n(A, B) = \left(\frac{q_n^A}{\bar{r}_{v,n}^A} - \frac{q_n^B}{\bar{r}_{v,n}^B} \right) + (V_n^A - V_n^B) \quad (8)$$

$\bar{r}_{v,n}$ is the average radius of the valence shell of the n th atom, and the q_n are screening charges. Thus the first term is the difference in screening potential between environments A and B . The second term is the difference in the Madelung potentials of A and B , where for V_n we may write

$$V_n = \sum_{n' \neq n} \frac{q_n}{R_{nn'}} \quad (9)$$

Here we sum over all surrounding ionic charges q_n centered at positions $R_{nn'}$ measured with respect to the atom n . Equation (8) has been shown to be a simple but good predictor of chemical shifts in solids.

Other Spectral Features. Photoelectron spectra exhibit features not solely ascribable to primary and secondary electrons. The lineshape, for example, is not a delta function, but is broadened. Taking into account the finite lifetime of the hole created by photoexcitation of a core level electron, the theoretical lineshape should be a Lorentzian with width inversely proportional to the core lifetime. There is also a further broadening caused by electron-phonon scattering. In real life, the shape is not a Lorentzian, but is convoluted with a Gaussian arising from instrumental limits such as detector energy resolution, monochromator resolution, the Doppler effect, and thermal broadening. The resulting lineshape is called a Voigt function and is extensively used in spectroscopy.

The hole can decay via radiative or Auger recombination. In the former case, an electron from a higher energy level drops down into the vacancy, and radiation with an energy corresponding to the difference between the levels is emitted and is called fluorescence. Luminescence refers to visible or UV light emitted from valence transitions. Both kinds of light can be used as chemical signatures for spectromicroscopy, as they are for two of the X-ray microscopes discussed in this article. This photon emission that accompanies photoemission, though it is not as surface-sensitive, can be exploited in a manner analogous to energy dispersive analysis of X rays (EDAX) in a scanning electron microscope (SEM) to acquire images mapping elements on the sample.

In the Auger process, the energy difference is used to ionize a higher-level electron. This Auger electron is ejected with a kinetic energy characteristic of the material in question. There is a finite set of permitted Auger transitions for a given element, and Auger peaks are independent of photon energy under non-resonance conditions.

Plasmons occur in metals in a series, with the plasmon peaks shifted from the core peak to lower kinetic (higher binding) energies by multiples of [small h, stroke] ω_p , the plasma frequency, if $\omega > \omega_p$. Thus plasmons are a form of energy loss for primary electrons. The conduction band electrons in a metal form an electron gas that can be set into collective oscillation by an excited photoelectron. A plasmon represents one quantum of this oscillation.

Excitons can be formed in the bandgap of semiconductors when a core hole and an electron pair up. For example, if the $2p$ level is excited in silicon, an exciton is formed that has a binding energy of about 0.9 eV that places it in the gap. It shows up in the photoabsorption spectra.

IMAGING MICROSCOPES

Imaging X-ray microscopes are somewhat similar in optical design to traditional visible-light microscopes in that an image of an object is formed solely with the aid of lenses operating on the detector side. Depending on the detection method, these instruments operate in either (X-ray) transmission or (electron) emission mode. Both types will be described below. Some use specialized X-ray optics, whereas others use electron optics to image the sample.

Transmission

The sample is illuminated with X rays at the region of interest, and the transmitted X rays are used to produce a magnified image of the sample. An example of such an instrument is that developed by Meyer-Ilse at the Advanced Light Source (ALS) of the Lawrence Berkeley National Laboratory (LBNL) (8). Shown in Fig. 3, it uses a condensing Fresnel zone plate (FZP), a diffractive optic similar to a circular diffraction grating whose pitch increased with radial distance from the center. This condensing FZP focuses the X rays onto a 15 μm pinhole, after which they emerge from vacuum into a small space filled with helium gas, where the sample is mounted. Helium is used instead of air or another gas because it has low absorption in the X-ray regime. The X rays pass through the samples (which are typically cells, tissues, or microorganisms encased in a SiNH window in their growing solution), where they are scattered, and then enter another vacuum chamber, where an objective FZP forms an enlarged image of the sample and projects it onto

Figure 3. Schematic of the XM-1 transmission X-ray microscope at the ALS of LBNL. (Courtesy of W. Meyer-Ilse.)

a CCD camera. This instrument has demonstrated a resolution of 43 nm (9). A similar X-ray microscope at the Aarhus electron storage ring in Denmark has been used to study systems as diverse as human spermatozoa at various stages of maturation and iron-precipitating bacteria used for water treatment (10).

Emission

Emission mode microscopes directly image the electrons (primary, secondary, or Auger electrons) ejected from the sample to produce a magnified image of it. The photon energy can be varied to take advantage of variations in the absorption spectra of materials. The incident X rays are coarsely focused onto the sample, chiefly to uniformly illuminate the region of interest and to minimize flux loss and its resultant degradation of the signal-to-noise ratio. The spatial resolution is limited by the electron optics and inherent aberrations.

Two imaging photoelectron microscopes will be discussed below. One uses electrostatic optics, and the other uses electromagnetic optics.

Photoemission Electron Microscope. The photoemission electron microscope (PEEM) uses electrostatic lenses to form an image of the sample with photoelectrons. An immersion lens is used as an objective to focus the electrons. Typically, it consists of a primary electrode at high voltage to accelerate the electrons, and a three-electrode lens that forms a real image. The sample itself serves as the cathode. The real image can then be magnified further using an intermediate objective lens. Next, it can be projected onto an assembly of a microchannel plate (MCP) and a phosphor screen, using a projector lens made up of another three-electrode lens and a two-stage decelerating lens designed to lower the kinetic energy of the electrons to the sensitivity range of the MCP (11,12).

The resolution of the objective lens is approximated by

$$\delta = \epsilon K_0 / |E| \quad (10)$$

where K_0 is the mean photoelectron kinetic energy and E is the electric field at the sample surface, and ϵ is a dimensionless constant of order unity (13). A typical resolution for a traditional PEEM (UV-PEEM) is several micrometers, but a resolution of 0.9 μm has been achieved (14). With very soft X rays, a resolution of 10 nm has been obtained using very low-kinetic-energy electrons (15). The theoretical total resolution is limited by chromatic aberration (since photoelectrons of different energies are focused at different positions) and residual spherical aberration in the objective lens itself, as well as by the aberrations arising from the high accelerating potential between the sample and the objective lens (16).

Improvements in the electron optics design can overcome some of these limitations. For example, a large accelerating potential of ≈ 20 kV can be used to decrease the angular spread of the photoelectrons, and to thus reduce the spherical aberration (which is proportional to the cube of the spread angle) and improve the resolution (17). The insertion of an aperture at the back focal plane of the objective lens also reduces chromatic aberration by blocking electrons that would not be focused exactly at the image plane. Smaller apertures improve spatial resolution more than larger apertures, but also reduce the signal level. Using a 20 μm aperture, De Stasio and coworkers

Figure 4. Schematic of the MEPHISTO photoemission electron microscope. (Courtesy of G. De Stasio.)

have demonstrated a 50 nm resolution using the Rayleigh criterion on a knife-edge (12% to 88% of full intensity) with their microscope MEPHISTO (18), which is shown in Fig. 4. This resolution is being improved by several microscopy groups even as this article is being written. It is also possible to add an energy-filtering detector to further reduce the chromatic aberration and to allow the extraction of more spectroscopic information by implementing photoelectron energy selection and analysis. In the case of the instrument PRISM, this was done by inserting an electrostatic "prism" energy filter between the intermediate and projector lenses. This "prism" consists of a sector of a hemispherical capacitor used in conjunction with circular apertures and coupling lenses at the input and output of the capacitor. The lenses preserve the image, and the capacitor behaves as a spherical mirror analyzer to provide the bandpass electron energy filtering. The ability to select the photoelectron energy also makes possible the acquisition of photoelectron energy distribution curves (EDCs). PRISM has achieved a spatial resolution of 0.6 μm in energy-filtering mode on a 25 μm pitch gold grid; the Au 4*f* core level could be measured with an energy resolution of 1.0 eV and was used for chemical imaging. Currently, PRISM is operating without the energy filter, that is, as a standard X-ray PEEM (X-PEEM). To date, PRISM has achieved a resolution of 0.25 μm in X-PEEM mode (19).

PRISM in X-PEEM mode was used to study the formation of titanium silicide (TiSi₂) in a patterned sample with microstructures ranging from 100 μm to 0.1 μm . TiSi₂ is an important material used for interconnects in ultra large-scale integration (ULSI) devices. It occurs in two phases: the high-resistivity (60 $\mu\Omega \cdot \text{cm}$ to 90 $\mu\Omega \cdot \text{cm}$) metastable C49 phase, and the desirable low-resistivity (12 $\mu\Omega \cdot \text{cm}$ to 15 $\mu\Omega \cdot \text{cm}$) stable C54 phase, into which C49 is transformed with higher-temperature annealing. The formation of C54 is, however, inhibited for sub-micron lines, leading to a rise in resistivity. This poses a problem since TiSi₂ is used to reduce contact resistance in modern MOS (metal oxide semiconductor) devices, which are now being fabricated with sub 0.25 μm linewidths. Since the trend is to

shrink linewidths (and, hence, devices) even further, the inhibition of the formation of the low resistivity phase of TiSi_2 at small linewidths is an important issue.

C54 has a face-centered orthorhombic crystal structure, while C49 has a body-centered orthorhombic crystal structure with different lattice constants. This leads to different bonding between Ti and Si in the two phases, and hence we should expect the chemical shift between core electron binding energies in C49 and C54 to be reflected in different photoelectron spectra. As seen in Fig. 5, photoelectron images acquired on the Ti $L_{2,3}$ absorption edge show dramatic differences at different photon energies, with the spoke tips and edges appearing brighter than the spoke centers at a photon energy of 455 eV. This suggests a local difference in chemical status of titanium silicide. In fact, absorption spectra taken on regions 1–4 as defined in Fig. 6(b) show that spectra acquired on a spoke tip and a spoke edge (regions 2 and 3) have a higher intensity in the 454 eV to 457 eV energy range than the spectra acquired on blanket silicide or on a spoke center (regions 1 and 4). (See Fig. 7.) This difference is consistent with C54 TiSi_2 being formed in spoke centers and C49 TiSi_2 remaining untransformed not only at spoke tips but also at spoke edges (20,21). This was the first successful application of spectromicroscopy to the study of TiSi_2 formation and revealed that C54 formation is inhibited not only in small features but at feature edges as well, suggesting a dependence on geometry that has been borne out by other experiments (22).

Other experiments facilitated by PEEM include mapping of domains on magnetic recording disks using magnetic circular X-ray dichroism (MCXD) (23,24) and spatial and temporal waves of oxidizing CO on platinum (25,26).

Magnetic Imaging Photoelectron Microscope. The MicroESCA manufactured by Surface Science Instruments is a commercial version of this type of X-ray microscope.

A superconducting (typically NbTi) solenoid is used to bathe the sample in a uniform magnetic field that diverges from the sample normal. The photoemitted electrons spiral about the diverging magnetic field lines and are projected on a resistive anode detector to form an image magnified by a factor of about 70. A supplementary magnification or demagnification is attained by using two field coils around the detector to modify the solenoid's magnetic field near the detector. This feature results in a possible magnification ranging from $20\times$ to $140\times$. An electron-retarding-grid energy analyzer placed before the detector acts as a high-pass filter and allows the acquisition of photoelectron spectra. Because the electrons are collimated along the field lines, there is little loss of signal at the analyzer as long as it intercepts enough of the field. This collimation results in the additional benefit of a high (0.1 eV) energy resolution for 100 eV photoelectrons. Such a resolution is well suited to the detection of subtle chemical shifts (27).

The spatial resolution is proportional to the radius of the helical path traveled by the electrons. For off-axis photoelectrons, this is the cyclotron radius:

$$R_{\text{max}} = (2mE_0)^{1/2} / eB_0 \quad (11)$$

where E_0 is the photoelectron kinetic energy and B_0 is the magnetic field strength at the sample. B_0 can range up to 8 T. The

(a)

(b)

Figure 5. Photoelectron images of silicided-Ti-on-Si resolution test pattern. In (a), acquired below the Ti $L_{2,3}$ edge at 445.5 eV, only the centers of the spokes show up, and these are dark (absorbing). In (b), acquired at 455 eV on a shoulder on the edge, the spoke tips and edges emit much more strongly than the spoke centers, indicating a change in bonding.

spatial resolution is estimated to range between $0.1R_{\text{max}}$ and $2R_{\text{max}}$. For electrons of kinetic energies from 10 eV to 1000 eV, the practical resolution ranges from $3\text{ }\mu\text{m}$ to $30\text{ }\mu\text{m}$ (28,29).

The commercial MicroESCA has seen various applications, ranging from geological samples to heterostructures. One experiment with Au/GaAs showed variations in the surface segregation of As as a function of gold distribution (29). One of the original research instruments is currently operating at

Figure 6. Photoelectron image of silicided STAR acquired at 464 eV. The width of the entire spoke pattern in (a) is 80 μm , and the spoke width at the points where it touches the edge of the square is 5 μm . A magnified view is shown in (b), where region 1 is on a blanket TiSi₂ area outside the pattern, 2 is on a spoke tip, 3 is on a spoke edge, and 4 is in the center of a spoke.

the Synchrotron Radiation Center (SRC) of the University of Wisconsin—Madison and has been used for spectromicroscopic study of spatial variation in the oxidation of Bi in a high- T_c Bi—Sr—Ca—CuO superconductor (30).

SCANNING MICROSCOPES

Scanning X-ray microscopes finely focus the X rays to a micrometer- to submicrometer-sized spot on the sample. This spot is then rastered across the sample, with a signal collected for each (x, y) point. The scanning is most simply achieved

by rastering the sample. The success of scanning X-ray microscopy is dependent on the quality and efficiency of the X-ray optics used for focusing the X rays to a point. Scanning X-ray microscopes exist in both transmission and emission flavors.

Transmission

The scanning transmission X-ray microscope (STXM) is the primary microscope of this type in existence. Developed by Schmahl (31) for use on the ACO ring in France, this type of microscope was also implemented by Kirz (32) at the NSLS of

Figure 7. Ti $L_{2,3}$ absorption spectra acquired on regions 1–4 as defined in Fig. 6(b) are shown in (a). A closeup of the Ti L_3 edge in (b) shows that the tips (as in region 2) and the edges (as in region 3) have a higher intensity in the range between 454 eV and 457 eV that is not present in the blanket silicide or at the centers of the spokes, suggesting a difference in bonding in narrow features and feature edges.

Figure 8. Transmission X-ray micrographs of a PC-PET polymer blend. (a) was acquired at a photon energy of 284.8 eV (energy A), and (b) at 285.1 eV (energy B). PET appears bright in (a), and PC in (b). (Courtesy of H. Ade.)

Brookhaven National Laboratory. It too uses a FZP to focus the X rays onto the sample, which is rastered using a scanning stage to obtain an image. The FZP was fabricated at IBM and has a focal length of 1 mm at a wavelength of 3.6 nm. Using the Raleigh criterion discussed below under “Diffraction-Limited Optical System,” the resolution δ of the first order (which is the most intense) is given by

$$\delta = 1.22 \Delta r \quad (12)$$

where Δr is the width of the outermost zone of the FZP. A central stop is used to block higher diffraction orders, and a pinhole is placed between the FZP and the sample to eliminate unfocused light. A wire proportional counter is used to measure the transmitted X-ray signal. The instrument operates in an atmosphere of helium (33). Biological studies, including those of live and wet specimens, are the primary application of this microscope, as they are for Meyer–Ilse’s imaging microscope described above in the subsection “Photoemission.”

Energies in the water window (between the carbon and oxygen K edges) are well suited because of the transparency of water and the absorptivity of carbon (in biological structures) in this range. Several experiments on chromosomes have been done (32,34). The STXM was later applied to chemical imaging using NEXAFS signals of other systems such as diagonally sectioned Kevlar fibers, which exhibit linear dichroism (35). This instrument has also been used to study a polycarbonate–polyethyleneterephthalate (PC–PET) polymer blend. By varying the incident photon energy, it is possible to track an electronic resonance between carbonyl groups and the phenylene in the polymers. Figure 8 shows X-ray micrographs of the sample acquired at 284.8 eV and 285.1 eV (36). The contrast is reversed in the two images, with the PET bright and PC dark at 284.8 eV and the PC bright and PET dark at 285.1 eV. The shift in the NEXAFS microspectra shown in Fig. 9, which were acquired on both PC and PET areas of the sample is responsible for this contrast. The NSLS STXM has achieved submicrometer resolution. A newer instrument installed at the ALS has attained a resolution of 0.12 μm (37).

Emission

There are several advantages the scanning emission microscope has over the imaging emission microscope, including (1)

the possibility of detecting transmitted X rays and luminescence signals in addition to photoelectron signals, (2) decoupling of the imaging mechanism from the signal collected, (3) a single optical element whose aberrations can be minimized, (4) a standard detector and its accompanying ease of obtaining spectra, and (5) a higher theoretical spatial resolution. Several different approaches will be discussed below.

Scanning Photoemission Microscope. The FZP-based design for the scanning photoemission microscope (SPEM) arose from the STXM discussed above in the subsection “Transmission.” It is a UHV instrument and is typically operated in the energy range of 650 eV to 680 eV with a resolution of 2 eV in order to maximize flux at the sample. At these wavelengths (1.8 nm to 1.9 nm) the focal length is about 5 mm, but the pinhole needed to block unfocused light needs to be placed about three-fourths of the focal length away from the FZP before the sample. The working distance, therefore, is less than 1.5 mm, and part of the microscope must be placed in the cylindrical mirror analyzer (CMA) used for electron energy analysis. The CMA has been modified to accommodate the FZP, the pinhole, and a tilt assembly to align the two. Both the sample current and the CMA signal can be used to acquire images, and the CMA can be used to obtain EDC as well. This instrument has reached submicrometer resolution and has been

Figure 9. NEXAFS spectra from 0.1 μm^2 areas of PC and PET from a 70:30 PC:PET blend. PET and PC spectra have peaks at energies A and B, respectively. This explains the contrast observed in (a) and (b) of the previous figure. (Courtesy of H. Ade.)

used in test experiments on a commercial device at the NSLS (38). A SPEM, which achieves scanning by moving the zone plate instead of the sample stage, thus facilitating in situ sample treatment such as heating or cooling, is operational at the ALS (68).

Another SPEM is already working at the third-generation ring in Trieste in the energy range of 300 eV to 400 eV. This microscope has submicrometer resolution and is being used for surface studies of metals and semiconductors (39). A high-energy SPEM is in place at the Advanced Photon Source (APS) of Argonne National Laboratory. It uses blazed phase-shifting FZPs, which can theoretically achieve an efficiency of 80%, compared to 10% for ordinary FZPs (40). This microscope can focus hard X rays down to a 0.25 micrometer spot. This spot can then be scanned across the sample while collecting the X-ray fluorescence signal, thus obtaining a chemical map of elements present in very dilute concentrations in the sample. Because of the high-energy X rays used, the experiments can be carried out in air. Biological samples such as plant roots from *Plantago* and *Arabidopsis* have been studied. The X-ray microprobe has also been used for strain measurements using microdiffraction techniques (41–43).

Hamburg Microscope. Designed by Christoph Kunz, this instrument uses a ring ellipsoid mirror to focus monochromatized X rays from wiggler radiation onto the sample. Unlike the FZP, the ellipsoid mirror's focal position is independent of the wavelength, allowing easy switching between wavelengths of interest without moving the sample or the optics to stay at the focus. Its efficiency is also higher because it operates at grazing incidence. In practice, the flux is limited because of problems in illuminating the mirror properly without loss. It is installed on the FLIPPER monochromator at HASYLAB of DESY, Hamburg. The source is situated at one focus of the ellipsoid, and the sample is placed at the other focus. A resolution of 0.4 μm has been achieved at 200 eV. The instrument can also operate at lower resolutions over the entire range of 20 eV to 1300 eV. Mirror quality is the obstacle in reaching higher resolutions. Since this is a grazing-incidence optical system, figure error is very important. The ellipsoidal mirror, custom manufactured by Carl Zeiss, is, like other aspheric mirrors, difficult to make. Because the tolerances for microscopy are so tight,

this limitation becomes significant. Surface finish is important too, since surface roughness leads to scattering and hence loss of useful flux at the sample.

EDCs can be acquired with this instrument, as can photoelectron images at different energies. In addition, the total luminescence signal can be collected, thus allowing a luminescence image to be acquired simultaneously with a photoelectron image. This technique has been applied to the study of transition metal compounds, including variously doped LaOBr powders and chemical Tl^{1+} -doped CsI (3).

Wolter Scanning Photoemission Microscope. The Wolter mirror is a glancing-optics objective consisting of an ellipsoidal section next to a section of a hyperboloid of revolution. The addition of the hyperboloid section corrects the aberrations of a single ellipsoid surface and increases the field of view. The application of these optics to X-ray microscopy was led by Hitachi, Ltd. and the University of Tsukuba, Japan. Like the ellipsoid mirror used in the Hamburg microscope, the Wolter mirror has a focus independent of the wavelength. It has less aberration than other grazing-incidence mirrors, but, since it too is aspheric, it also suffers from the same difficulties in accurate fabrication as the ellipsoid mirror, although the manufacturing techniques are different. (For the Wolter mirror, a vacuum replication process using epoxy resin and a precision-ground and -polished mandrel is used (44,45), whereas a direct grinding and polishing technique is used for Hamburg's ellipsoid.) The Wolter SPEM has been installed on a bending-magnet beamline at the Photon Factory synchrotron of the National Laboratory for High Energy Physics of Japan. Figure 10(a) shows details of the mirror design, while the actual experimental setup is depicted in Figure 10(b) (46). The mirror demagnifies the pinhole-defined source by a factor of 29.8. At a photon energy of 150 eV, the reflectivity is $\approx 77\%$ for a Au-surfaced mirror, and the energy resolution is about 1 eV (47). The microscope has demonstrated a 0.3 μm resolution in total photoyield mode (in which all of the photoelectrons emitted are collected with the microchannel plate) and 2.0 μm in energy-selected mode (when a single electron energy is selected by the electron energy analyzer) (48). The latter value can be greatly improved by increasing the signal-to-noise ratio by operating with higher X-ray flux on an undulator beamline.

Figure 11. SO geometry and image formation.

The relationship between the signal-to-noise ratio and resolution is discussed below in the subsection "Resolution: Limiting Factors."

Schwarzschild Objective. The Schwarzschild objective (SO) was described by Schwarzschild in 1905 and has been used in telescopes for a long time, but was applied to X-ray microscopy only some 20 years ago by Haelrich (49), following the suggestion of Eberhard Spiller that multilayers could be used as high-energy reflectors. A commercial SO from Ealing was coated with some of the first X-ray multilayers with sufficiently high reflectivity in normal incidence. The first synchrotron-based microscope using these optics was constructed at DESY's HASYLAB. The resolution at a photon energy of 62 eV was 1.5 μm , 25 times the diffraction limit. This was due to the poor alignment tolerances of the Schwarzschild objective used (49). Lovas, Spiller, and coworkers built a modified instrument with a SO designed to minimize aberration (comatic aberration in particular) and make diffraction-limited performance attainable. They forecasted a resolution of 0.1 μm in 1981 (50).

This did not prove so simple, however, and MAXIMUM, a soft-X-ray spectromicroscope developed at the University of Wisconsin—Madison, was the first and only such SO-based instrument to reach that resolution, more than a decade later (51). The design optical setup and design parameters of the SO used in MAXIMUM are shown in Fig. 11 and Table 1, respectively. Photographs of the mirrors coated with Ru/B₄C multilayers for a peak reflectivity at 130 eV are shown in Fig. 12. As shown schematically in Fig. 13, X rays emitted by an undulator are monochromatized to 130 eV and focused on a pinhole. The pinhole defines a source that is demagnified 20 times to form an X-ray microspot on the sample. The sample is scanned using a piezo-driven flexural hinge stage, and the photoemitted

electrons are detected by an electron energy analyzer (a cylindrical mirror analyzer or CMA) to produce a two-dimensional photoelectron image. In another mode of operation, the sample is held fixed, and the CMA is used to collect an EDC of the photoelectrons.

In a TiSi₂ formation study done with MAXIMUM on beamline 6.3.2 of the Advanced Light Source of the Lawrence Berkeley National Laboratory, static random access memory (SRAM) wafers from IBM, East Fishkill, were subjected to Ti deposition and rapid thermal anneal (RTA) steps in an ultrahigh-vacuum (UHV) chamber attached to the main microscope chamber. This was done to avoid exposure to air, which would cause surface contamination and oxidation, and allowed a clean photoemission signal to be obtained from the TiSi₂ formed. TiSi₂ was expected to form on top of polysilicon features overlying a silicon dioxide base layer. The polysilicon pads and lines of the SRAM sample were silicided by depositing ≈ 30 nm Ti *in situ* after subjecting the wafer to a light chemical clean, then annealing at $\approx 800^\circ\text{C}$ for 20 s and flashing to $\approx 1000^\circ\text{C}$. Figure 14(a) and (b) show two 100 $\mu\text{m} \times 100 \mu\text{m}$ photoelectron micrographs acquired at 25.74 eV and 20.48 eV, respectively, of the same area of a SRAM sample. These energies correspond in turn to the unshifted and oxide-shifted, respectively, Si 2*p* core levels shown in the EDCs in Fig. 14(c). The two EDCs were taken on a pad (region A) and on an area near the pad edge (region B) that appears bright in Fig. 14(b). The photon energy was 129.3 eV.

The lines and pads appear to be unaffected in Fig. 14(a), but exhibit a different morphology in Fig. 14(b). Images acquired with secondary photoelectrons were similar to Fig. 14(b) as well. However, secondary-electron images taken *before* the (unusually high) formation anneal resembled Fig. 14(a), as did images taken on samples silicided with the normal 700°C to 900°C sequence. This suggests that the differences observed in Fig. 14 and are due to the high-temperature processing, namely the resulting agglomeration of the silicide in the lines and also lateral growth of the TiSi₂ onto the SiO₂ at the edges of the silicided polysilicon regions. Because Fig. 14(b) is tuned to the SiO₂ signal, we can conclude that the bright regions in this image represent a larger amount of SiO₂ at the surface. This is because some regions of the SiO₂ are exposed by agglomeration of the overlying laterally grown TiSi₂. The laterally grown silicide is also thinner on the SiO₂ than the main silicide formed on the polysilicon, whence the higher oxide signal there. Neither effect is evident in Fig. 14(a), which is tuned to the unshifted Si 2*p* because the Si concentration is always higher in the main silicide formed on the polysilicon than on the Ti-covered silicon oxide or the thin laterally grown silicide. SEM analysis showed a similar morphology to that observed in Fig. 14(b), reflecting the differences in emissive characteristics of the materials and corroborating the presence of agglomeration.

MAXIMUM has also been applied to the study of another type of interconnect used in the semiconductor industry: Al—Cu alloy. Electromigration in interconnect lines is the transport of material along with electron flow when a current is passed through the line. This can lead to the formation of voids and, eventually, an open circuit. The presence of Cu is thought to retard the electromigration process. Cu is, however, not very soluble in Al and hence may segregate to different phases such as θ -Al₂Cu as well as to different locations in the line such as grain surfaces and interfaces.

Table 1. Design Parameters of Schwarzschild Objective

Object distance d_o	1298 mm
Image distance d_i	120.78 mm
Distance between mirrors, t	55.498 mm
Primary mirror:	
Radius of curvature	66.336 mm
Outer diameter	25.5 mm
Inner diameter	12.5 mm
Secondary mirror:	
Radius of curvature	117.253 mm
Outer diameter	80 mm
Inner diameter	25.5 mm
Demagnification	20×
Numerical aperture	0.2

Figure 12. Primary and secondary mirrors of the Schwarzschild objective coated with Ru/B_4C multilayers. Note the pinholes in the coating that allow light through.

A $5\text{ }\mu\text{m}$ wide line patterned in a 4% Cu Al–Cu alloy on thermal oxide grown on Si was stressed (by passing current and heating *in situ* in the microscope chamber) to induce electromigration. The line was examined with MAXIMUM before and after electromigration. Images acquired at different photoelectron energies before and after stressing are shown in Fig. 15. Already before electromigration, the image acquired at 122 eV (the Cu 3d core level) shows bright spots corresponding to Cu-rich precipitates. A comparison between spectra acquired on the precipitate labeled P and a uniform, “ordinary” area O is shown in Fig. 16(a). P exhibits a stronger Cu 3d signal than O, as expected, in Fig. 16(a). The presence of Cu in the Al film at P shifts the Al 2p core level to lower binding energy (higher kinetic energy) with respect to O, as can be seen in Fig. 16(b). This explains why the image in Fig. 15(a), acquired using 50 eV photoelectrons, shows the precipitates brighter than the uniform film area, while that acquired using 47 eV photoelectrons shows them darker. The chemical shift to higher kinetic energy results in more emission from the precipitates at 50 eV and more from the O area at 47 eV.

After electromigration, it is seen from Fig. 15(b) that the Cu-containing precipitates have not moved and that voids

have formed in the line. The void areas in the photoelectron image acquired at 42 eV appear bright because of surface charging of an Al_2O_3 skin left behind over the void. This charging causes the Al 2p core level to be shifted to higher

Figure 14. $100\text{ }\mu\text{m} \times 100\text{ }\mu\text{m}$, $1\text{ }\mu\text{m}$ step photoelectron maps of the same silicided area taken at the unshifted (25.75 eV) and oxide-shifted (20.48 eV) peaks of the Si 2p core level shown in the EDC.

Figure 13. Schematic of the spectromicroscope MAXIMUM.

Figure 15. (a) Micrographs of 5 μm wide Al-4% Cu line before electromigration. P labels a Cu-containing precipitate, and O labels an "ordinary" point on the line. (b) Micrographs of 5 μm wide Al-4% Cu line after electromigration. V marks a void. Images are acquired at the indicated photoelectron energies. (Courtesy of M. Solak.)

binding energies (since the sample becomes positively charged during photoemission because the void prevents a good earth connection to supply electrons, thus causing electrons to be more tightly bound) and hence lower kinetic energies, resulting in the void appearing bright at the shifted Al 2p peak at 42 eV (69).

There are other implementations of the SO microscope as well. Another microscope has been designed to run the SO with C $K\alpha$ radiation (277 eV). This relatively high energy (for normal-incidence optics) is made possible by the use of NiCr/C multilayers. The objective's resolution has been measured to be better than 0.5 μm (52).

IMAGE FORMATION

So far we have discussed many different approaches to X-ray microscopy and have compared the resolutions achieved and have listed experiments performed, but we have not yet done a detailed analysis of the image formation itself. We will do so here for microscopes utilizing X-ray optics and synchrotron radiation.

Synchrotron radiation can be generated by three types of devices: bending magnet, wiggler, and undulator. The first two types are similar in their broad energy spectrum and their large opening angles of radiation and can be treated together. In both a bending magnet and a wiggler, the radiation from one electron at one point is independent of that at a different point in the synchrotron, and photons are emitted incoherently along the tangent at each point of the electron trajectory. However, when the emittance of the electron beam becomes very small (as it does for third-generation synchrotron sources such as the ALS), diffraction effects arise along the electron trajectories (53). The interference effect is very strong in undulators because of the small opening angle of the radiation and results in a spectrum with harmonic peaks at certain wavelengths. This spectral purity implies a high degree of inherent temporal coherence in undulator radiation, unlike bending-magnet and wiggler radiation. The photon field and the trajectory remain in phase over a large distance. Again, when the emittance of the electron beam is very small, the radiation cannot be assumed to be spatially incoherent.

It is convenient to define the following phase-space relationship for quasimonochromatic sources such as undulators:

$$d \cdot \theta \geq \lambda/2\pi \quad (13)$$

where d is the source (electron beam) diameter, and θ is half the opening angle of the radiation, which is determined solely by the electron trajectory. If the source has an opening angle θ at a wavelength λ , any points separated by less than $\delta = \lambda/\sin \theta \approx \lambda/\theta$ cannot be resolved, that is, the source is *spatially coherent*, or *diffraction-limited*. The source size d is larger than δ in practice, however. Currently the ALS has undulators with a phase-space at least 5 to 50 times larger than the diffraction limit (54).

As stated earlier, even the radiation from bending magnets and wigglers has some spatial coherence and, although not temporally coherent, is typically monochromatized before entering the X-ray imaging system. Thus we can speak in general of the quasimonochromatic synchrotron radiation used in X-ray microscopes as being *partially coherent*.

Figure 16. (a) EDCs acquired at points P (precipitate) and O (ordinary) of Fig. 15(a) showing higher Cu 3d signal at P. (b) EDCs acquired on an Al film area O and a Cu-rich area P, showing that the presence of Cu shifts the Al 2p to higher kinetic energy (lower binding energy). (Courtesy of M. Solak.)

The Frequency Response of an Optical System

Spatial-Frequency Cutoff. Following the treatment of Born and Wolf (55), let us consider the two limiting cases of coherent and incoherent illumination. $\mathcal{K}$, the *frequency response function* in the coherent case, is actually equivalent to the pupil function G with a change of variables, and we may write

$$\mathcal{K}(f, g) = G(\lambda Rf, \lambda Rg) \quad (14)$$

where R is the radius of the Gaussian sphere of reference (which is centered on the geometric image point and passes through the center of the exit pupil). Because the pupil function has a value of zero outside the exit pupil itself, frequencies above a certain value are not transmitted. In particular, if the exit pupil is approximated by a circle of radius a , then the pupil function will be zero for points outside the circle and only those frequencies will be transmitted for which

$$(\lambda Rf)^2 + (\lambda Rg)^2 < a^2 \quad (15)$$

holds. For an optical system with a small image-side angular aperture that obeys the sine condition

$$M = \frac{y_1}{y_0} = \frac{n_0 \sin \theta_0}{n_1 \sin \theta_1} \quad (16)$$

where M is the magnification and n_0 and n_1 the indices of refraction in the object and image spaces, respectively—we may make the approximation

$$\frac{a}{R} = \tan \theta_1 \approx \sin \theta_1 \quad (17)$$

where θ_1 is the half angle. For a one-dimensional (1-D) object, if $\Delta y_0 = 1/g$ is the period corresponding to the spatial frequency g , we may write that only those frequencies corresponding to the spatial periods that satisfy

$$P_y > \frac{\lambda_0}{A_1} \quad (18)$$

where $\lambda_0 = n_1 \lambda$ is the vacuum wavelength and $A_1 = n_1 \sin \theta_1$ is the image-side numerical aperture, are transmitted.

In the incoherent case, $\mathcal{L}$ is the frequency response function and, because of the connection between $\mathcal{K}$ and the pupil function G shown in Eq. (14), is also the autocorrelation function of the pupil function. If we again consider a circular exit pupil of radius a , the autocorrelation function will have a non-zero value only if there is some overlap between two displaced pupil functions, for example, if the maximum displacement between the two pupil functions is less than the pupil diameter $2a$. Thus only those frequencies will be transmitted that satisfy

$$(\lambda Rf)^2 + (\lambda Rg)^2 < (2a)^2 \quad (19)$$

Then, for a 1-D object, only those spatial frequencies will be transmitted whose spatial periods satisfy

$$P_y > \frac{\lambda_0}{2A_1} \quad (20)$$

The spatial frequency cutoff for the partially coherent case falls between the cutoffs for the coherent and incoherent cases. In general, the minimum spatial period resolvable, Δ , is the reciprocal of the cutoff frequency. For

$$\Delta = d \frac{\lambda_0}{A_1} \quad (21)$$

we have

$$\begin{aligned} d = 1 & \quad \text{coherent} \\ d = \frac{1}{2} & \quad \text{incoherent} \\ \frac{1}{2} < d < 1 & \quad \text{partially coherent} \end{aligned} \quad (22)$$

Accordingly, incoherent illumination can resolve the smallest spatial period, and hence can produce the highest spatial resolution, followed by partially coherent, and then by coherent illumination. It is important to note, however, that the results obtained here apply rigorously only for an unobstructed circular exit pupil in an optical system that has a small angular aperture and satisfies the sine condition. Other pupil illumination functions may increase or decrease the resolution.

Diffraction-Limited Optical System. All axially symmetric X-ray scanning systems (e.g., SO-based microscopes, the SPEM, and the STXM) have a central obstruction. All microscopes, both scanning and imaging, also have aberrations. These and other effects in real systems can be taken into account in the formulation of the complex transmission function K and are reflected in its inverse Fourier transform $\mathcal{K}$, which is directly related to the frequency response function in the coherent, incoherent, and partially coherent cases. We will not treat the complex topic of aberrations here. Rather, we will treat the opposite, ideal case of the *diffraction-limited optical system*.

The term “diffraction-limited” is often bandied about in X-ray microscopy. We have used it ourselves when talking about third-generation synchrotron sources, but it is different for photons. An imaging optical system is called diffraction-limited if it converts a spherical wave emanating from a point source into another spherical wave converging to the Gaussian image point in the imaging plane (56). If the wavefront leaving the exit pupil is not perfectly spherical, it is an indication of aberrations in the system. In a diffraction-limited system, then, only the functional form of K is important in determining the system’s imaging properties. We consider an optical system of small enough angular aperture to justify the paraxial approximation and the lens equation

$$\frac{1}{d_0} + \frac{1}{d_1} = \frac{1}{F} \quad (23)$$

where d_0 is the object distance, d_1 is the image distance, and F is the focal length of the lens.

For such a system and coherent illumination, the complex transmission function K is given by the Fraunhofer diffraction pattern of the lens aperture centered on the geometrical image point (56). Then for a lens with a circular aperture and a central circular obstruction we may write

$$K(x, y) = \frac{1}{1 - \epsilon} \left(\frac{J_1(\nu)}{\nu} - \frac{\epsilon J_1(\epsilon\nu)}{\nu} \right) \quad (24)$$

where J_1 is a Bessel function of the first order, $\nu = 2\pi, x^2 + y^2$, with x, y measured in units of λ/A_1 , and ϵ represents the fraction of aperture obstructed and ranges from 0 to 1. It can be seen that if $\epsilon = 0$ Eq. (24) reduces to the Fraunhofer diffraction pattern from a circular aperture. $K(x, y)$ is also called the amplitude point spread function and is the impulse response of the optical system. $\mathcal{K}(f, g)$, the inverse Fourier transform of $K(x, y)$, is the frequency response of the system, as stated earlier.]

For incoherent illumination, the frequency response of the system is (f, g) , and the impulse response (also called the intensity point spread function) is given, for an annular aperture, by the square of K as defined in Eq. (24). For a circular aperture, $\epsilon = 0$ and the impulse response is the Airy pattern.

Scanning emission microscopes like MAXIMUM are *incoherent* imaging systems in that, even though the illumination may be partially coherent, the photoelectron signal collected per pixel has no relation to the phase of the incident light and hence is incoherent with that of neighboring pixels.

What is the Meaning of Resolution?

There are several criteria than can be used to determine the resolution of an imaging optical system. One commonly used criterion is the Rayleigh criterion. Strictly speaking, it applies only to an aberration-free, unobstructed optical system. According to this treatment, two monochromatic and mutually incoherent point sources can just barely be resolved if their separation is such that the maximum of the Airy pattern of one point falls on the first minimum of the other’s Airy pattern, resulting in a saddle point between the two maxima of the summed pattern. This separation δ is given by

$$\delta = \frac{1.22\lambda}{2A_1} \quad (25)$$

and is also the diameter of the Airy disk. For a scanning microscope, the two point sources are replaced by two small pinholes with a diameter much smaller than their separation, but the same analysis applies. Often, δ is quoted for a microscope although the preconditions of incoherence and lack of aberration may not be satisfied. This is permissible only as an approximation. In addition, strictly speaking, $\lambda/2A_1$ is the diffraction-limited resolution of an *incoherent* imaging system. (λ/A_1 is the diffraction-limited resolution of a *coherent* imaging system.) However, since this is close to the Rayleigh criterion [Eq. (25)], the two terms are sometimes used interchangeably, and the factor of 1.22 crops up.

Although, the diffraction-limited resolution has long been thought to be the ultimate resolution for an optical system, it is in principle possible to resolve certain types of objects that are smaller. Goodman (57) states two theorems that apply to bounded objects. The first theorem states that the Fourier transform of a function bounded in the (x, y) plane is an analytic function in the (f, g) plane. The second theorem states that if an analytic function in the (f, g) plane is known exactly in an arbitrarily small finite region, then the whole function can be found uniquely by analytic continuation. For an optical system and a bounded object, this means that the entire object frequency spectrum can be calculated by analytic continuation if a finite portion of it can be determined exactly (in the absence of noise) from the image frequency spectrum, which is determined by the frequencies passed by the point spread function of the optical system. Thus, because the entire object frequency spectrum is then known, the object itself can be reconstructed exactly, thus allowing a kind of *superresolution*. This may be possible, for instance, in the ubiquitous case of the circular aperture. If the surrounding material is not completely opaque to the incident light, but rather induces a phase shift, it is possible to narrow the diameter of the Airy disk. Since the diameter of the Airy disk is a good estimate of the resolution, this will improve the resolution too.

Actually, assuming that a finite portion of the object frequency spectrum is an analytic function is a highly restrictive hypothesis, since it is difficult to have a priori knowledge of the object. Normally we have an unknown object to which we apply criteria such as the Rayleigh criterion to determine the resolution. But in that case we have available only the information that is transmitted by the optical system, and not intrinsic information about the object. Thus it appears that the amount of information that can be transmitted by an optical system is fixed, and if the resolution is to be improved, it must be at the expense of something else. In theory superresolution should be

feasible in some controlled cases, but in the real world there is significant noise, which limits the accuracy with which the frequency spectrum of the bounded object can be measured within the spatial-frequency bandpass of the optical system. This effect, together with the effect of aberrations, can preclude not only superresolution, but diffraction-limited resolution as well.

Resolution: Limiting Factors. Often the first question asked about a particular X-ray microscope is “What’s its resolution?” The answer, once extracted, must include three values: the everyday resolution, the best resolution achieved, and the theoretical best resolution. The everyday resolution is the poorest of the three and arises from a compromise between spatial resolution, signal level, noise level, and other experimental parameters such as acquisition time and energy resolution. The best resolution is a much touted number and is typically obtained only with painstaking alignment and fine tuning followed by a lengthy data acquisition period. The theoretical best resolution depends on the image formation under different types of illumination, as discussed earlier. It is instructive to discuss the practical limitations on resolution in a quantitative way in order to understand and predict experimental results.

Effect of Noise. The signal measured in an image acquired with an X-ray spectromicroscope is a combination of the true signal and the background signal. The background signal can be a function of the photon energy or the photoelectron energy as well as of the spatial frequency. There is also noise accompanying both signals, and it reduces the image contrast. What is actually measured in the image is always intensity, regardless of the illumination. Thus we need to know the frequency spectrum of the intensity. For an incoherent system, which is linear in intensity, it is straightforwardly given by Eq. (26). For partially coherent and coherent systems, the intensity cannot be expressed in terms of a frequency transfer function acting as a linear filter to transform the object intensity $\mathcal{I}_0$ into the image intensity $\mathcal{I}_1$. As mentioned earlier, scanning emission microscopes are incoherent systems. Even transmission X-ray microscopes rely on the incoherence in partially coherent light to deliver higher resolution because of the higher spatial-frequency cutoff. It is useful, then, to examine the effect of noise in the mathematically simpler incoherent case:

$$\mathcal{I}_1(f, g) = \mathcal{I}_0(f, g) \mathcal{L}(f, g) \quad (26)$$

where $\mathcal{L}$ is the frequency response function for incoherent illumination. Another name for the normalized $\mathcal{L}(f, g)$ is the *optical transfer function* (OTF). The *modulation transfer function* (MTF) is simply $|\mathcal{L}(f, g)|$, the modulus of the OTF, and is a useful quantity for describing the resolving capability of an optical system under incoherent illumination. The MTF $\mathcal{T} = |\mathcal{L}(f, g)|/|(0, 0)|$ for the simple case of a diffraction-limited optical system with an unobstructed circular aperture can be obtained with K as in Eq. (24) and $\epsilon = 0$. Because of circular symmetry, radial coordinates may be used and the MTF may be computed to be

$$\mathcal{T}(f) = \begin{cases} 0, & f > f_0 \\ \frac{2}{\pi} \left[\cos^{-1} \left(\frac{f}{2f_0} \right) - \frac{f}{2f_0} \sqrt{1 - \left(\frac{f}{2f_0} \right)^2} \right], & f \leq f_0 \end{cases} \quad (27)$$

where f_0 is the incoherent cutoff spatial frequency $2A_1/\lambda$ (58). Using a linear approximation for the transmitted frequencies, we may write

$$\mathcal{T}(f) = 1 - \frac{f}{f_0} \quad (28)$$

and for a one-dimensional object we may rewrite Eq. (26) as

$$\mathcal{I}'_1(f) = \mathcal{I}'_0(f) \mathcal{T}(f) \quad (29)$$

where the primed quantities indicate normalization. Following Cerrina’s treatment (59) of the limiting effect of statistical noise on spatial resolution, we study the signal levels in the image. Since the intensity is measured as a count rate, the signal $\mathcal{I}$ is obtained by multiplying $\mathcal{I}'$ by the counting time Δt . Then, the background can be taken into account in the same fashion, and the total signal may be written as

$$\mathcal{I}_T = \mathcal{I}_R + \mathcal{I}_B \quad (30)$$

$$= (\mathcal{I}'_{0,R} \mathcal{T} + \mathcal{I}'_{0,B} \mathcal{T}) \Delta t \quad (31)$$

where subscripts R and B refer to the “real” and background signals, respectively. In order to resolve a feature, $[\text{Sscr}]_R$ must be higher than the noise level. This can be quantified by

$$\mathcal{I}_R = \mathcal{I}_T - \mathcal{I}_B \geq n(\sigma_T + \sigma_B) \quad (32)$$

where n is a positive nonzero integer indicating the level of confidence and σ_T and σ_B are the noise levels in the total and background signals, respectively.

Because Poisson’s distribution describes statistical noise, for N counts a random noise of $\sqrt{N}$ will be observed. Then we may substitute $\sqrt{\mathcal{I}_T}$ and $\sqrt{\mathcal{I}_B}$ for σ_T and σ_B , respectively. After defining the signal-to-noise ratio R as $\mathcal{I}'_{0,R}/\mathcal{I}'_{0,B}$ we may write

$$\mathcal{I}_R \geq \frac{n^2}{\mathcal{T}} \left(\sqrt{1 + \frac{1}{R}} + \sqrt{\frac{1}{R}} \right)^2 \quad (33)$$

For a small signal-to-noise ratio ($R < 1$), then, we may write the real object frequency distribution $\mathcal{I}'_{0,R}$ as

$$\mathcal{I}'_{0,R}(f) \geq \frac{4n^2}{\mathcal{T}(f) \Delta t R} \quad (34)$$

With the help of Eq. (28), we may solve this for the frequencies transmitted by an idealized incoherent optical system of circular aperture in the presence of statistical noise. We obtain

$$f \leq f_0 \left(1 - \frac{4n^2}{\mathcal{I}'_{0,R} \Delta t R} \right) \quad (35)$$

which shows that the maximum distinguishable frequency passed by a system with statistical noise is reduced, thus increasing the minimum period resolvable and hence decreasing the resolution. If the counting time Δt is sufficiently long for the desired level of confidence n , this frequency will approach the pure incoherent cutoff frequency for a diffraction-limited system. The counting time is directly related to the

absolute intensity level of the image, which in turn is related to the brightness. This is true not just for incoherent scanning systems, but for X-ray microscopes in general, as long as there is no significant temporal oscillation in the true signal or the noise.

Importance of Brightness. Brightness is often defined for synchrotrons and insertion devices as the number of photons per unit time per unit angle per unit area per unit fraction of bandwidth (typical units are photons/s.mrad².mm².0.1%). Without deriving expressions for the brightness in specific cases, we simply note that it is a measure of the ability of a source to illuminate a small area with small angular divergence. Clearly a high-brightness source (such as a third-generation synchrotron and its insertion devices) results in more incident flux per unit area on the sample in a X-ray microscope using that source. In a sequential imaging system such as a scanning microscope, this higher flux automatically means that the intensity level goes up, and thus, for a given counting time Δt , the signal goes up. Hence, better resolution can be obtained for the same optical system by counting for the same amount of time if all other parameters remain the same. In a parallel-imaging X-ray microscope such as the PEEM, although the X rays are not focused to a microspot, the electrostatic optics accept only those photoelectrons from a small area of the sample whose size is determined by the field of view for different magnifications and potentials of the optical column, the signal also increases.

Thus, the brighter the source is, the greater is the incident X-ray intensity on the area of interest, the higher the signal level in the photoelectron image, and the greater the capability to acquire spectra from small regions in reasonable real time. This time is longer for nonsynchrotron X-ray sources such as plasma point sources, which have a lower-flux output. The actual intensity at the image depends on various factors, including detector efficiency, sample quantum efficiency, acquisition time, and source brightness. Brightness can overcome shortcomings in the efficiencies and dramatically reduce the acquisition time, thus enabling higher spectromicroscopic resolution. This includes the ability to acquire higher-energy-resolution spectra from the samples, with a concurrent high spatial resolution. With fourth-generation synchrotrons like SOLEIL (France) and SLS (Switzerland) in the offing, the future of X-ray microscopy shines only brighter.

DATA ACQUISITION AND RECORDING

RADIOTELEMETRY

Radiotelemetry, by definition, is the science and technology of automatically measuring and transmitting data by radio from remote sources, as from space vehicles, to receiving stations for recording and analysis. It involves preparing of data generated at remote sources, transmitting data through radio channels, and processing data at the receiving stations. Behind these three tasks, how to convey the information in a reliable and timely manner through a communication link is the most fundamental problem in this field.

There are many ways to define a communication link, depending on where the link starts and ends. Customarily, a communication link is the transmission path through which information-bearing waveform flows from one point to another. A generic link includes the modulator, the transmitter, the channel, the receiver, and the demodulator. Another popular view of a link is to include error-correction coding and encoding as part of the link because, as we see in a later discussion, link performance is a function of both modulation and coding. Yet, for a communication system that uses data compression, one might want to take an end-to-end view and include the error propagative effect of data compression in link design and analysis, because the error propagative property affects the integrity and throughput of the link. In the following sections, we briefly discuss some important elements of a communication link: data compression, forward error-correction coding, modulation, demodulation, and synchronization. However, before moving on to these individual topics, we first discuss a higher level consideration of the overall link reliability, namely, the link-budget analysis.

The main objective of link-budget analysis is to maximize the data return for a communication link subject to (1) the available communication resources and (2) the required data quality. Power and bandwidth are the two primary resources in communication, and data quality is usually expressed in terms of the frequency of errors in the received data, that is, the bit-error rate (BER). To design a communication system, the first step is to understand what the available resources are. Whether a system is power-limited (e.g., deep space communications) or bandwidth-limited (e.g., near-Earth satellite communications) determines the available options for modulation and error-correction coding schemes.

COMMUNICATION LINK-BUDGET ANALYSIS

The link budget is a balance sheet of the gains and losses in decibels (dB) of various parameters in the communication path. Many of these parameters are statistical or time-varying or both. The required BER is a direct function of the bit signal-to-noise ratio (SNR), denoted as E_b/N_0 , which in turn is a function of the modulation and error-correction coding used. Because of the statistical nature (uncertainty) of these parameters, a safety margin M is built in to guarantee the transmission data quality at any given time.

To put link-budget analysis into perspective, more parameters need to be defined and they are given as follows. To begin with, the total received signal-power-to-noise-power-spectral-

density ratio, P_T/N_0 , which encompasses all the power gains and losses in the communication path, is conveniently expressed as (1)

$$\frac{P_T}{N_0} = \frac{\text{EIRP}(G/T)}{kL_sL_0} \quad (1)$$

where EIRP is the effective isotropic radiated power of the spacecraft, G/T is the receiver sensitivity of the ground system, k is Boltzmann's constant, $L_s = (4\pi d/\lambda)^2$ is the space loss where d is the distance between the transmitter and receiver, λ is the wavelength, and L_0 denotes all other losses and degradation factors not specifically addressed in the above equation. Note that all gains and losses are statistical quantities. Then, let R_s be the symbol rate and R_c be the code rate expressed as the ratio of the number of information bits in a code word to the number of coded bits in a code word. The data rate or bit rate, denoted as R_b , is related to the symbol and code rates via $R_b = R_s R_c$. The bit SNR is written as

$$\frac{E_b}{N_0} = \frac{P_T/N_0}{R_s R_c} \quad (2)$$

Finally, let $(E_b/N_0)_{\text{req}}$ be the required E_b/N_0 to guarantee a certain BER. To ensure a reliable link, the constraining dependency is expressed in dB as follows:

$$\left(\frac{E_b}{N_0}\right)_{\text{req}} + M \leq \frac{P_T}{N_0} - R_s - R_c \quad (3)$$

The essence of link-budget analysis is to determine how much link margin M is required and this, in turn, is determined by how well the statistics of various link parameters are known. If M is too small, one might get a large data return but the data might have frequent errors. If M is too large, one might get continuous clean data but the throughput might be low. The analyst needs to make the right tradeoff on quantity versus quality, depending on the requirements and objectives of the service the link supports. Also, in an operational scenario, one usually starts out with a large M (a conservative approach) for a newly deployed system, and gradually reduces M (an aggressive approach) as more experience and confidence accumulates.

DATA COMPRESSION

In the midst of the Information Age, when new data—texts, images, sensor data, and many other forms of knowledge—are generated at a lightning pace, how these data are efficiently communicated and/or archived becomes increasingly important. Data obtained directly from sources usually contains much redundancy, and data compression is the process of applying “pressure” to remove the redundancy. The processes of compression and decompression add complexity to the overall system. The main issue in the use of data compression is the tradeoff between the efficiency of data handling and the complexity of signal processing to retrieve the information.

In the English language, letters like “a” and “e” are used more frequently than “y” and “z”, and words like “and” and “the” are much more often than “data” and “compression”. For images and sensor data, the differences between adjacent samples are small rather than large. This nonuniform frequency distribution of data associated with most information sources allows one to assign shorter bit patterns to represent the more frequent elements from the source and longer bit patterns to represent the less frequent elements from the source. This is the simplest view of data compression.

Data compression is broadly classified in two categories: lossless and lossy compression. Lossless compression denotes compression in which the decompressed or reconstructed data exactly match the original. Lossy compression represents compression methods where some degradation of quality is tolerable if a more compact but approximate representation is achieved. Next, we give brief surveys on text compression (lossless) and image compression (lossless and lossy). However, the compression of audio, video, and facsimile is beyond the scope of this article. Interested readers are encouraged to consult specialized books and technical journals in these areas.

Textual data is probably the first area where people applied compression. In 1832 Samuel Morse developed a code using dots, dashes, and spaces to represent letters, numbers, and punctuation for telegraph transmission. Each dot or dash is delimited by a space. A dot and a space take the same time. A dash is three times longer. Morse assigned fewer time units to more commonly occurring letters (e.g., “e” is a dot), and more time units to ones (e.g., “q” is dash-dash-dot-dash) that rarely occur. Today, most popular text compression schemes are different variations of the Lempel–Ziv (LZ) scheme developed in 1977 (2) and 1978 (3). LZ schemes use a dictionary approach. Dictionary coding operates by replacing groups of consecutive characters with indices in some dictionary. It exploits the frequent reoccurrence of certain exact patterns that are very typical of textual data. Other than compressing text, LZ schemes are reasonably good at compressing images and other sources. LZ schemes are generally considered universal compression algorithms. The UNIX command “compress” and the modem standard V42.bis are examples of applications using LZ schemes.

Image compression and other waveform compression is lossless or lossy. For scientific and medical applications that demand further processing and analysis, one might prefer lossless compression to ensure data accuracy. In other applications, such as image database, electronic photography, and desktop publishing, where transmission and storage bandwidths are limited, lossy compression is usually employed to reduce the data size at the expense of image quality.

Lossless image compression consists of two steps, modeling and coding. A predictive model predicts a pixel value based on a previously transmitted one, and compares it with the current value. The error value is coded instead of the original pixel value. On the receiver side, because the errors and the predictive scheme are known, the receiver recovers the value of the original pixel. An example of lossless image compression is the Rice code used in space and satellite communications.

Lossy image compression involves an irreversible quantization step that causes distortion between the original and the reconstructed image. Popular techniques in lossy image

compression include differential pulse code modulation (DPCM), transform coding, subband coding, vector quantization, and some hybrid techniques. The Joint Photographic Expert Group (JPEG) established an international standard on still image compression that uses the discrete cosine transform along with scalar quantization and entropy coding. Currently, JPEG encoder and decoder chips are available from many semiconductor manufacturers.

FORWARD ERROR-CORRECTION CODING

In 1948, the landmark paper “A Mathematical Theory of Communication” (4) by Claude Shannon provided a mathematical framework for analyzing communication, the process of sending information from one point to another through a noisy media, by using the concept of entropy. He provided an existence proof which shows that communication systems can be made arbitrarily reliable as long as the fraction of redundant signals in the signal stream exceeds a certain value, which is a function of the signal and noise statistics. The process of introducing redundancy in the signal stream to combat noise, so that retransmission is not needed, is called forward error-correction coding. Shannon did not show how this could be done in his famous theorem. Later on, much research effort has yielded a variety of interesting theoretical and practical results in this area.

Because redundant signals are deliberately introduced in the signal stream as error-correction coding, bandwidth expansion is expected. Encoding and decoding processes inevitably also add complexity to the overall system. However, it can be shown that, with a proper choice of coding scheme, the resulting E_b/N_0 can be considerably lower compared with an uncoded system. Thus error-correction coding allows one to trade power for bandwidth and complexity. In this article, the application of two popular error-correction coding schemes, block codes and convolutional codes are explained, without providing the detailed performance analysis of these codes. Other more advanced coding schemes, like trellis codes and turbo codes, are not covered here. Interested readers are encouraged to consult specialized books and technical journals in this field.

In block coding, a block of k bits is encoded into a block of n bits, where $n > k$. There are 2^k code words in a code space of 2^n . The code rate R_c , which is the ratio k/n , is a measure of the amount of added redundancy. The minimum distance $d_{\min}$, which is the Hamming distance between two closest code words, is a measure of the error-correction capability of the code. It can be shown that $d_{\min} \leq n - k + 1$ (Singleton bound). For bounded-distance decoding, the number of errors t that the code can correct is related to $d_{\min}$ by

$$2t + 1 \leq d_{\min} \quad (4)$$

In convolutional coding, sequences of k information bits long are encoded as continuous sequences using a kK -stage shift register, where K is called the constraint length. n output sequences are produced, each of which is generated by a selected set of combinations of these K input sequences. The n output sequences are multiplexed into a single-bit stream for transmission. Similar to a block code, the

ratio k/n is a measure of the redundancy of the convolutional code. The minimum distance d_{free} between two closest code sequences, is a measure of the error correction capability of the code.

The most popular block code used today is the class of Reed–Solomon (RS) codes. RS codes are maximum-distance-separable codes that achieve maximum error-correction capability in the bounded-distance decoding sense. Well-known encoding and decoding algorithms exist that are reliable in software and hardware. RS codes are flexible. Long, powerful RS codes exist for demanding applications, and short RS codes for simple applications. Deep space communications use the (255, 223) RS code as the outer code of the concatenated coding system. This code is block-interleaved and is used in conjunction with an inner convolutional code to provide reliable communications between the spacecraft and the ground stations. The concatenated coding system is designed to combat the additive white Gaussian noise of the deep space communication links. Simpler RS codes are used in compact disks (CD), a mass-marketed consumer product. The coding system used, called the cross-interleaved Reed–Solomon code (CIRC), is composed of two RS codes with (n,k) values (32, 28) and (28, 24). In between the two encoders are sets of delay lines which scramble the data stream. The CIRC coding system is designed to correct the burst-like errors, typical of a CD channel.

The most popular decoding scheme for convolutional codes is the Viterbi algorithm. The complexity of Viterbi decoding grows exponentially with the constraint length of the code, which is the number of memory elements in the encoder shift register. As mentioned earlier, convolutional codes are used in deep space communications. In the past, short constraint-length codes (7 or 9) are used because of the limitations in hardware technologies. Today, long constraint-length Viterbi decoders (up to 15) are designed and built. Convolutional codes are also popular in satellite communications and wireless communications. Presently, only short constraint-length convolutional codes are used in these areas.

INTERACTION BETWEEN DATA COMPRESSION AND ERROR CONTROL IN A COMMUNICATION SYSTEM

This section addresses the interaction between data compression and error control (containment/detection/correction) processes, two indispensable building blocks in modern digital communication systems. Data compression conserves transmission and storage bandwidth by removing redundancy in the source data. Error correction introduces controlled redundancy to the data to eliminate channel errors. A combination of both techniques ensures efficient and reliable transmission of information from one point to another. The famous separation principle indicates that data compression and error control processes can be completely separated, that is, the task of transmitting the output of a source through a channel can be separated without loss into the task of forming a binary representation of the source output and the task of sending a binary sequence through the channel. This is not quite true in practice, however. In evaluating an end-to-end communication system, we have to consider effects, like instrument failures, adverse weather conditions, synchronization loss, and other

unpredictable phenomena in the communication system and the channel. The error-control process cannot handle all possible kinds of errors. Thus the effect of error propagation should be considered when evaluating a data compression scheme in a communication system.

There are two issues to be dealt with: how to prevent errors from occurring and, if errors occur, how to contain the errors. The former issue can be dealt with easily (at least in the conceptual sense) by using higher transmission power or more powerful error-correction coding techniques on the channel and better fault-tolerance techniques on various system components. The second issue of how to contain errors is more intricate and has commonly been overlooked. There are mainly two approaches (or a combination of both) to deal with the problem. The first approach is to add extra redundancy to the compressed data to detect and confine errors. Some simple ways are adding a delimiter pattern at regular intervals and forcing fixed block-size transmission by appending filling 0's, etc. These techniques reduce compression performance. The second approach is to choose data compression schemes which are less susceptible to error propagation. These schemes usually transmit the compressed data in fixed block size or inherently have delimiter patterns in their compressed data streams. We illustrate the interaction between data compression and error-correction coding with an example in a later section.

MODULATION AND DEMODULATION

Modulation

Modulation is the process of transforming signals into waveforms suitable for transmission through a certain type of medium or channel. For example, when transmitting electronic signals through free space with an antenna which converts electronic signals into electromagnetic (EM) waves, the physical dimensions of the antenna aperture are at least of the same order of the wavelength of the EM wave. Therefore, a baseband signal has to modulate a sinusoidal signal at radio frequency (RF), called the carrier, before transmitting it by antennas of reasonable size.

The typical modulation procedure for digital signal transmission starts with a baseband pulse code modulation (PCM) which converts the analog signal into a binary data stream. Depending on the subsequent RF modulation schemes, this binary data stream is fed into different devices. For example, fixed-length blocks of the binary data are used to determine the instantaneous frequencies of the carrier for a frequency-shift-keyed (FSK) system. On the other hand, the binary data drive a pulse generator whose output modulates the subcarrier (if used) and the RF carrier in a typical phase-shift-keyed (PSK) system. There are several different binary data formats (5). For example, non-return-to-zero (NRZ) and bi-phase (also known as the Manchester code) are the ones more commonly used. In some applications, pulse shapes other than the square pulse are selected to represent a binary digit in the data stream. The choice of a particular data format and pulse shape is determined by several factors, for example, considerations of bandwidth efficiency, inherent synchronization features, and the noise immunity of each data format.

PSK modulation has been widely adopted for deep space communications mainly because it is a very efficient type of

modulation in bit-error performance and the resulting signal has a constant envelope which allows the power amplifier to achieve the maximum efficiency by operating at the saturation point. In general, a communication system using the PSK modulation is designed to have a multiple phase-shift-keyed (MPSK) signal of which the number of phasor states, denoted by M , is any power of 2. The increased BER with M for MPSK signals, however, prevents its use when M is large. Furthermore, because of the ease of being decomposed into two orthogonal channels for further signal processing, the MPSK modulated signals commonly used for radio-telemetry are limited to the cases where $M = 4$ or lower, namely, the binary phase-shift-keying (BPSK), the quadrature phase-shift-keying (QPSK) or its variations, such as offset QPSK, unbalanced QPSK, and pulse-shaped QPSK, etc. For some applications, the quadrature amplitude-shift-keying (QAM) modulation is used to allow multilevel signals transmitted on either one or both of the mutually orthogonal channels.

It is possible to include subcarrier(s) for BPSK modulation. The purpose of using subcarrier(s) is to separate data sidebands of different signals and the carrier so that they do not interfere with each other. Whether or not to use subcarrier(s) depends on the mission design. For example, a subcarrier is preferred when a residual carrier component is preserved for spacecraft navigation or certain radio science experiments. On the contrary, it may not be a good idea to keep a subcarrier when transmission power is weak or the bandwidth efficiency becomes a major concern. Two types of subcarriers, the sine wave and the square wave, are commonly used. The sine-wave subcarrier along with the phase-modulated carrier produces fast-decaying data sidebands and, therefore, is recommended for near-Earth space missions where the interference caused by the power spillover to the adjacent frequency bands is the major concern (6). The same recommendation also suggests using the square-wave subcarrier for deep space missions because of the ease of generating a square wave onboard spacecraft and the relatively less stringent bandwidth allocation for this type of mission.

A phase-modulated (PM) telemetry signal is represented mathematically by

$$S_T(t) = \sqrt{2P_T} \sin \left(\omega_c t + \sum_{i=1}^N m_i S_i(t) \right) \quad (5)$$

and raised cosine pulse waveform, are selected where P_T is the total power of the received signal, ω_c is the carrier frequency, m_i is the modulation index associated with the i th data source, and

$$S_i(t) = \begin{cases} \sum_{k=-\infty}^{\infty} d_{k,i} P_i(t - kT), & \text{for PCM/PM (without subcarrier)} \\ \left[\sum_{k=-\infty}^{\infty} d_{k,i} P_i(t - kT) \right] \sin(\omega_{sc_i} t), & \text{for PCM/PSK/PM with a sine-wave subcarrier} \\ \left[\sum_{k=-\infty}^{\infty} d_{k,i} P_i(t - kT) \right] \text{sgn}[\sin(\omega_{sc_i} t)], & \text{for PCM/PSK/PM with a square-wave subcarrier} \end{cases} \quad (6)$$

represents either a normalized baseband waveform (with $d_{k,i} = \pm 1$) or a normalized BPSK modulated subcarrier waveform (at the frequency ω_{sc_i}). $P_i(t)$ is the pulse function of unit power and T is the reciprocal of the symbol rate. Note that, when more than one data sources are included (that is, $N > 1$ in Eq. (5)), only one data source output is allowed to directly modulate the carrier, denoted by its processing order as PCM/PM, and the rest must be put on subcarrier(s) before modulating the carrier, similarly denoted as PCM/PSK/PM in Eq. (6). An exception of this single PCM/PM rule is the code division multiplexing, in which multiple data sources are put directly on the carrier and remain distinguishable because of the unique code sequence (for example, pseudo-random codes or Walsh-Hadamard codes) used by each of them.

Typically, a deep space downlink signal (i.e., a signal sent from spacecraft to Earth) consists of two or more data sources of which, besides the telemetry signal, a ranging signal is included for spacecraft navigational purpose (7). For example, a mathematical expression of a downlink signal consisting of a sinusoidal ranging signal at the frequency ω_1 and a binary telemetry signal of NRZ format, $d(t)$, which is modulated onto a square-wave subcarrier, is given by

$$\begin{aligned} S_T(t) &= \sqrt{2P_T} \sin \{ \omega_c t + m_1 \sin(\omega_1 t) \\ &\quad + m_2 d(t) \text{sgn}[\sin(\omega_{sc} t + \theta_{sc})] + \theta_c \} \\ &= \sqrt{2P_T} \left\{ \begin{aligned} &J_0(m_1) \cos(m_2) \sin(\omega_c t + \theta_c) \\ &+ d(t) J_0(m_1) \sin(m_2) \text{sgn}[\sin(\omega_{sc} t + \theta_{sc})] \cos(\omega_c t + \theta_c) \\ &+ \cos(m_2) \left[\sum_{n=1}^{\infty} 2J_{2n}(m_1) \cos(2n\omega_1 t) \right] \sin(\omega_c t + \theta_c) \\ &+ \cos(m_2) \left\{ \sum_{n=0}^{\infty} 2J_{2n+1}(m_1) \sin[(2n+1)\omega_1 t] \right\} \cos(\omega_c t + \theta_c) \\ &+ d(t) \sin(m_2) \left[\sum_{n=1}^{\infty} 2J_{2n}(m_1) \cos(2n\omega_1 t) \right] \\ &\quad \text{sgn}[\sin(\omega_{sc} t + \theta_{sc})] \cos(\omega_c t + \theta_c) \\ &- d(t) \sin(m_2) \left\{ \sum_{n=0}^{\infty} 2J_{2n+1}(m_1) \sin[(2n+1)\omega_1 t] \right\} \\ &\quad \text{sgn}[\sin(\omega_{sc} t + \theta_{sc})] \sin(\omega_c t + \theta_c) \end{aligned} \right\} \end{aligned} \quad (7)$$

where $J_n(\cdot)$ is the n th order Bessel function and θ_c and θ_{sc} are random carrier and subcarrier phases, respectively, each uniformly distributed over 0 to 2π . The first term in this expression is the residual carrier component which is fully suppressed if the data modulation index m_2 equals $\pi/2$. The second term is the desired data-bearing component containing the telemetry information which needs to be demodulated. The third and the fourth terms contain the ranging information to be extracted separately, and the rest are from intermodulation of telemetry and ranging signals. Typically, on one hand, the ranging modulation index m_1 chosen is small (around 1/2 or smaller) so that the power consumption by this ranging signal is relatively small. On the other hand, the data modulation index selected is large (close to its upper limit $\pi/2$) to ensure that only sufficient

power goes to the residual carrier component and the rest of power is allocated solely for telemetry data transmission. The strategy of optimizing modulation indices for efficient power allocation is discussed in (8).

A QPSK phase-modulated telemetry signal is usually treated as a combination of two orthogonal BPSK signals. Mathematically, a general QPSK (or, more specifically, an unbalanced QPSK) signal takes the form

$$S_T(t) = \sqrt{\alpha P_T} \sin \left(\omega_c t + \sum_{i=1}^M m_{c,i} S_{c,i}(t) \right) + \sqrt{(1-\alpha) P_T} \cos \left(\omega_c t + \sum_{i=1}^N m_{s,i} S_{s,i}(t) \right) \quad (8)$$

where α is the percentage of transmitted power in one of the two channels. When only one binary signal of NRZ format is transmitted on each channel, that is, $M = N = 1$, with the modulation indices $m_{s,1} = m_{c,1} = \pi/2$, the QPSK signal is rewritten as

$$S_T(t) = \sqrt{\alpha P_T} S_{c,i}(t) \cos(\omega_c t) - \sqrt{(1-\alpha) P_T} S_{s,i}(t) \sin(\omega_c t) \quad (9)$$

a combination of two BPSK signals on two orthogonal basis functions. As long as the orthogonality is maintained, these two BPSK signals do not interfere with each other and the bandwidth efficiency, measured as how many bits of information transmitted over a unit bandwidth, of a QPSK signal is twice that of a BPSK signal (5). Several variants of QPSK modulation, including the offset QPSK (OQPSK) and the minimum-shift-keying (MSK), are also commonly used in near-Earth space missions. A detailed description of these modulation schemes is not covered here.

Demodulation

Demodulation is the process of transforming received waveforms back into their original state by reversing the modulation procedure. After traveling through various types of media or channels, the received waveform is corrupted in many ways. For example, it is corrupted by receiver's internally generated noise which is typically modeled as an additive white Gaussian noise (AWGN), or externally introduced interference, such as multipath, fading. Hence, for demodulation, it is important to correctly estimate the vital parameters in the transmitted signal from the corrupted waveform and apply the locally generated reference signals to remove the modulation. The following simple example illustrates how an AWGN corrupted BPSK signal is demodulated. The received signal is given by

$$r(t) = \sqrt{2P_T} \sin \left(\omega_c(t + \tau) + \left(\frac{\pi}{2} \right) \sum_{k=1}^{\infty} d_k P(t + \tau - kT) + \theta \right) + n(t) \quad (10)$$

where τ is the random propagation delay, θ is a uniformly distributed (over 0 to 2π) carrier phase, and $n(t)$ is a noise modeled as an AWGN with a two-sided power spectral density level at $N_0/2$ W/Hz. For the signal of NRZ format, the phase-modulated

signal is equivalent to the product of the carrier and the base-band binary data waveforms, which is rewritten as

$$r(t) = \sqrt{2P_T} \left[\sum_{k=1}^{\infty} d_k P(t + \tau - kT) \right] \cos(\omega_c t + \theta_c) + n(t) \quad (11)$$

where $\theta_c = (\theta + \omega_c \tau)_{\text{mod } 2\pi}$ is the total carrier phase. To demodulate the carrier, the receiver needs to generate a local reference, say $\sqrt{2} \cos(\omega_c t + \phi_c)$, where $\text{thgr}^{\text{circ}}_c$ is an estimate of θ_c . A low-pass filtered version of the product of the local carrier reference and the received signal becomes

$$r'(t) = \sqrt{P_T} \left[\sum_{k=1}^{\infty} d_k P(t + \tau - kT) \right] \cos(\phi_c) + n'(t) \quad (12)$$

where $\phi_c = \theta_c - \text{thgr}^{\text{circ}}_c$ is the phase error between the actual and the estimated carrier phases. For constant or at least slowly varying ϕ_c , the factor $\cos(\phi_c)$ represents a signal amplitude attenuation, which is inevitably translated into degradation in bit-error performance. To make a decision on each of the transmitted bits, say, the i th bit d_i , the resulting signal $r'(t)$ is sent to a matched filter whose operation is mainly to form a product of the input signal and a local replica of the pulse function followed by an integrate-and-dump (I&D) operation. The accurate timing estimate $\text{thgr}^{\text{circ}}$ is very important in this matched filter operation because an error renders integrating across two bits, which reduces the detected symbol (for coded system) or bit (for uncoded system) energy when adjacent bits are of opposite polarities and results in a higher probability of decision error.

Additional signal power degradation due to imperfect sub-carrier synchronization, similar to the carrier case given here, is expected when a subcarrier is used. The power degradation resulting from each of the carrier, subcarrier, and symbol tracking operations is discussed later.

SYNCHRONIZATION

The process of estimating the phase and timing parameters from the incoming noise-corrupted signal and using this information to keep the locally generated reference signal aligned with these estimates and, therefore, with the incoming signal is called synchronization.

As indicated previously, coherent reception and demodulation require phase information about the carrier and subcarrier (if used) and also symbol-timing information. This information must be provided and updated for coherent receivers all the time because they are usually time-varying with the changing characteristics of the channel. Therefore, individual tracking loops which continuously update their estimates of specific parameters are required to track and provide the needed information for a coherent receiver.

Although the tracking of carrier, subcarrier, and symbol timing are individually discussed in the following, one should keep in mind that, strictly speaking, all these loops are effectively coupled together in the sense that no one achieves lock without help from others, except for residual carrier tracking in which a carrier tone is separately tracked. However, in practice, each loop's performance is usually analyzed independently to keep the problem manageable.

It is also important to know that all the tracking loops discussed later are motivated by the maximum *a posteriori* (MAP) estimation which suggests only the open-loop structure of a one-shot estimator. The closed-loop structure derived by differentiating the likelihood function and equating the resulting loop feedback signal (also known as the error signal) to zero is only motivated by the MAP estimation (8).

Carrier Tracking

BPSK. The most commonly used device to track the phase of a sinusoidal signal, for example, the residual carrier component in Eq. (7), is the phase-locked loop (PLL). The PLL is composed of a phase detector, a loop filter, and a voltage-controlled oscillator (VCO) or, in a digital PLL design, a numerically controlled oscillator (NCO). The low-pass component of the phase detector output is a periodic function (of period 2π) of the phase error ϕ_c , which is called the S-curve of the loop. A stable lock point exists at $\phi_c = 0$, one of the zero-crossing points where the S-curve has a positive slope. The phase error for the first-order PLL, which has its loop filter implemented as a constant gain, is a Tikhonov distributed random variable and its probability density function (pdf) is given by (5)

$$p(\phi_c) = \frac{\exp[\rho_{\phi_c} \cos(\phi_c)]}{2\pi I_0(\rho_{\phi_c})} \quad |\phi_c| \leq \pi \quad (13)$$

where $I_k(\cdot)$ denotes the modified Bessel function of order k and $\rho_{\phi_c} = (\sigma_{\phi_c}^2)^{-1}$ is the loop SNR defined as the reciprocal of the phase error variance in radian². The loop SNR for the first-order PLL is expressed by

$$\rho_{\phi_c} = \frac{P_c}{N_0 B_L} \quad (14)$$

where B_L is the loop bandwidth. The detailed description of a PLL is discussed in another article in this encyclopedia and is not to be repeated here.

For the suppressed carrier in which no discrete carrier component appears in its spectrum, the carrier phase, embedded in the data-bearing component as the second term of Eq. (7), must be tracked by the Costas loop. The Costas loop is a phase-tracking loop whose functionality is similar to that of a PLL. Except for the same feedback path comprised of a loop filter and an NCO, a Costas loop has a double-arm loop structure, denoted, respectively, as the in-phase (I) and quadrature (Q) arms, with a phase detector and a low-pass arm filter in each. The incoming signal is first mixed with each of the two locally generated reference signals 90° apart, that is, $\sqrt{2} \sin(\omega_c t + \text{thgr}^{\text{circ}}_c)$ and $\sqrt{2} \cos(\omega_c t + \text{thgr}^{\text{circ}}_c)$, at the corresponding phase detector and then passed through the arm filter. Although the low-pass arm filter is either a passive RC-type filter or an active filter, it turns out that a matched filter (that is, an active filter) is the optimal design. The output of the two arm filters are multiplied, which effectively removes the data modulation, to form the loop feedback signal before it is fed into the loop filter. Because of this multiplication, a Costas loop is actually tracking twice the error phase. Accordingly, the Costas loop has two equally stable lock points at $\phi_c = 0$ and $\phi_c = \pi$, each corresponding to a zero-crossing point in the S-curve (of period π) where the slope is positive. These dual lock point inevitably introduce phase ambiguity such that the demodulated data has

inverted polarity if the loop locks at $\phi_c = \pi$. This 180° phase ambiguity is resolved in several ways. For example, a known sequence pattern is inserted in the transmitted symbol stream from time to time so that the inverted polarity is detected by examining the received sequence pattern. However, the most efficient method is employing a differential encoding scheme in the transmitted data so that the information is kept in the relative phase between adjacent symbols instead of in the absolute phase of each symbol (5). On the receiver side, a corresponding differential decoding scheme is applied to extract the relative phase (or the transmitted information) after the symbol decision. A small penalty in terms of error performance exists for this differential encoding/decoding scheme because one incorrect symbol decision creates two consecutive errors in the relative phase.

The phase error for the first-order Costas loop with I&D arm fitters is similarly found as a Tikhonov distributed random variable and its pdf is given by

$$p(\phi_c) = \frac{\exp\left[\frac{\rho_{\phi_c}}{4} \cos(2\phi_c)\right]}{\pi I_0\left(\frac{\rho_{\phi_c}}{4}\right)} \quad |\phi_c| \leq \frac{\pi}{2} \quad (15)$$

and the associated loop SNR is given by

$$\rho_{\phi_c} = \frac{P_d}{N_0 B_L} \left(1 + \frac{1}{2E_s/N_0}\right)^{-1} \quad (16)$$

where $E_s/N_0 = P_d T/N_0$ is the symbol SNR. Note that the term in the parentheses is usually called the squaring loss, which results from the signal-noise product in the loop feedback signal. At low symbol SNR, the squaring loss is significant.

As discussed previously, transmitted power is allocated to the residual carrier component and data-bearing component by the choice of the modulation index for the telemetry data. It has been proved that a fully suppressed carrier is the best way to maximize data throughput (9). However, if a residual carrier component is desired for purposes other than communications, it is always a dilemma to set this modulation index because, on one hand, sufficient power must be given to the residual carrier so that it is successfully tracked by a PLL, and, on the other hand, the power allocated for data transmission should be kept as high as possible to maximize data throughput. Because the residual carrier and data sidebands are coherently related, a hybrid loop (10) which consists of the phase-locked loop and Costas loop structures is used to exploit this coherence and thereby improve carrier phase tracking in this scenario. This technique is also known as sideband aiding because it utilizes the power in the data-bearing component as the second term of Eq. (7) to help residual carrier tracking.

In the hybrid loop, both error signals from the single-arm PLL structure and the double-arm Costas loop structure are weighted and added together to form an effective loop feedback signal. As a result, there are usually dual lock points for the hybrid loop, that is, $\phi_c = 0$ and $\phi_c = \pi$ and similar to those of a Costas loop. Yet, these two lock points generally are not equiprobable. It can be shown that (11) the lock point at $\phi_c = \pi$ vanishes when the modulation index is smaller than a threshold as a function of the symbol SNR.

With a given modulation index, an optimal relative weight between the PLL and Costas loop portion is derived to minimize

the hybrid-loop tracking jitter. Because the relative tracking performance between a PLL and Costas loop is determined by the relative power allocation and the additional squaring loss incurred in the Costas loop, it is not surprising to find that the optimal weight is a function of the modulation index and the symbol SNR.

QPSK. The carrier tracking of a QPSK signal is usually done by a generalized Costas loop motivated by MAP estimation theory. There are basically two variants of this generalized Costas loop: the polarity-type known as the crossover Costas loop for high SNR scenarios and the squaring-type for low SNR scenarios (7). In the crossover loop, two products are formed by multiplying the hard-limited version of one arm-filter output with the other arm-filter output before they are combined as the loop error feedback. The phase error for the first-order crossover Costas loop is a Tikhonov distributed random variable with pdf given by

$$p(\phi_c) = \frac{2 \exp\left[\frac{\rho_{\phi_c}}{16} \cos(4\phi_c)\right]}{\pi I_0\left(\frac{\rho_{\phi_c}}{16}\right)} \quad |\phi_c| \leq \frac{\pi}{4} \quad (17)$$

The associated loop SNR for this first-order cross-over loop is

$$\rho_{\phi_c} = \frac{P_d}{N_0 B_L} \times \left\{ \frac{\left[\operatorname{erf}\left(\sqrt{\frac{E_s}{2N_0}}\right) - \sqrt{\frac{2}{\pi}} \left(\frac{E_s}{N_0}\right) \exp\left(-\frac{E_s}{2N_0}\right) \right]^2}{1 + \frac{E_s}{N_0} - \left[\sqrt{\frac{2}{\pi}} \exp\left(-\frac{E_s}{2N_0}\right) + \sqrt{\frac{E_s}{N_0}} \operatorname{erf}\left(\sqrt{\frac{E_s}{2N_0}}\right) \right]^2} \right\} \quad (18)$$

where the error function $\operatorname{erf}(\cdot)$ and its complimentary $\operatorname{erfc}(\cdot)$ are defined as

$$\operatorname{erf}(x) = 1 - \operatorname{erfc}(x) = \frac{2}{\sqrt{\pi}} \int_0^x e^{-\alpha^2} d\alpha$$

Note that, similar to Eq. (16) of the Costas loop, the term in the braces in Eq. (18) is the squaring loss of the crossover Costas loop. The squaring-type loop has a different squaring loss which is smaller than that of its polarity-type sibling in low SNR region. More details about the crossover Costas loop can be found in (13). Another alternative in tracking a QPSK signal is to use the demod-remod quadriphase tracking loop which can be viewed as a fourth-power loop with a multiplication done at the IF level (7).

Subcarrier Tracking

Subcarrier tracking is almost identical to suppressed carrier tracking for BPSK signals because there is no residual tone left for the binary-phase-shift-keyed subcarrier. The Costas loop is used here to remove the data modulation and a squaring loss associated with this process is inevitable. However, depending on the use of a sine-wave or square-wave subcarrier, tracking performance is quite different. For the sine-wave subcarrier, there

is no difference between its tracking and that of a suppressed carrier. On the contrary, additional improvement in the square-wave subcarrier tracking is realized by using a time-domain windowing function on the quadrature arm (13). In this case, the windowing function around the midphase transition of the Q-arm reference signal is treated as an approximation of the time-domain derivative of its I-arm counterpart. According to the derivation of the MAP estimation, which implies the existence of an optimal open-loop structure when one of the I-arm and Q-arm reference signals is the derivative of the other, the resulting loop SNR is greatly improved by shrinking the window size. The first-order loop SNR is given by

$$\rho_{\phi_{sc}} = \left(\frac{2}{\pi}\right)^2 \frac{P_d}{N_0 B_L} \left(\frac{1}{W_{sc}}\right) \left(1 + \frac{1}{2E_s/N_0}\right)^{-1} \quad (19)$$

where W_{sc} is the quadrature window size (between 0 and 1) relative to a subcarrier cycle. It is clear that the loop SNR is inversely proportional to the window size. However, using a small window inevitably reduces the loop's pull-in range and raises the issue of loop stability. A reasonable window size of one-quarter or one-eighth is usually used to provide a 6 to 9 dB improvement in loop SNR.

No such improvement from quadrature windowing is realized for a sine-wave Costas loop of which the I-arm and Q-arm reference signals are two sine functions separated by 90° and, therefore, have the derivative relationship between them as suggested by the MAP estimation. Applying a quadrature window in this case actually destroys the derivative relationship and renders inferior loop performance.

Symbol-Timing Tracking

Symbol synchronization has a direct impact on the data detection process because inaccurate symbol timing reduces the probability of making a correct decision. Although a separate channel may be used to send timing signals for synchronization, to extract the synchronization information directly from the data-bearing signal has the advantage that no additional power and frequency spectrum are required. Of course, to successfully extract symbol timing information from the transmitted symbol stream relies on the presence of adequate symbol transitions (zero-crossings).

The data transition tracking loop (DTTL) is widely used for symbol synchronization. Similar to the Costas loop, DTTL has a double-arm loop structure with a hard decision followed by a transition detector in its in-phase arm and a delay in its quadrature arm to keep signals on both arms properly aligned. It is important to note that the term "in-phase" refers to an operation synchronous with the timing of the received symbols and, therefore, the I-arm phase detector becomes a matched filter integrating from one symbol epoch to the next. The Q-arm phase detector performs another integration within a window, which is of a size W_{sym} (between 0 and 1) relative to the symbol interval and centered at the symbol epoch, causing the midpoint of the Q-arm integration interval offset by a half-symbol from its I-arm counterpart. Similar to square-wave subcarrier tracking, the time-domain windowing function on the quadrature arm improves the tracking performance but inevitably raises the issue of loop stability at the same time (5).

The DTTL has a single stable lock point at $\phi_{sym} = 0$. The phase error for the first-order DTTL is a Tikhonov distributed

random variable and its pdf is given by

$$p(\phi_{\text{sym}}) = \frac{\exp(\rho_{\phi_{\text{sym}}} \cos(\phi_{\text{sym}}))}{2\pi I_0(\rho_{\phi_{\text{sym}}})} \quad |\phi_{\text{sym}}| \leq \pi \quad (20)$$

with the corresponding loop SNR given as

$$\rho_{\phi_{\text{sym}}} = \frac{1}{(2\pi)^2} \frac{P_d}{N_0 B_L} \left(\frac{1}{W_{\text{sym}}} \right) \times \left\{ \frac{2 \left[\text{erf} \left(\sqrt{\frac{E_s}{N_0}} \right) - \frac{W_{\text{sym}}}{2} \sqrt{\frac{1}{\pi}} \left(\frac{E_s}{N_0} \right) \exp \left(-\frac{E_s}{N_0} \right) \right]^2}{1 + \frac{W_{\text{sym}}}{2} \left(\frac{E_s}{N_0} \right) - \frac{W_{\text{sym}}}{2} \left[\sqrt{\frac{1}{\pi}} \exp \left(-\frac{E_s}{N_0} \right) + \sqrt{\frac{E_s}{N_0}} \text{erf} \left(\sqrt{\frac{E_s}{N_0}} \right) \right]^2} \right\} \quad (21)$$

SYMBOL SNR DEGRADATION

Symbol SNR degradation is the direct cause of poor bit-error performance and is translated into the telemetry system loss as seen in the next section when the receiver performs a hard decision on each demodulated symbol. When no hard decision is performed by the receiver, symbol SNR degradation directly affects decoder performance because the demodulated symbols, called soft symbols, are fed to the decoder without going through a hard-decision device.

Because of the difficulty of analyzing the coupled-carrier, subcarrier, and symbol-tracking loops, SNR degradation of the demodulated symbol (for a coded system) or bit (for an uncoded system) caused by imperfectly synchronized references is usually approximated as a product of degradation factors of the individual loops, each factor being derived on the basis of assuming perfect tracking in other loops. The overall degradation, conditioned on the corresponding phase errors, for the telemetry signal given in Eq. (7) is expressed by

$$\begin{aligned} D_{\text{SNR}}(\phi_c, \phi_{\text{sc}}, \phi_{\text{sym}}) &= D_c(\phi_c) D_{\text{sc}}(\phi_{\text{sc}}) D_{\text{sym}}(\phi_{\text{sym}}) \\ &= [\cos(\phi_c)]^2 \left[1 - \frac{2}{\pi} |\phi_{\text{sc}}| \right]^2 \left[1 - \frac{|\phi_{\text{sym}}|}{\pi} + \frac{\phi_{\text{sym}}^2}{2\pi^2} \right] \end{aligned} \quad (22)$$

where $D_c(\phi_c)$, $D_{\text{sc}}(\phi_{\text{sc}})$ and $D_{\text{sym}}(\phi_{\text{sym}})$ are the degradation factors for the imperfect carrier, subcarrier, and symbol (or bit) synchronization, respectively. Hence, the averaged symbol (or bit) SNR degradation due to imperfect synchronization becomes

$$(\overline{D_{\text{SNR}}})_{\text{dB}} = (\overline{D_c})_{\text{dB}} + (\overline{D_{\text{sc}}})_{\text{dB}} + (\overline{D_{\text{sym}}})_{\text{dB}} \quad (23)$$

where $\overline{D_c}$, $\overline{D_{\text{sc}}}$ and $\overline{D_{\text{sym}}}$ are the averaged power degradation factors obtained by averaging over the corresponding Tikhonov distributed phase errors.

In addition to the degradation caused by imperfect synchronization, it is also important to know that there are other

sources of SNR degradation, for example, the intermodulation terms and possible interference from the ranging signal found in Eq. (7), and the subcarrier and symbol waveform distortion introduced by the bandlimited channel.

BIT-ERROR PERFORMANCE (UNCODED SYSTEM) AND TELEMETRY SYSTEM LOSS

Telemetry information is extracted from the demodulated data stream by a symbol decision process. For binary signals, it is typically a hard-limiting decision on an AWGN corrupted, antipodal, random variable. For an uncoded system, the bit- (or symbol) error probability of a BPSK signal is well known as

$$P_b = \int_{-\pi}^{\pi} \frac{1}{2} \text{erfc} \left[\sqrt{\frac{E_b}{N_0}} \cos(\phi_c) \right] p(\phi_c) d\phi_c \quad (24)$$

where $p(\phi_c)$ is the pdf of the carrier phase error given in Eq. (13), when the carrier is tracked by a PLL so that no phase ambiguity exists. However, with a fixed-loop SNR, an irreducible error probability exists no matter how large the bit SNR. This irreducible error probability is characterized solely by the carrier tracking loop SNR and, for a given loop bandwidth, is reduced only by allocating more power to the residual carrier component which serves no purpose in transmitting telemetry except being tracked by PLL.

For suppressed carrier tracking of a BPSK signal by the Costas loop, the phase ambiguity exists and must be resolved. The bit-error probability for a special case of perfect phase ambiguity resolution (say, by other means, such as a periodically inserted known sync pattern) is given by

$$P_b = \int_{-\pi/2}^{\pi/2} \frac{1}{2} \text{erfc} \left[\sqrt{\frac{E_b}{N_0}} \cos(\phi_c) \right] p(\phi_c) d\phi_c \quad (25)$$

where $p(\phi_c)$ is the pdf in Eq. (15).

If a differential coding scheme is utilized to resolve the phase ambiguity, the bit-error probability becomes (7)

$$\begin{aligned} P_b &= \int_{-\pi/2}^{\pi/2} \text{erfc} \left[\sqrt{\frac{E_b}{N_0}} \cos(\phi_c) \right] \\ &\times \left\{ 1 - \frac{1}{2} \text{erfc} \left[\sqrt{\frac{E_b}{N_0}} \cos(\phi_c) \right] \right\} p(\phi_c) d\phi_c \end{aligned} \quad (26)$$

where $p(\phi_c)$ is the pdf in Eq. (15). No irreducible error probability exists in the suppressed carrier tracking because the tracking loop SNR for a fixed loop bandwidth and bit duration product increases with the bit SNR.

So far, only the impact of bit-error probability from carrier tracking has been discussed and one can find the SNR degradation from imperfect carrier tracking, that is, $\cos^2(\phi_c)$ appears repeatedly in Eqs. (24)–(26). When the overall impact of bit-error performance from all levels of imperfect tracking, including carrier, subcarrier, and symbol, is considered, the bit-error probability becomes a threefold integration involving the

overall symbol SNR degradation given in Eq. (22). For example,

$$P_b = \int_{-\pi}^{\pi} \int_{-\pi/2}^{\pi/2} \int_{-\pi/2}^{\pi/2} \frac{1}{2} \operatorname{erfc} \left[\sqrt{\frac{E_b}{N_0} D_{\text{SNR}}(\phi_c, \phi_{sc}, \phi_{\text{sym}})} \right] p(\phi_c) p(\phi_{sc}) p(\phi_{\text{sym}}) d\phi_c d\phi_{sc} d\phi_{\text{sym}} \quad (27)$$

where $p(\phi_{sc})$ and $p(\phi_{\text{sym}})$ are Tikhonov distributed pdfs of subcarrier and symbol phase errors, respectively. In fact, $p(\phi_{sc})$ takes the form of Eq. (15) of the Costas loop and $p(\phi_{\text{sym}})$ is given by Eq. (20). Note that the product of pdfs of individual phase errors is used in lieu of the hard-to-establish joint pdf from the coupled loops.

For QPSK signals, the bit-error probability is given by (7)

$$P_b = \int_{-\pi/4}^{\pi/4} \left(\frac{1}{4} \operatorname{erfc} \left\{ \sqrt{\frac{E_b}{N_0}} [\cos(\phi_c) - \sin(\phi_c)] \right\} + \frac{1}{4} \operatorname{erfc} \left\{ \sqrt{\frac{E_b}{N_0}} [\cos(\phi_c) + \sin(\phi_c)] \right\} \right) p(\phi_c) d\phi_c \quad (28)$$

where $p(\phi_c)$ is the pdf in Eq. (17).

The telemetry system loss is defined as a loss factor $L \geq 0$ dB, which represents the amount of additional bit SNR required for a lossy system to meet the same bit-error performance of a perfectly synchronized system. For example, the bit-error probability for a perfectly synchronized BPSK or QPSK system is given by

$$P_b = \frac{1}{2} \operatorname{erfc} \left(\sqrt{\frac{E_b}{N_0}} \right) \quad (29)$$

and, therefore, the required bit SNR for this ideal system at a given bit-error probability P_b^* is expressed by

$$\left(\frac{E_b}{N_0} \right)^* = [\operatorname{erfc}^{-1}(2P_b^*)]^2 \quad (30)$$

The lossy system with a system loss L needs L times as much bit energy, namely, $E_b/N_0 = L(E_b/N_0^*)$, to achieve the same bit-error probability or, in other words, to compensate for the loss incurred within.

ADVANCED TOPICS

Antenna Arraying

With recent space missions moving toward high data rate and low transmitting power operations, combining signals from several antennas to improve the effective SNR becomes the only viable option when the existing technologies of building larger single-aperture antenna and lowering the system noise temperature are pushed to their limits.

Three arraying techniques (14) are briefly discussed here: symbol-stream combining, baseband combining and full spectrum combining, each combining signals at a different stage of signal processing.

For symbol-stream combining, each participating antenna performs carrier, subcarrier, and symbol synchronization individually. Then the symbols at each receiver output are combined, with the appropriate weights, to form the final symbols for detection or decoding. This scheme has the advantage of a small combining loss. It is also suitable for real-time combining from intercontinental antenna sites because combining is performed at a relatively low processing rate, that is, the symbol rate. The disadvantage is that each antenna needs a full set of receiver hardware and must lock on the signal individually.

In baseband combining, each antenna needs to lock on and remove the (residual) carrier by itself. Then the resulting baseband signals, including the data-modulated subcarrier, are combined for further synchronization and demodulation. The advantage of this scheme is that less hardware is required because only a single set of subcarrier and symbol tracking devices is needed to process the combined signal. The disadvantage is that each antenna still must lock on, at least, the carrier, individually.

In full spectrum combining, signals are combined at an intermediate frequency (IF). Before they are combined, the relative time delay and phase difference must be properly estimated and compensated for so that signals are coherently combined. Then the resulting IF signal is directed to a single receiver for further synchronization and demodulation. The advantage of this scheme is that only one of the participating antennas must lock on the combined IF signal, which allows including smaller antennas in this arraying scheme even though they cannot lock on the signal. The disadvantage is the very large transmission or recording bandwidth required to carry the IF signals through the networked antenna sites for combination.

Besides the above-discussed arraying techniques, a scheme called the carrier arraying, which employs coupled carrier tracking devices from participating antennas should be mentioned here. This scheme by itself does not combine the signals and, thus, must be operated with symbol-stream or baseband combining to array the telemetry. In a carrier array scenario, a large master antenna generally locks on the signal by itself and then helps other smaller antennas to track by estimating and removing the signal dynamics in their input.

Buffered Telemetry Processing

The Deep Space Communications Complex (DSCC) Galileo Telemetry (DGT) is developed and implemented by the Jet Propulsion Laboratory to support the Galileo S-Band Mission. Many advanced technologies have been developed for this mission to cope with the failure to fully deploy the high-gain antenna of the Galileo spacecraft, making itself a showcase of future signal processing technologies in the radiotelemetry field. In the following, selected key features of the DGT and the technologies behind these features are briefly described to illustrate the concept of buffered telemetry processing in which telemetry is recorded, processed, and re-processed to minimize data loss in space missions operated with low link margins.

DGT is composed of four major subsystems, the full spectrum recorder (FSR), the full spectrum combiner (FSC), the buffered telemetry demodulator (BTD), the feedback concatenated decoder (FCD), and other control functions to coordinate the operations of these subsystems. Except for the FSR, the rest of the DGT is implemented in software and can be run on general-purpose workstations, which allows greater

flexibility of signal processing without expensive custom-made hardware.

The FSR downconverts the RF signal to IF for digitization and then further open-loop downconverts each data sideband to the baseband, individually and coherently, before it is sampled and recorded. This significantly reduces the required bandwidth for transmission through the intercontinental antenna network because the processing rate is linked to the symbol rate, instead of the much higher subcarrier frequency.

The recorded signals (residual carrier and data sidebands centered at the first four harmonics of the square-wave subcarrier are kept for the Galileo S-Band Mission) from arrayed antennas are combined by the FSC, which estimates and adjusts the time delay and phase for each recorded sideband coherently to a reference point chosen as the center of the Earth, and then combines the time- and phase-aligned signals from arrayed antennas to form an enhanced signal. The combined telemetry is archived and transferred to the BTM upon request for synchronization and demodulation.

The BTM, known as the software receiver, is the signal processing core of DGT, which provides acquisition, synchronization, demodulation, and miscellaneous monitoring functions through its carrier, subcarrier, symbol-tracking loops and associated lock indicators (15). In the BTM, the individually combined data sidebands are processed coherently and then are synthesized to form an equivalent signal as if it were a single signal processed by a regular receiver. The end product of the BTM is a demodulated soft symbol stream which is written to a file and transferred to the FCD upon request for decoding and decompression.

Because the FSR/FSC combined data are recorded on tape, the BTM is actually designed to be able to work on any segment of data off-line in either direction, forward or backward in time. In fact, with the availability of multiple CPU workstations, simultaneous BTM sessions are initiated on different segments of data. For example, one session is dedicated to process real-time samples forward (in time) while the others reprocess other recorded segments as needed. Then the soft symbol streams from these simultaneous sessions are merged into a single stream because each of them is properly time tagged. By taking advantage of the flexibility in software implementation, many noncausal signal processing techniques can be performed to process or reprocess the data to further enhance the quality of the telemetry. One important feature of the BTM is the so-called gap-closure processing (16) which greatly reduces possible data loss due to receiver acquisition, resynchronization, and loss of lock.

The need to reprocess a segment of sampled data arises from the failure of the BTM to maintain the in-lock status in any of its tracking loops or the failure of the FCD to properly decode the soft symbols. A segment of sampled data on which the telemetry cannot be extracted reliably is called a gap, and the processing of a gap to extract any valid information not available when that segment of samples was first processed is called gap-closure processing. Gaps caused by acquisition are found in the beginning of each pass or at instants when the receiver drops out of lock, whereas gaps generated by cycle slips in one of the loops occur randomly in a pass. Along with its demodulation efforts, the BTM tracks its internal states, including the lock indicators, the symbol SNR estimates, and the state variables inside the loop filter and the NCO for all three loops. These state variables are recorded at fixed intervals as

checkpoints and, with them, a software receiver is easily restored to its state at a checkpoint immediately before or after a gap. By estimating the parameters of a phase process in a region near a restored checkpoint where the phase tracking was successfully carried out, gap closure processing can start from this checkpoint and move into the gap. Two configurations, one for closed-loop and the other for open-loop, are used here. The closed-loop configuration needs to initiate the loop filter with phase parameter estimates in a particular way, so that, when the loop is closed and starts to track at the checkpoint, the loop virtually starts immediately with steady state tracking. For a relatively stable phase process and a gap of small size, an open-loop configuration is applied by using an estimated phase profile as the reference without resorting to a loop operation. Both configurations are applied to gap-closure processing in either direction, forward or backward in time, because the buffered data can be processed in either order. This is especially useful when a gap occurs at the beginning of a track so that all of the available checkpoint information is from the region behind this gap.

Another useful feature of BTM is its capability of seamless tracking through symbol rate changes. The reason for changing the symbol rate during a pass is to take advantage of the changing G/T figure as the elevation angle of an antenna changes in a pass. With a higher elevation angle, an antenna has a higher G/T figure and supports a higher symbol rate when the symbol SNR is fixed. The software implementation of BTM handles symbol rate changes without dropping a lock on symbol timing, as long as the rate changes follow a set of specific rules and their schedule is roughly known in advance.

The FCD is a subsystem that performs error-correction decoding and data decompression in the DGT. Implemented in software on a multiprocessor workstation, it employs a feedback mechanism that passes intermediate decoding information from the outer code of the concatenated code to the inner code to facilitate multipass decoding which achieves a final bit error rate of 10^{-7} at a 0.65 dB bit SNR. The architecture and the detailed operations of the FCD are described in the next section.

Advanced Source and Channel Coding for Space Applications

In this section, we use the Galileo S-Band Mission again as an example to illustrate the application of advanced source and channel coding schemes to enhance telemetry return (17). First, using the integer cosine transform (ICT) for lossy image compression is briefly explained. Then, an advanced error-correction coding scheme used to protect the heavily edited and compressed data is discussed, followed by a discussion of the interaction between data compression and error-control (containment/detection/correction) processes.

Galileo's Image-Compression Scheme. Galileo image compression is a block-based lossy image-compression algorithm that uses an 8×8 ICT. The ICT was first proposed in (18), and was streamlined and generalized in (19,20). It is an integral approximation of the popular discrete cosine transform (DCT), which is regarded as one of the best transform techniques in image coding. Its independence from the source data and the availability of fast transform algorithms make the DCT an attractive candidate for many practical image processing applications. In fact, the ISO/CCITT standards for image

processing in both still-image and video transmissions include the two-dimensional DCT as a standard processing component in many applications.

The elements in an ICT matrix are small integers with sign and magnitude patterns resembling those of the DCT matrix. Besides, the rows of the ICT matrix are orthogonal. The integral property eliminates real multiplication and real addition operations, thus greatly reducing computational complexity. The orthogonality property ensures that the inverse ICT has the same transform structure as the ICT. Notice that the ICT matrix is only required to be orthogonal, but not orthonormal. However, any orthogonal matrix may be made orthonormal by multiplying it by an appropriate diagonal matrix. This operation is incorporated in the quantization (dequantization) stage of the compression (decompression), thus sparing the ICT (inverse ICT) from floating-point operations and, at the same time, preserving the same transform structure as in the floating-point DCT (inverse DCT). The relationship between the ICT and DCT guarantees efficient energy packing and allows the use of fast DCT techniques for the ICT. The ICT matrix used in the Galileo mission is given as follows:

$$\begin{bmatrix} 1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 \\ 5 & -3 & -2 & -1 & -1 & -2 & -2 & -5 \\ 3 & -1 & -1 & -3 & -3 & -1 & -1 & -3 \\ 3 & -1 & -5 & -2 & -2 & -5 & -1 & -3 \\ 1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 \\ 2 & -5 & -1 & -3 & -3 & -1 & -5 & -2 \\ 1 & -3 & -3 & -1 & -1 & -3 & -3 & -1 \\ 1 & -2 & -3 & -5 & -5 & -3 & -2 & -1 \end{bmatrix}$$

Figure 1 shows the rate-distortion performance of the ICT scheme compared with the JPEG scheme. Simulation results indicate that the difference in performance between the use of floating-point DCT and the ICT is insignificant.

Galileo's Error-Correction Coding Scheme. The Galileo error-correction coding scheme uses a (255,k) variable redundancy

Figure 1. Rate-distortion performance of ICT.

RS code as the outer code and a (14,1/4) long constraint-length convolutional code as the inner code. The RS codewords are interleaved to depth 8 in a frame. The redundancy profile of the Reed–Solomon codes is (94, 10, 30, 10, 60, 10, 30, 10). The staggered redundancy profile was designed to facilitate the novel feedback concatenated decoding strategy (21,22). This strategy allows multiple passes of channel symbols through the decoder. During each pass, the decoder uses the decoding information from the RS outer code to facilitate the Viterbi decoding of the inner code in a progressively refined manner. The FCD is implemented in software on a multiprocessor workstation. The code is expected to operate at a bit signal-to-noise ratio of 0.65 dB at a bit error rate of 10^{-7} . Figure 2 shows a schematic of the FCD architecture. In this article, only the implementation and operational aspects of the FCD task are discussed. The FCD novel node/frame synchronization scheme is discussed in (23) and its code selection and performance analysis are discussed in detail in (24).

The (255,k) Variable-Redundancy Reed–Solomon Code. All RS codes for the Galileo mission use the same representation of the finite field $GF(256)$. Precisely, $GF(256)$ is the set of elements

$$GF(256) = \{0, a^0, a^1, a^2, \dots, a^{254}\} \quad (31)$$

where a , by definition, is a root of the primitive polynomial

$$p(x) = x^8 + x^7 + x^2 + x + 1 \quad (32)$$

[i.e., $p(a) = 0$].

In the encoding/decoding process, each power of a is represented as a distinct nonzero 8-bit pattern. The zero byte is the zero element in $GF(256)$. The basis for $GF(256)$ is descending powers of a . Note that this is the conventional representation, not Berlekamp's dual basis (25). The RS generator polynomial is defined as

$$g(x) = \prod_{i=0}^{n-k-1} (x - a^{\beta(i+L)}) = \sum_{i=0}^{n-k} g_i x^i \quad (33)$$

where n denotes the codeword length in bytes, k denotes the number of information bytes, and a^b is a primitive element of $GF(256)$. The parameter b is chosen in some applications to minimize the bit-serial encoding complexity. Because the Galileo RS encoders are implemented in software, there is little advantage in preferring a particular value of b . The parameter L is chosen so that the coefficients of $g(x)$ are symmetrical. This reduces the number of Galois field multiplications in encoding by nearly a factor of 2.

The Galileo mission utilizes four distinct RS codes. We define $RS(n,k)$ as an RS code which accepts k data bytes as input and produces n bytes as a code word, where $n > k$. An $RS(n,k)$ code corrects t errors and s erasures if $2t + s \leq n - k$. These codes are referred to as $RS(255,161)$, $RS(255,195)$, $RS(255,225)$, $RS(255,245)$. Specifically, the parameters b and L of these four codes are as follows:

- $RS(255,161)$ $b = 1, L = 81$
- $RS(255,195)$ $b = 1, L = 98$
- $RS(255,225)$ $b = 1, L = 113$
- $RS(255,245)$ $b = 1, L = 123$

Figure 2. Schematic of the FCD.

These RS codes, being interleaved to depth 8, are arranged in a transfer frame as shown in Fig. 2. The RS decoders use a time-domain Euclid algorithm to correct errors and erasures. The details of the decoding algorithm are discussed in (26).

The (14,1/4) Convolutional Code and Its Parallel Viterbi Decoder. The (14,1/4) convolutional code used for the Galileo mission is the concatenation of a software (11,1/2) code and an existing hardware (7,1/2) code, which is hardwired in the Galileo Telemetry Modulation Unit (TMU), and by the processing speed of the ground FCD. The generator polynomials of the (11,1/2) code and the (7,1/2) code in octal are (3403, 2423) and (133, 171), respectively. The generator polynomials of the equivalent (14,1/4) code are (26042, 36575, 25715, 16723).

The Viterbi decoder for the (14,1/4) code is implemented in software in a multiprocessor workstation with shared memory architecture. The use of a software decoder is possible because of the slow downlink data rate of the Galileo S-Band Mission. The advantages of a software-based decoder are that the development cost is low and it allows the flexibility to perform feedback concatenated decoding. We examined two different approaches to parallelize the Viterbi algorithm: (1) state-parallel decomposition in which each processor is equally loaded to compute the add-compare-select operations per bit and (2) round-robin frame decoding that exploits the multiple processors by running several complete but independent decoders for several frames in parallel. Our early prototypes indicate that the first approach requires a substantial amount of interprocessor synchronization and communication and this greatly reduces the decoding speed. The second approach requires much less synchronization and communication because each processor is now an entity independent of the others. The performance scaling is nearly perfect. We chose the round-robin approach for the FCD Viterbi decoder. The details of the FCD software Viterbi decoder implementation are described in (27).

Redecoding. Redecoding, as shown in Fig. 2, uses information fed back from code words successfully decoded by the RS decoder to improve the performance of Viterbi decoding. A correctly decoded RS bit forces the add-compare-select operation at each state to select the path that corresponds to the correct bit. Thus the Viterbi decoder is constrained to follow only paths consistent with the correct path. The Viterbi decoder is much less likely to choose a long erroneous path because any path under consideration is pinned to coincide with the correct path at the locations of the known symbols. Each RS frame is decoded with four feedback passes. In the first pass, only the first code word RS(255,161) is decoded. In the second pass, the fifth code word RS(255,195) is decoded. In the third pass, the third and seventh code words RS(255,225) are decoded, and finally, in the fourth pass, the second, fourth, sixth, and eighth code words RS(255,245) are decoded. During each pass, the decoder uses the decoding information from the Reed-Solomon outer code to facilitate Viterbi decoding of the inner code in a progressively refined manner. The details of the FCD redecoding analysis are given in (24).

Interaction Between Data Compression and Error Control Processes. Packet loss and other uncorrectable errors in a compressed data stream cause error propagation, and the way the error propagates depends on the compression scheme. To maximize the scientific objectives with the limited transmission power of the low-gain antenna used in the Galileo S-Band Mission, most of the data (image and nonimage) are expected to be heavily edited and compressed. These valuable compressed data must be safeguarded against catastrophic error propagation caused by packet loss and other unforeseeable errors.

The ICT scheme for solid-state imaging (SSI) data is equipped with a simple but effective error-containment strategy. The idea is to insert synchronization markers and

counters at regular intervals to delimit uncompressed data into independent blocks so that, in case of packet loss and other anomalies, the decompressor searches for the next available synchronization marker and continues to decompress the rest of the data. In this case, the interval chosen is eight lines of uncompressed data. The error-containment strategy guarantees that error propagation does not go beyond the compressed code block where errors reside. Other options to prevent error propagation are also considered, but these options usually result in great onboard implementation complexity or excessive downlink overhead. For example, a self-synchronizing feature in Huffman code may be used to contain errors, but it is difficult to implement. A packetizing scheme with varying packet sizes may also be used to contain errors (by matching packet boundaries and the compressed data block boundary), but the packet headers introduce excessive downlink overhead in SSI data.

The SSI ICT error-containment scheme works as follows. On the compression side, every eight lines of data are compressed into a variable-length, compressed data block. The dc (steady-state bias) value is reset to zero at the start of each compressed data block, thus making every block independent of the others. A 25-bit synchronization marker and a 7-bit modulo counter are inserted at the beginning of every compressed data block. The sync marker is chosen to minimize the probability of false acquisition in a bursty channel environment. The 25-bit synchronization marker pattern is 024AAAB in hex. Simulation results indicate that this synchronization marker gives a probability of false acquisition of less than 10^{-8} . The decompression scheme consists of two program modules, the SSI ICT decompression module and the error detection/sync module. The SSI ICT decompression module reconstructs the data from the compressed data stream, and the error detection/sync module checks the prefix condition of the Huffman codes to detect any anomaly. When an anomaly is detected, a synchronization marker search is initiated to find the next available one. Decompression resumes from there on, and the reconstructed blocks are realigned by using the modulo counter. The corrupted portion of the data is flagged and reported.

The downlink overhead of the SSI ICT error-containment scheme is a function of compression ratio (CR) and image width W. It is measured by the percentage of sync data (sync marker and counter) compared to the compressed data and is given by the following equation:

$$\frac{4 \times \text{CR}}{8 \times W}$$

For example, an 800×800 SSI image has the following overhead as a function of the compression ratio:

Compressed Ratio	Overhead
2	0.00125
4	0.00250
8	0.00500
16	0.01000

Multiple Spacecraft Support

Traditionally, every spacecraft is supported by one of the ground antennas for its uplink and downlink. This dedication requires efficient scheduling of the resources on the ground,

including hardware, software, and personnel. With more and more concurrent missions, the need for multiple spacecraft support by a single ground antenna to alleviate the scheduling problem becomes evident. For example, several proposed future missions to Mars by various joint efforts of international space agencies will place more than a dozen spacecraft, including orbiters, landers, and rovers, on or around Mars in the next 10 years. For these missions, it is highly possible that more than one spacecraft will come within the same beam width of a single ground antenna, and it constitutes the opportunity to communicate with them by using this single antenna with a considerable amount of operational cost saving over multiple antennas. In multiple spacecraft support, a telecommand uplink from a single ground antenna will be shared by the supported spacecraft, and multiple telemetry downlinks originated from these spacecraft will also have to be established by a single ground antenna.

Several options have been studied to support this multiple spacecraft scenario (28). The most straightforward (and the most inefficient) option is to carefully assign different sub-carrier frequencies to the supported spacecraft, allowing sufficient guard band to accommodate Doppler effects and tolerating some degree of spectrum overlapping in data sidebands in exchange for more simultaneous support. This method requires very tedious planning and is extremely inflexible when facing a dynamic scenario.

Another option is to redesign the spacecraft transponder so that the coherent turnaround ratio (TAR), which specifies the uplink to downlink carrier frequency ratio, is programmable. Each supported spacecraft receives its unique TAR from the uplink commands. As a result, different spacecraft will be instructed to use different downlink carrier frequencies because their TARs are distinct. Currently, a new digital transponder, known as the Small Transponder Modem developed by the Jet Propulsion Laboratory, has such a built-in feature.

The third option is to use code division multiple access (CDMA) techniques similar to those used in commercial mobile cellular systems. CDMA offers far more simultaneous support than that of the previous two options. However, to support various types of spacecraft, the power dissimilarity problem between weak rover and strong orbiter signals has to be properly solved to avoid severe performance degradation for weaker signals. This option may be the best choice when more and more multiple spacecraft support scenarios emerge in the future.

DATA RECORDING

Data are items of information. We walk through the information superhighway. Data are all around us—weather data, sports data, stock data, sonar data from underwater objects, seismic data from an earthquake, satellite data from the Mars; one-dimensional speech data, two-dimensional image data, three-dimensional video data; analog data, and digital data; some data are natural, some are synthetic.

Data are recorded for later retrieval and use. Archeological findings are recorded to trace back the past. Current scientific findings are recorded to strive for the future. Musical data are recorded to listen at a later time on demand. So, what is data recording? Data recording refers to a system that can store data and restore it as faithfully as possible. A data recording device, therefore, involves both the storage and retrieval mechanisms. A data recording system may be viewed as shown in Fig. 1.

The source generates the raw data. Data acquisition is the process of measuring and gathering data from the source in some usable format. Acquired data are usually compressed to reduce the burden on the storage media. Each of these processes will be discussed next.

DATA ACQUISITION

As mentioned earlier, data acquisition collects data in a usable format from the data source. This usually comprises a sensor, calibrator, and/or data converter. Figure 2 shows typical components of a data acquisition system. For example, for the recording of temperature of a system, a thermocouple may be used to sense the temperature that will yield a sequence of electric potential data values. This may be followed by proper calibration and finally may need to be converted to a discrete sequence of data using an analog-to-digital converter.

Data Telemetry

When the data source is at a distance of actual storage media, then data need to be transmitted through this distance. This technique of distant measurement of data is called data telemetry. The problem here is to get the data from one point to the other without having to go and physically retrieve it. With the progress of satellite communication and Internet distribution, this is becoming a wider application area day by day. The Global Positioning System (GPS) is the most active application

Figure 1. A data recording system flow.

Figure 2. A data acquisition system flow.

area of data telemetry. The Automated Vehicle Locator (AVL), interactive monitoring and control of remote equipment and processes, stolen vehicle recovery systems, and interactive vehicle messaging systems are some of the application areas of GPS.

DATA COMPRESSION

Consider a sequence of National Television Standards Committee (NTSC) standard satellite video data. Each frame when represented in 24-bit true color takes up approximately 1 MB of storage space. With 30 frames/s, 1 min recording of the satellite data thus requires 1800 MB (1.8 GB), which is sufficient to fill the entire hard disk space of a modern day personal computer. Is there a way to reduce the size of these image data? That is what data compression is all about. Based on the requirements of reconstruction, there are two types of compression: lossy and lossless compression. Lossless compression is generally used for text, computer-generated data, and some types of image and video information. A particular application is the compression of bank account and credit information. Lossy compression, on the other hand, can tolerate some loss of information. For example, a reconstructed video image sequence from a compressed sequence may be well within the tolerance of viewer.

Lossless Compression

Lossless compression, in general, employs some coding techniques to reduce the size of data.

Coding Techniques

Huffman Coding. Consider a coding system in which the symbols that occur more frequently will have shorter-length codeword than the symbols, which are less likely to occur. The result is a variable-length coding having a smaller average code size. In the context of a 256-level gray image, each pixel is coded as an 8-bit code. Now assume that analyzing the probabilities of the gray levels, it is possible to have an average code size of 5 bits per pixel. That gives a compression ratio of 1.6.

Arithmetic Coding. This is used for shorter-codeword sources and instances in which the codewords have highly skewed probabilities.

Dictionary Coding. A popular realization of this is the LZW approach, which is a variation of the seminal work by Ziv and Lempel in 1977. A dictionary codeword is created from the patterns of the source. The codewords consist of the index, length, and symbol of a frequently used pattern. The LZW technique is used in industry standard applications as in the UNIX `compress` command, graphical image format (GIF) image coding, and the V.42 bis modem data compression.

Differential Encoding. Instead of directly encoding a source, the next data element is predicted from its neighboring elements and then the difference between the actual and

predicted model is encoded. This reduces the length of code size by reducing the dynamic range of possible values. The basic differential encoding is called differential pulse coded modulation (DPCM). DPCM attempts to minimize the variance of the predicted model and the actual values. The popular JPEG (joint photographic expert group) technique uses differential encoding for compressing image data.

Lossy Compression

Lossy compression reduces the data size with an acceptable loss of resolution of data. The technique of quantization is used in general for lossy compression, which is then followed by coding. Quantization maps a larger dynamic range of the original source into a smaller range of quantized values. The compression ratio now is a function of the levels of quantization desired, which obviously is much higher than that of lossless compression. The set of quantizer output values is called the codebook.

Coding Techniques

Differential Encoding. As in the case of lossless compression, this technique may also be used for lossy compression. Here the differentials of input values go through the process of quantization. Different variants of differential encoding exist in literature.

Subband Coding. Here, a data sequence is first decomposed into different bands or resolutions. A bit allocation technique is then used for an optimal combination of these bands. This may be used in both lossless and lossy compression. Wavelet decomposition is an example of subband coding. Different types of filters used for subband decomposition result in different types of information.

Transform Coding. The data sequence is first converted to another sequence using some transforms. Use of quantization and other compression techniques is then used in the transform domain instead of the original data domain. One of the goals of transformation is to have a smaller number of data samples that are representative of the original data sequence. This process is called decorrelating the input sequence, which means that the sample-to-sample correlation of the original data sequence is zero. The transform samples that do not contain much information are discarded. The reverse transformation is then applied on this compressed sequence for reconstruction. There are different types of transforms available, all of which are, to some extent, data dependent. The Karhunen–Loeve transform is an optimal transform in the sense that it minimizes the geometric mean of the variances of transform coefficients, thus resulting in an optimal decorrelation providing the largest coding gain of any transform coding method. The discrete cosine transform (DCT), discrete sine transform, and discrete Walsh–Hadamard transform are some of the other useful transforms.

Transform coding operate in three steps: First the transformation is applied. The second step involves quantization of the transformed sequence into the desired number of bits. Finally, some types of coding techniques such as fixed-size code, Huffman, or arithmetic coding are used. The JPEG standard is one of the most widely used techniques for lossy compression of images. It uses DCT as the transform and goes through the following steps.

1. The input image is first level-shifted. This is obtained by subtracting 2^{M-1} from the image having pixel values in the range $\{0, 2^M - 1\}$. Here, M is the number of bits used to represent each input pixel.
2. Block transformation with a block size of 8×8 using DCT is then applied on the level-shifted image.
3. Quantization on the transform coefficients is then done using a variable step size. The idea is to use a small step size for low-frequency components and a large step size for high-frequency components.
4. Huffman coding method is then applied on the quantized coefficients. Note that a large number of 0 values are obtained after the quantization process and these values do not need to be coded.

As mentioned earlier, the compression ratio really depends on the fidelity of the reconstructed image. In general, a ratio of 25:1 results in an acceptable reconstruction for typical image applications.

The MPEG (motion pictures expert group) standard, which is used for the compression of motion pictures, also uses the DCT transform. Here the next frame is predicted from the current frame. DCT is taken for the difference of a frame and its predicted frame.

DATA STORAGE

The ever-increasing demand for data storage coupled with multimedia requirements for text, image, video, and audio storage requirements is growing at an exponential rate. In practice, we encounter three main types of storage: primary or on-line, secondary or near-line, and archival or off-line memory. The range of on-line, near-line, and off-line data storage systems may consist of a variety of technologies such as magnetic tape drives, magnetic disk drives, optical tape, electron trapping optical memory (ETOM), holographic optical storage, and optical disk drives such as the compact disk read-only memory (CD-ROM), CD recordable (CD-R), digital versatile disk (DVD), and write-one read-many (WORM).

Storage Modes

Data storage may be analog or digital. The audio tape is an example of analog recording, whereas a CD is an example of digital recording. An analog signal is a continuously varying smooth signal having no discontinuity in it. A digital signal, on the other hand, consists of a sequence of discontinuous pulses. The amplitude of the digital signal is fixed, whereas the amplitude of an analog signal is a changing parameter that imposes a requirement on the dynamic range of an analog storage device. Figure 3(a) shows an analog signal along with discretization in 15 samples. Figure 3(b) shows how each discretized value is represented by using 4 bits.

Storage Media

Depending upon the media and technology used, storage devices may be classified as semiconductor storage, magnetic storage, optical storage, and magneto-optical storage.

Figure 3. (a) Analog signal and the digitization process. (b) Coding as a digital signal.

Semiconductor Storage. In a computer system, semiconductor storage is used as a faster access media, which is called primary storage. This is primarily divided into read-write memory (RWM) and read-only memory (ROM). RWM historically was called random access memory (RAM), although ROM is also random access. Random access, in contrast with sequential access of a tape, means any piece of data item can be accessed randomly without accessing other data items. RAM is volatile in the sense that its content is destroyed when the power is turned off. Depending on the technology used, RAM can be static or dynamic. Static RAM (SRAM) does not need any refreshing and is usually faster than dynamic RAM (DRAM). DRAM, on the other hand, can be made denser and is thus less costly. One variant of ROM, called programmable ROM (PROM), can be programmed only once, sometimes also referred to as one-time programmable (OTP). Erasable PROM (EPROM) can be programmed and reprogrammed many times.

The basic building block of a semiconductor storage system is called a flip-flop. Figure 4 shows the storage of 1 bit of information using a complementary metal oxide semiconductor (CMOS) SRAM cell. Note that many variations of this configuration are available, resulting in different storage

Figure 4. CMOS realization of 1-bit storage of static RAM.

capability. With the tremendous success of very-large-scale integration (VLSI) technology, semiconductor memory has become the storage device with the highest density and fastest speed. Following are some of the off-the-shelf semiconductor storage devices.

PC Cards. PC cards can be either storage or input/output (I/O) cards, which is defined by the internationally accepted Personal Computer Memory Card International Association (PCMCIA) standard. PC cards use little power and are compact, highly reliable, and lightweight, making them ideal for battery-powered notebook and palmtop computers, handheld personal digital assistants (PDAs), and personal communicator devices. Their low power, small size, and portability facilitate the use of memory cards in a wide variety of new applications, such as electronic cameras, voice recorders, portable phones, and in the area of data telemetry in general.

ROM and OTP Cards. Because the information stored on a ROM card is inseparable from the hardware, a ROM card usually is device-dependent and will not work in a computer system other than that for which it is specifically manufactured. By contrast, OTP cards are built *blank*. After manufacture, these chips can be written to with a special device. While they have the advantage of providing a form of nonvolatile storage, the biggest disadvantage is that once information is stored on the card, it cannot be altered in any way. In addition, the custom manufacturing involved in producing ROM chips makes ROM cards expensive unless produced in large quantities.

SRAM Cards. SRAM cards have an advantage over ROM and OTP cards: users can write, modify, or delete the information stored on them. However, SRAM chips are volatile. Affordable SRAM cards are available in capacities of up to 4 MB. Beyond that, the cost of SRAM is prohibitive. Therefore, SRAM cards are used primarily for low volumes of user storage.

Flash Cards. One of the latest innovations in memory cards is the use of flash memory technology. Flash cards combine the best features of both ROM/OTP and SRAM cards. Like ROM and OTP chips, flash components are nonvolatile—they retain data even without a power source. And, like SRAM, users can write, modify, or delete the information stored on them. However, use of flash memory currently is prohibitive due to cost and device capacity.

Magnetic Storage. Magnetic storage uses electromagnetism. When electric current flows through a conductor, it generates a magnetic field around that conductor. This magnetic field can influence the magnetic material in the field. When the direction of current reverses, the polarity of the magnetic field is also reversed. So, particles of the magnetic substance can be polarized magnetically in one of the two directions with an electromagnet. Thus, magnetic polarization can be used to distinguish 0 and 1. This two-way operation of electromagnetism makes it possible to record data on a disk or tape and read the data later. Magnetic disks and tapes are the two variants of magnetic storage devices.

Magnetic Disks. Magnetic disks, which were preceded by magnetic drums, are of two major types: hard disks and floppy disks. Hard disks cannot be bent or flexed—hence the term hard disk. Also, the platters of the hard disk are not removable, and for that reason it is also called a fixed disk.

Construction and Geometry. Disks consist of circular platters made of glass, plastic, or metal and coated with a magnetic

Figure 5. Magnetic disk drive components.

substance. A driver motor rotates the disk platter about its central axis. The disk drive has also head motors, which cause head rotation. Heads move radially in and out across the disk surface. Heads are connected to head motors through a moving arm. Usually there is one head per surface. Figure 5 shows the components of a typical magnetic disk drive.

Figure 6 shows the logical geometry of platters of a disk. Data are stored in concentric tracks on the surfaces of each platter. The number of tracks is an indicator of the storage capacity of the disk. Track density, which is the number of tracks per unit of radial length, is expressed in tracks per millimeter or tracks per inch. A typical disk drive can have more than 2000 tracks per inch (TPI) on its recording surface. A pair of tracks on each side of the disk with the same track number is called a cylinder. In the case of disk packs several tracks may constitute a cylinder. Each track is divided into sectors, which can store a data block. The process of organizing the disk surface into tracks and sectors is called formatting. In almost all systems, including PCs and Macintoshes, sectors typically contain 512 bytes of user data plus addressing information used by the drive electronics.

In earlier hard drive designs, the number of sectors per track was fixed, and, because the outer tracks on a platter have a

Figure 6. Logical components of a disk system.

larger circumference than the inner tracks, space on the outer tracks was wasted. The number of sectors that would fit on the innermost track constrained the number of sectors per track for the entire platter. However, many of today's advanced drives use a formatting technique called multiple zone recording that allows the number of sectors per track to be adjusted so more sectors are stored on the larger, outer tracks. By dividing the outer tracks into more sectors, data can be packed uniformly throughout the surface of a platter, disk surface is used more efficiently, and higher capacities can be achieved with fewer platters.

Read/write heads are the single most important component of a hard disk drive, and their characteristics have a great impact on drive design and performance. A head is a piece of magnetic material, formed almost in the shape of a C with a small opening or gap. A coil of wire is wound around this core to construct an electromagnet. In writing to the disk, current flowing through the coil creates a magnetic field across the gap that magnetizes the disk-coating layer under the head. In reading from the disk, the read/write head senses an electronic current pulse through the coil when the gap passes over a flux reversal on the disk.

Several different types of read/write heads exist. Among the earliest were monolithic ferrite heads or those made of a single block of ferrite, a magnetic ceramic material. An improvement on all-ferrite heads were composite heads, consisting primarily of nonmagnetic material with a small ferrite structure added. Next came metal-in-gap or (MIG) heads with very thin metal layers added inside the gap to improve magnetic performance. Currently, many drives use thin-film heads, the name of which reflects the fact that their structural elements are deposited on a substrate similar to way that microchips are manufactured. Thin-film technology allows head vendors to achieve much smaller physical dimensions and to better control the fabrication process, both of which result in higher-performance products.

Storing and Retrieving Data. The mechanism of storing and retrieving data is almost same for both the hard disk and floppy disk. The only difference is that the floppy disk has one disk platter and for this, the number of surfaces is two: the top and bottom surface of the single platter. Most hard disks contain several disk platters all mounted on the same axis.

When data are retrieved from a hard disk drive, a command is issued to open an existing file. The application program that is running prompts the user to enter the name of the file to open. It then passes the file name to the operating system, which determines where the file is located on the disk drive—the head number, cylinder, and sector identification. The operating system transfers this information to the disk controller, which drives an actuator motor connected to the actuator arm to position the heads over the correct track. As the disk rotates, the appropriate head reads the address of each sector on the track. When the desired sector appears under the read/write head, the entire contents of the sector containing the necessary data are read into the computer's main memory.

Storing data on a hard drive is a similar process to retrieving data, only reversed. The host computer operating system is responsible for remembering the addresses for each file on the disk and which sectors are available for new data. The operating system instructs the controller where to begin writing information to the disk. The controller moves the read/write

heads to the appropriate track and writing begins. When the first track is full, the heads write to the same track on successive platter surfaces. If still more track capacity is required to store all the data, the head moves to the next available track with sufficient contiguous space and writes the data there. Now let us see the encoding process involved in the read/write.

Encoding. Traditionally, drives have used analog peak-detection read channels. During a write operation, an analog peak-detection read channel converts binary, digital data into an analog signal, which the drive's read/write head uses to cause magnetic flux changes on the platter surface [Fig. 7(a)]. During a read operation, the read/write head detects the magnetic flux changes from the data and generates an analog readback signal, in the form of a wave, that it transmits to the read channel. The read channel analyzes the incoming signal to determine the high/positive peaks and low/negative peaks. Finally, it decodes each of these peaks. The limitation of analog peak-detection read channels is that, as data densities increase, the analog signal peaks start to overlap, which causes data degradation. To counter this effect, hard drives employ a data encoding scheme during write operations that separate the analog signal peaks. One of these techniques is called the partial response maximum likelihood (PRML).

With the use of sophisticated digital coding and filtering techniques, PRML read channels sample the analog signal wave at a number of points, as opposed to just at the high and low peaks, as shown in Fig. 7(b). By taking these samples, PRML read channels can determine the "shape" of the readback signal and thus can interpret the high and low peaks that represent data bits very accurately. Although using the

Figure 7. (a) Analog peak detection encoding. (b) PRML encoding.

Table 1. Comparison of Codes in Magnetic Recording

Code	Rate	Capacity	d, k	Packing Density	Detection Window	Dc ^a Free
NRZ-L	1	1	0	1	T	No
NRZ-M	1	1	0	1	T	No
E-NRZ	7/8	1	0, 13	0.875	T	No

^a Dc Free means average value is zero.

same read/write heads and media, the use of PRML technology provides a much more space-efficient error detection scheme, which yields a 25% improvement in data bit density while achieving the same, low bit error rate as analog peak detection.

Recording Codes. Numerous codes for recording are available. Table 1 shows a comparison of them. The code rate is the ratio of the number of information symbols (m) and the number of code symbols (n), $m/n \leq 1$.

The detection or sample window relates to the interval during which the recorded bit may be sampled on playback to determine its value. It is normally measured in terms of bit-cell duration T . The capacity $C = \log x$, where x is the largest root of the equation

$$F(x) = x^{k+1} - x^k - d - x + 1 = 0 \quad (1)$$

where d is the minimum number of 0s between adjacent 1s and k is the maximum number of 0s between adjacent 1s.

The density ratio (DR) is a measure of the packing density of the code: $DR = m/n(d + 1)$.

Disk Performance Specifications

Data Access Time. Access time is a measure of how long it takes to position a read/write head over a particular track and find the sectors of interest within the track for reading or writing. Thus, data access time is a combination of seek time, head switch time, and rotational latency and is measured in milliseconds.

Seek Time. The amount of time it takes the actuator arm to move the read/write head between tracks is called seek time. For a platter having N tracks on each side, moving from the current track to the next requested bit of data might entail moving just one track or up to $N - 1$ tracks. Seek time is measured in milliseconds (ms). Seek times between adjacent tracks can be as short as 2 ms, while a full-stroke seek (movement between the outer and inner track) consumes about 20 ms. The average seek time is defined as the time it takes to position the drive's read/write heads for a randomly located request and usually ranges from 8 to 14 ms.

Head Switch Time. The actuator arm moves all of the read/write heads over the platters simultaneously. However, only one of the read/write heads can be reading or writing data at a time. Head switch time measures the average time the drive takes to switch between two of the read/write heads when reading or writing data.

Rotational Latency. Once the read/write head is positioned over the proper track, it must wait for the drive to spin the platter to the correct sector. This waiting period called rotational latency, is measured in milliseconds, and is dependent on the drive's revolutions per minute (rpm). On average, the disk needs to spin half-way around before the next sector to be read or written to. Increasing the disk's rotational speed decreases this latency. However, the faster the disk rotation, the hotter the drive runs and the more wear on the drive's moving parts. Still, manufacturers are overcoming these problems, and the once universal 3600 rpm (with an average latency of 8.3 ms) is being supplanted by faster speeds like 7200 rpm (with a latency of 4.2 ms).

Data Transfer Rate. The data transfer rate depends heavily on two measures: the disk transfer rate, or how fast data are passed from the disk to the hard drive's controller, and the host transfer rate, or how fast the controller passes data to the computer's central processing unit (CPU). The data transfer rate is measured in megabytes per second (MB/s). To speed up the host transfer rate and minimize mechanical delays (from seeking and rotational latency), manufacturers have added cache buffers to the hard drive. A cache buffer built into the drive electronics provides a temporary storage space that eliminates or reduces any bottleneck in the flow of data between the disk and CPU. A cache buffer coupled with an effective caching algorithm can improve the effective data transfer between a drive and the CPU by a significant factor—often 50% to 100%.

Data Throughput Rate. Data throughput rate is a measurement reflecting both data access time and data transfer rate. It represents the total amount of data that the CPU can access in a unit of time. As such, it is a fairly comprehensive measure that factors in most of the major drive performance measurements.

Storage Capacity. Capacities are stated in two different ways: unformatted and formatted. Formatted capacity represents the real capacity, the amount of data that a user can store, while unformatted capacity represents a higher number usually used in advertisements. The unformatted capacity is the maximum number of bytes that can be recorded assuming that each track is continuously and completely recorded with 0s and 1s. The unformatted capacity of a disk is, therefore, the product of the maximum number of bytes per track times the number of tracks times the number of recordable sides. For modern modes of recording such as modified frequency modulation (MFM), one bit is represented by one flux transition. The

number of flux transitions for a track equivalent to one complete revolution, that is, 2π radian, is therefore calculated as follows:

$$\text{Flux transitions/track} = \text{flux transitions/rad} \times 2\pi = \text{bits/track}$$

The unformatted capacity C_u , of the 2-MB 3.5-in. diskette (15,916 flux transitions/rad, 80 tracks, 2 sides) is $C_u = (2\pi \times 15,916 \times 80 \times 2)/8 = 2,000,063 \text{ bytes} \approx 2 \text{ MB}$.

For a certain standardized format, the real formatted capacity is the product of the number of data bytes per sector times the number of sectors per track times the number of tracks per side times the number of sides. For the same diskette using the standardized MS-DOS format, the formatted capacity, C_r is

$$C_r = 512 \times 18 \times 80 \times 2 = 1,474,560 \text{ bytes} \approx 1.47 \text{ MB}$$

For this type of diskette the formatted capacity is about 73.7% of the unformatted capacity.

The performance of magnetic storage devices has been enhanced greatly by the emerging technologies. Two of these are mentioned below. One relates to capacity and the other to speed.

- Material improvements such as thin-film and magnetoresistive (MR) heads, have been made. Unlike current head technologies—all of which are basically tiny inductive electromagnets—MR technology uses a different material whose electrical resistance changes in the presence of a magnetic field. A small stripe of MR material is deposited on the head structure, and, as it passes over the magnetic patterns on the disk, it senses the strength of the magnetic field and creates electrical pulses corresponding to the flux reversals. This mechanism cannot be used for writing, so a conventional thin-film inductive write element is deposited alongside the MR stripe. MR head technology began to appear in drive designs in 1994, with wider acceptance and inclusion in more designs by 1995. IBM recently announced their MR-head-based disk that holds 3×10^9 bits of data per square inch.
- Seek command reordering of the disk drive is also an improvement. In the absence of command reordering techniques, the disk drive would execute the commands in the queue in the order it received them. The result is that the read/write head randomly sweeps over the surface of the platter executing each command in the queue in sequence. Command reordering minimizes this random movement of the read/write head. One technique for command reordering is called *shortest seek time-first* ordering that selects the command with the shortest seek time for the next execution. The problem with the method is that it gives higher priority to the tracks located near the middle compared to the commands requiring data from the outer and inner tracks because their seek times are usually longer. *Elevator seeking* overcomes this problem by also ordering commands such that the read/write heads move back and forth across the entire platter surface. *Optimized reordering command algorithm (ORCA)* takes command reordering one step further to calculate the optimum sequence of seeks so as to minimize the combined total of seek time as well as rotational latency. Thus it ex-

amines both the track location of the seek on the disk and the sector location of the seek on the track. Therefore, it orders the seek command tasks in a more efficient sequence, increasing the data throughput of the drive by an average of 20%.

Magnetic Tape. Commonly used on early mainframe computers, one of the first computer storage technologies was the magnetic tape drive, or simply tape drive. Magnetic tape is a sequential data storage device. To read data, a tape drive winds through a spool of tape to the exact location of the desired information. To write data, the tape drive encodes it sequentially on the tape. Because tape drives cannot randomly access or write data like disk drives and are thus much slower, they have been replaced as the primary storage device in most computer applications. However, with its high storage capabilities and low cost-to-megabyte ratio, magnetic tape is still very much in use as a storage medium for archiving large amounts of data. Recent advances in tape technology, such as faster tape drives, DLT, and digital audio tape (DAT) cartridges, have also made tape the preferred technology for backing up network servers and other critical data.

Optical Storage. Currently, optical memory devices are widely used as secondary memory in computer systems. The most widely known optical storage device is the CD-ROM, which has significantly enhanced the replication, distribution, and utilization of software, games, audio, and video intended for use in computers or in entertainment instruments. For instance, a CD-ROM containing 680 MB of data can be mass-duplicated by injection molding in a few seconds costing less than 10 cents per piece. The main attractive features of an optical data storage system are removability, portability, and reliability.

Optical Disk. An optical disk is usually constructed from a plastic or glass substrate coated by one or more thin-film layers and contains a number of tracks along which information is stored. The manufacturer may record the information on the substrate surface or it may be recorded by the user on one or more of the thin-film layers along the tracks. The storage layer is generally sandwiched between two dielectric layers and the stack is covered with a metal layer for better reflectivity. The functions of the dielectric and reflective layers include reduction of thermal cross-talk during writing, optimization of absorptivity and/or reflectivity, and protection of the storage layer.

Figure 8 shows the basic building blocks of an optical disk system. The light beam emanating from the laser is collimated and directed toward a high-numerical-aperture objective lens via a beam splitter. The objective lens focuses the light beam on the surface of the disk where information is written to or read from a given track. The light reflected from the disk surface is collected by the objective lens and directed toward one or more detectors through the beam splitter. The detector extracts the data readout signal as well as the focusing and error-tracking signals.

The main features of an optical disk are shown in the right-hand side of Fig. 8. The access window is used by the read/write head to gain access to the disk. The hub provides the mechanical interface with the drive for mounting and centering the disk on the spindle. The track shown in Fig. 8 may be concentric rings of width W_t , and adjacent tracks are separated from each other

Figure 8. Basic building blocks of an optical disk system: W_t is width of track.

by a guard band of width W_b . If the binary digits (0 and 1) are stored as transparent and opaque marks of length L_m and the entire disk surface of radius r is covered with such marks, then the capacity of the optical disk may be expressed as

$$C = \frac{\pi r^2}{(W_t + W_b)L_m} \quad (2)$$

where C is expressed in bits per surface. For a typical 5.25-in. optical disk, $r = 67$ mm, $L_m = 0.5 \mu\text{m}$ (determined by the read/write laser wavelength), and $W_t + W_b = 1 \mu\text{m}$. Then the capacity of this disk, using Eq. (2), becomes approximately equal to 3.5 GB per surface, which is pretty close to reality.

In optical disk and tape storage systems, semiconductor laser diodes, having the shortest possible wavelength that can provide enough power for read, write, and erase operations for several thousand hours, are generally used. In general, the size of the focused spot varies directly with the wavelength. Therefore, shorter-wavelength lasers can be focused to smaller spots at the diffraction limit. The diameter d of the focused spot may be expressed as

$$d \approx \frac{\lambda}{\text{NA}} = \frac{\lambda}{\sin \theta} \quad (3)$$

where NA refers to the numerical aperture of the objective lens, λ is the wavelength of light, and θ is the half angle subtended by the focused cone of light at its peak. Equation (3) implies that a higher-numerical-aperture objective lens should be used for smaller spots. But the depth of focus δ of the objective lens may be expressed as

$$\delta \approx \frac{\lambda}{(\text{NA})^2}, \quad (4)$$

insinuating that the depth of focus will be smaller for higher-

numerical-aperture objective lens. The range of NA usually varies from 0.4 to 0.6.

Optical Tape. Figure 9 shows the main components of an optical tape, which consists of a substrate onto which an active layer and a dielectric film are sputtered flanked by a back and a top coating for better reliability. The active layer usually consists of thin metallic film, dye polymer, or phase change material. Information is hole-punched (called marks) into the active layer by a focused semiconductor laser beam. For data readout, the tape is scanned by a focused laser beam and the marks cause the amplitude of the reflected light to vary. These variations are detected by a detector array to generate the appropriate data readout signal.

Figure 9. Basic building blocks of an optical tape system.

Figure 10. Basic building blocks of a volume holography storage system.

Optical tape is mainly used for high volume storage. It is so thin that staggering amounts of data can be stored in a very small volume of it. For instance, optical tape has at least 25 times the volumetric density of CDs. Although magnetic tape is economical, it is not suitable for long-term archiving because the magnetic medium is degraded by creep, track deformation, and print-through, which requires the transfer of stored information to a new magnetic tape after a given interval. Optical tape is more durable, does not suffer from print-through, and is more reliable than magnetic tape. The effective data rate for a magnetic tape is very low since the read/write process is inherently sequential. On the other hand, the effective data rate for an optical tape can be enhanced significantly by exploiting parallel read/write channels as depicted in Fig. 9.

Electron Trapping. Electron trapping optical memory (ETOM) exploits multilevel encoding through amplitude modulation, which allows it to store one of several intensity levels at a given location. For instance, if any of eight amplitude levels can be detected reliably, then 3 bits can be stored in a single location, thus tripling the storage capacity.

ETOM usually consists of an active layer of phosphorlike material coated on a substrate. To store information, the trapping material is exposed to light of one wavelength, which excites electrons into the conduction band where they are trapped. The number of electrons trapped is directly proportional to the intensity of light. To read data, the trapping material is exposed to light of another wavelength, which causes the conduction-band electrons to drop by emitting photons of a third wavelength. The number of photons emitted is proportional to the number of electrons trapped initially. Thus by counting the number of photon multiple values can be stored at a location.

The main limitations of an ETOM are that it requires a complex read/write head and three different lasers. Furthermore,

adding an extra bit for a given location requires a decibel level twice as large, thus causing the loss in signal-to-noise ratio.

Holographic Storage. Figure 10 shows the general features of a holographic data storage system. A hologram is created by recording the spatial interference pattern of two coherent beams, called the object beam and the reference beam, which are usually generated from the same laser source using a beam splitter and mirror combination. The object beam carries the information to be recorded while the reference beam is just a plane wave. The information or the data to be stored are usually a two-dimensional arrangement (called pages) of transparent and dark patterns representing binary 1s and 0s. This two-dimensional pattern is displayed in a spatial light modulator (SLM) in the data plane and modulates it onto the object beam. The object beam interacts with the reference beam in the holographic material to form a fringe pattern, which is recorded by the material, thus forming the hologram. When the hologram is illuminated with the original reference beam, it reconstructs the object beam, thus retrieving the information stored in the hologram.

As the hologram recording material becomes thicker, the reconstruction becomes particularly sensitive to the angle between the two interfering beams. Therefore, multiple holograms may be superimposed in the same volume by changing the angle of incidence of one of the beams, that is, the reference beam. This is accomplished by employing another SLM called the reference plane SLM. Each hologram can be accessed independently by using an appropriate set of reference beams.

The Bragg effect governs the diffraction from a hologram, which implies that if the reference beam is applied to the holographic medium at an angle other than that used during recording, it will not diffract the stored fringe pattern or the hologram. Therefore thousands of holograms can be recorded in a

small-volume hologram (on the order of 10^{11} bit/cm³) using a reference beam with a Bragg angle unique to each of the stored patterns. Furthermore, the page-oriented parallel access to data in a hologram offers low access times (less than 1 ms) and potentially high data rates (gigabit/s).

Magneto-Optical Storage. Magneto-optical (MO) disk systems combine the technology of traditional magnetic media, such as hard disk drives, with optical disk technology. MO technology allows users to pack hundreds of megabytes of data on a disk that looks similar to a traditional 3.5-in. floppy disk and typically comes in a 3.5- or 5.25-in. form factor. A MO disk is made out of materials that cause it to be highly resistant to magnetic fields, or coercive force, at room temperature.

A MO drive writes to the disk using a read/write head assisted by a laser. A laser heats up the disk surface to its Curie point. Then, the read/write head passes over the disk, polarizing those areas that have been heated by the laser. Because a laser can be focused on a much narrower field than a traditional, magnetic read/write head, data written on a MO disk with the assistance of a laser results in a very high data density not available with traditional hard disk drive technology. During a read operation, the MO drive uses the same laser to sense the data stored on the disk. As the laser scans the disk surface, the drive detects a reflection of light by the data bits oriented in one direction and no reflection from the data bits oriented in the opposite direction. Thus, a MO drive can distinguish between the 0 and 1 data bits stored on the disk. MO disks have many advantages:

- They provide very high data densities, achievable because of the use of a laser.
- Data can be changed at will—added, modified, or deleted.
- Data are resistant to magnetic fields. Unlike a traditional floppy or hard disk, a magnetic field alone cannot alter the data without the additional heat provided by a laser.
- Because of the use of the laser to assist in reading and writing data, the read/write head does not need to be as close to the surface of the disk as with a hard disk drive.

The disadvantage of MO technology is that, because of the high intensity of the magnetic field created with the combined use of the read/write head and laser, the drive cannot change the field polarity very quickly. Therefore, the drive must pass over the disk twice to write to it. Of course, attempts are going to compress the writing process into a single disk rotation. Thus, MO drives with one-pass writing capabilities should be available soon.

RECORDERS

Recorders are used in instrumentation and measurement to record the variations in time of some physical quantity for later analysis. This is in distinction to many audio and video recordings for which the purpose is to play back the recorded material. Recording is essential to the instrumentation, measurement,

and analysis processes, because many phenomena that must be measured occur much too rapidly to be analyzed in real time.

Modern high speed recorders share much in common with digital storage oscilloscopes. While these are often used as recorders, the emphasis in design is different. The primary design focus of the digital storage oscilloscope is convenience of capturing and displaying data to be instantly analyzed with the resolution of the eye. The primary focus in recorder design is to capture data for later analysis at potentially much higher resolution.

Important elements of any recording system are the transducers, to convert the physical quantities to be recorded into electrical signals, and the signal conditioners and instrumentation amplifiers to convert the signal to a form acceptable for recording. These elements are covered in other articles. Also covered in other articles are video recording, the medium that records the time history of two dimensional images, and data recording, the medium that records digital data. This article will be confined to a discussion of recording multiple channels of analog data that have already been converted to a voltage signal.

ANALOG-TO-DIGITAL CONVERSION IN MODERN RECORDERS

Modern recorders rely very heavily on analog to digital conversion. The signals to be recorded are converted to digital form by an analog-to-digital converter (ADC); the digital words are then recorded on media compatible with a personal computer (PC) such as magnetic disk or tape or magneto-optical or optical disk. This is generally the most economical approach, since digital data recording has become so inexpensive because of the large PC market. This approach is also very convenient, because a PC is usually the tool that will be used to analyze the recorded data. Often the recording will be done on a PC while the signal conditioning and analog to digital conversion will be on an add-in board to the PC.

IMPORTANT RECORDER CHARACTERISTICS

Sampling Rate and Bandwidth

The individual numbers stored by the recorder, which represent the amplitude of the recorded signal at a specific time, are called *samples*. The rate at which these samples are collected is called the *sampling rate* and is expressed in samples per second (Sa/s). Sampling rates of commercially available recorders vary from 1 Sa/s to 1 TSa/s (10^{12} Sa/s). Choosing an appropriate sampling rate for any particular application is important, because using too low a rate will result in loss of data while using too high a rate can add appreciably to the cost and complexity of the recorder.

The dynamic response of a recorder is usually modeled as a low pass filter followed by a perfect recorder. The frequency at which the response of this filter is 3 dB below its value at zero frequency is called the *bandwidth* of the recorder. Generally, bandwidth limitation is caused by nonidealness of all parts of the recorder between its input and (including) the ADC. Bandwidths of recorders commercially available range from 1 Hz to 10 GHz (10^{10} Hz).

Figure 1. The signal of Eq. (1) sampled at 1 kSa/s (sample points indicated by + signs.) The short pulse at $t = -10$ ms is completely missed by the sampling. However, the Fourier transform of the signal (shown in Fig. 18) and the usual “rules-of-thumb” indicate that 1 kSa/s is an adequate sampling rate.

There is a relationship between the bandwidth required to record a signal and the sampling rate required. This comes from the sampling theorem (1,2) which states (roughly) that a signal can be reconstructed from samples taken at a rate of twice the signal's bandwidth but cannot be reconstructed from samples taken at a lower rate. In practice, it is often desirable to use a higher sampling rate. If the sampling rate is ten times the bandwidth, the signal can be reconstructed quite accurately by straight line segments between the sampled values. As the sampling rate is reduced to the theoretical limit of twice the bandwidth, much more complicated approaches to interpolation must be used to reconstruct the original signal. These are covered in Refs. (2,3).

Figures 1 and 2 show the different effects of inadequate sampling rate and inadequate bandwidth. Figure 1 is the signal

$$v(t) = \frac{1}{\sqrt{2\pi\tau_1^2}} \exp[-t^2/2\tau_1^2] + .005 \frac{1}{\sqrt{2\pi\tau_2^2}} \exp[-(t+10)^2/2\tau_2^2] \quad (1)$$

where $\tau_1 = 10$ ms and $\tau_2 = 0.1$ ms. The cross marks are every 1 ms and show where the signal might be sampled with a sampling rate of 1 kSa/s. The spike at $t = -10$ ms is almost completely missed, but if the samples were offset by 0.5 ms there would be one point at the peak of the spike. Figure 2 shows the same signal after having passed through a 500 Hz bandwidth filter. The spike has become much smaller and much wider.

Figure 2. The signal of Fig. 1 filtered with a 500 Hz bandwidth low-pass filter. Only a minuscule hint of the pulse at $t = -10$ ms remains, but the 1 kSa/s sampling adequately represents the resulting signal.

Resolution and Dynamic Range

The resolution of a recorder is a measure of the precision of the digital words that are used to represent the sample values, though this terminology is not universal. Typically, the ADCs in a recorder convert the amplitudes to binary words, and the resolution is expressed as the number of bits in one of these words. If the resolution is N bits, the number of different values representable is 2^N . The resolutions of commercially available recorders range from 6 bits to 24 bits. For some lower speed recorders the ADC converts directly to a decimal number. In this case the resolution will be expressed as the number of digits in the decimal number. If the resolution is N digits, then the number of possible values is 10^N . Frequently ADCs produce 4×10^N different values; these are said to have N -and-one-half digits of resolution.

The dynamic range of a recorder is the ratio of the largest to the smallest signal magnitude that can be measured in a single record. This term has significant uncertainty in its meaning due to the lack of precision of the phrase "smallest signal magnitude that can be measured"; this will be covered in more detail later in the article. In most cases an upper bound on the dynamic range of a recorder with a resolution of N bits is 2^N . The dynamic range is frequently lower than this because of noise signals generated in the recorder that interfere with the measurement of small signals. Dynamic range is usually expressed in decibels rather than as a pure ratio.

Amplitude Accuracy

The accuracy of a recorder is a very complex subject that will be dealt with in more detail later in the article. It can depend very strongly on the signal being measured, and it can't be adequately quantified with a single number or even several numbers. However, for many recorders the accuracy is significantly poorer than the resolution and there are a few specifications that are often given which help quantify it. A fairly overall measure of the accuracy is the *effective number of bits*, N_e . This is specified for a specific frequency (or several of them) and means that the errors in recording a sinusoidal signal of that frequency are of the same size as would be made by an ideal ADC with N_e bits of resolution. Sometimes an accuracy specification is given as a percentage of full scale. This usually refers to the measurement of a direct current (dc) or very slowly varying signals.

Time Base Accuracy

For a digital recorder there are two primary measures of time base accuracy—the sampling rate accuracy and the aperture error. The sampling rate accuracy is the difference between the actual sampling rate and the nominal sampling rate. For time bases controlled by a crystal oscillator, this is usually in the range of 1 Hz/MHz to 100 Hz/MHz. The aperture error is either the maximum or the root-mean-square (rms) deviation between the time at which a sample is taken and the time the sample would have been taken if the sample spacing were perfectly uniform. The effect of aperture error on the accuracy of a sampled signal value is proportional to the rate of change of the signal. The error in amplitude units (e.g., volts) is the product of the aperture error in seconds and the slew rate of the signal in amplitude units per second.

Superior time base accuracy is one of the by-products of digital techniques of recording. When analog tape is used for recording the slippage of the tape in the rollers that propel it and variations in motor speed due to mechanical vibrations play a significant role in the accuracy of the time base. Similar problems occur in almost all analog recording mechanisms.

Output and Controls

A recorder should supply the recorded signals to the user in a form that is convenient for the analysis that is to be carried out. In most cases the analysis will be carried out (at least partially) on a PC, and means of transferring data from the recorder to the PC are essential. If the recorder is an attachment to the PC and records directly to the PC's hard disk, there is no problem. In other cases some additional means must be supplied. Some recorders have an integral floppy disk drive which allows the data transfer with no additional hardware or software. Often it is desirable to transfer data from the recorder to the PC without human intervention. If the recorder supports a common protocol, such as RS232 (a standard for data communications interfaces from the Electronics Industry Association) or the General Purpose Interface Bus (GPIB), this is facilitated. Sometimes it is necessary to transfer data faster than the aforementioned protocols allow, so another means, such as through a parallel port on the computer, must be available.

It is often necessary for the computer to be able to control the recorder. In this case the ability of the recorder to accept control commands through RS232 or GPIB is usually most practical. In complex instrumentation systems, recorders often interface to a standard bus, such as the Computer Automated Measurement and Control (CAMAC) bus or VXI (a high speed bus standard defined by the VXIbus Consortium), and transfer data and control commands through an intermediate controller on the bus.

Many recorders are able to output their data visually along with the outputs to a computer. This is typically through a cathode ray tube (CRT) or a liquid crystal display and/or on paper using a self-contained printing mechanism.

Other Characteristics

A few other characteristics that might be important in some recorder applications are listed here. The existence of differential inputs could be required and, if so, the common mode rejection ratio is of importance. If the recorder has multiple input channels, the maximum cross talk between channels is

of interest. If the input signals are not adequately limited, the over voltage recovery time is important. If the recorder does not record at its maximum rate continuously, then there are a few important characteristics: (1) the range of record lengths that can be recorded, (2) the *cycle time*, which is the required time delay between the end of one record and the beginning of the next, and (3) the *throughput*, which is the rate at which data can be continuously transferred out of the recorder while recording is taking place.

RECORDER CONFIGURATIONS

In this section various common recorder configurations will be covered with a description of the limitations and problems usually found in each configuration. This is not all inclusive, and there are variations on each configuration. In particular, the fact that certain problems and limitations are stated to exist for a particular configuration doesn't imply that designs haven't been successfully carried out to circumvent the particular limitations. For the most part, the more complex configurations are used to overcome sampling rate, bandwidth, or amplitude resolution limitations of the simpler configurations.

ADC—Permanent Recorder Configuration

This is the simplest configuration, in which the input signal passes through a buffer amplifier to an ADC, and the output of the ADC is recorded (usually with intervening buffer memory) on a permanent recording device. The permanent recording device could be hard magnetic disk, digital magnetic tape, magneto-optical disk, floppy disk, optical disk (CD-ROM or audio CD) or, for the slowest data rates, printed paper. These media are listed in order of decreasing speed. In this configuration there may be numerous channels, each with its own ADC, feeding the same recording medium.

Data can be written to PC compatible hard disks at rates of up to 100 Mbit/s. However, if one wishes to record at near the maximum rate, extra care must be taken. One must take special care with the software that is storing data on the disk; going through the Windows or Mac operating system is not likely to work. Also hard disks designated for audio/video use, which don't have lengthy temperature calibration cycles, must be used.

To get a perspective, the 100 Mbit/s rate can record 100 channels of audio with a 50 kSa/s sampling rate and a resolution of 20 bits. Digital audio workstations typically use this configuration with up to 50 channels.

Multiplexer Before ADC

This is the same configuration as the previous section with an analog multiplexer preceding the ADC. This is used for the economy gained by sharing one ADC among many (typically 16 to 64) channels. This configuration leads to potential cross talk problems from two sources. First, the settling time requirement for the ADC or the sample-and-hold preceding it is much more stringent than for single channel operation. Even when input signals are constant, with a multiplexer the input to the ADC will abruptly switch from the level of one channel to the level of another just before the second channel is to be converted. This can cause the reading of the second channel to be influenced by the amplitude of the first. The second cross talk

source is the bringing together on one chip of several analog channels.

ADC and Solid State Memory

When sampling rates are higher than can be recorded on a permanent medium, recorders typically store their data in solid state memory at a high sampling rate and transfer it to permanent memory later at a slower rate. This approach is necessary when sampling rates exceed 10 MSa/s. The sampling rates attainable with this approach are limited only by the ADC. Record lengths are limited by the amount of memory installed in the recorder. As memory densities increase and memory costs decrease, this becomes less of a limitation.

Frequently, for economic reasons, memories that have cycle times longer than that required by the sampling rate are used. The data from the ADC is sent thorough a demultiplexer and interleaved into several memories. For example, to interleave the data into three memories, the demultiplexer would send the first data value to memory number one, the second value to memory number two, the third to memory number three, and the fourth to memory number one, etc. Each memory in this example receives data at one-third the sampling rate.

This configuration is used at sampling rates up to 500 MSa/s. Currently at rates above 100 MSa/s technology limits the resolution attainable in this configuration to eight bits.

Interleaved ADCs

Several ADCs can be combined in one analog channel to increase the sampling rate. With n ADCs each sampling the same analog signal at a sampling rate of r_0 Sa/s, one adjusts the timing so that ADC $k + 1$ samples the signal at time $1/nr_0$ s after ADC k . When the data from the n ADCs are interleaved, one obtains the signal sampled at a rate of nr_0 Sa/s.

The technological problems involved in accomplishing this are larger than they appear on the surface. The sample and hold circuit preceding each ADC must have speed and bandwidth commensurate with the higher sampling rate of the interleaved system. The most difficult problem is caused by the requirement for very precisely matching the frequency response of the path from the recorder input to each ADC. This problem can best be illustrated with a hypothetical example. From results in later parts of this article one can determine that to maintain eight effective bits with an input signal of 500 MHz requires an rms uncertainty of less than 1 ps in the time any ADC samples the signal. A 1 ps delay error will result, at 500 MHz, from a 5×10^{-4} rad (0.18°) phase shift. This means that to meet the stated requirement (eight effective bits) the phase shift of each signal path must match to 5×10^{-4} rad.

Analog Memories

At sampling rates of 100 MSa/s and higher, current ADC technology limits resolution to eight bits. Figure 3 illustrates a configuration that has been used to obtain higher resolution at high sampling rates. The signal to be recorded is sampled repetitively by a sample-and-hold circuit, and these samples are recorded, temporarily, in an analog memory. After the entire record is recorded, the data is read from the analog memory at a much slower rate than at which it was recorded and stored in digital memory. Analog memories have substantial imperfections that must be corrected for before the data is delivered

Figure 3. Representation of a recorder using analog memory. The fast clock operates at the sampling rate and stores samples into the memory. The slow clock begins after recording is completed and retrieves data from the memory at a rate at which the ADC can operate. The computer makes corrections to the data to produce a representation of the input signal and controls the calibrations which allow these corrections to be made.

to the user. The advantage of these recorders can be increased signal resolution for small signals and the resulting increase in dynamic range.

The analog memories used are of two types—sequential access and random access. In both types the signal is recorded as the amount of charge on a capacitor. Random access analog memories are constructed much like Complementary Metal Oxide Semiconductor (CMOS) dynamic RAMs, except that the write circuitry stores a variable amount of charge, and the read-out circuitry generates a voltage proportional to the amount of charge stored. Sequential access memories are charge-coupled-devices (CCDs). These contain several hundred charge storage elements coupled in a linear array. When a strobe signal is given to the device, the charge stored in each element is transferred to the next element in the array. The signal to be recorded is transferred to the first element, and the readout is taken from the last element. Analog memories that are adequate for recording applications are not off-the-shelf items; they are generally proprietary devices made by the recorder manufacturers.

This approach has difficult technical problems due to the lack of idealness of the analog memories. The relationship between the charge read in to the memory and the charge read out of the memory is nonlinear and typically different for each memory element. The charge read out may also depend on the charge stored in neighboring memory elements. Recorders in

this configuration typically require extensive internal calibration to characterize the memories and extensive calculation to correct the data. These corrections are usually far from perfect. The errors remaining after the corrections have been made are roughly proportional to the instantaneous signal amplitude, and, for signals near the full scale of the recorder are often larger than would have been obtained with an ADC operating at the full sampling rate. The advantage is potentially lower noise at small signal levels.

Sampling Oscilloscope

If the signal to be recorded can be produced repetitively, it can be recorded with a sampling oscilloscope. Sampling oscilloscopes have bandwidths of up to 50 GHz and unlimited sampling rates. They take one sample on the signal for each occurrence of the signal. Figure 4 shows the functioning of a sampling oscilloscope simplified form. A trigger signal that is synchronized with the signal must be available. To capture the leading edge of the signal, it must occur before the signal. The trigger signal starts a variable delay circuit. At the end of the programmed delay time the sample-and-hold is strobed. The voltage stored by the sample-and-hold circuit is digitized and the value is stored as the amplitude value of the signal. The corresponding time value is that which was programmed

Figure 4. Representation of a sampling oscilloscope. The sample-and-hold produces a pulse whose amplitude is proportional to the signal at the time of the strobe signal. This pulse is stretched to be long enough for its amplitude to be measured by the ADC. One recorded data point is produced for each pair of synchronized input and trigger signals.

Figure 5. Representation of a recorder using many copies of sampling oscilloscope circuitry to record a single transient.

into the variable delay. The time delay is incremented by the reciprocal of the desired sampling rate, and the next sample is taken. Programming the variable delay to N different delay values gives N samples of the signal at different times. This approach is referred to as *equivalent time sampling*, because the differences in the time values associated with successive samples are not the actual time differences between when the samples were taken but represent equivalent time differences relative to the signal.

The subsystems that make up a modern sampling oscilloscope are very specialized systems. The sample-and-hold circuit must be precisely constructed out of components specifically designed for the purpose. To obtain good linearity, the sample-and-hold usually measures the difference between the applied signal and a feedback signal. The feedback signal is an estimated value of the applied signal. To obtain high accuracy with reasonably long delays, the programmable variable delay is typically an elaborate subsystem.

Multiple Samplers

One can construct recorders that use the very high bandwidth sample-and-hold circuitry of the sampling oscilloscope and record single transients. This is illustrated in Fig. 5 and in Ref. 4. This approach requires one sample-and-hold for each sample of the signal; such recorders have been made which take from 20 to 100 samples. Both the signal to be measured and the strobe signals must be distributed to each of the sample-and-hold circuits. The strobe signal must be delayed to each sample-and-hold taking into account the time, relative to the

trigger signal, that the sample is to be taken and the delay time of the signal to the particular sample-and-hold.

The construction of this type of recorder has all the problems covered earlier for interleaved ADCs, but on a larger scale. The signal must be routed to a large number of distinct circuits while maintaining the same frequency response on each path. Since this type of system is used for extremely high bandwidth, the tolerances on the matching of frequency responses (in particular phase shifts) are very tight.

Equivalent Time Sampling

The sampling oscilloscope is the simplest example of using equivalent time sampling to obtain higher sampling rates for repetitive signals. The same principal can be applied to increasing the effective sampling rate of recorders based on real time digitization. This works much the same as the sampling oscilloscope illustrated in Fig. 4, except that the trigger signal causes the recorder to sample the signal at the rate r_1 rather than to take only one sample. To increase the effective sampling rate by a factor of n , $n - 1$ additional trigger signals cause the recorder to take records delayed, with respect to the repetitive signal, by amounts of k/r_1 . This is illustrated, for $n = 4$, in Fig. 6. This approach is frequently used in digital storage oscilloscopes.

Although equivalent time sampling is applicable to any of the recording methods that have been covered in this article, it is not a trivial matter to add it to a recorder. It requires, with an exception described shortly, synchronization between the sampling times and the repetitions of the signal being measured. This is problematic if the sampling times are derived from a

Figure 6. A step signal as recorded using interleaving. Points using the same symbol are recorded with the same ADC. This example shows four interleaved channels.

crystal oscillator. One means of solving this problem is called *random equivalent time sampling*, in which the phase relationship between the trigger signal and the sampling clock is made random, and the time is measured (rather than controlled) between the trigger signal and the first sampling time after the trigger. The time value associated with j th amplitude value of the i th record is then given by $t_{ij} = t_0 + j/r_1 - \tau_i$, where t_0 is a constant and τ_i is the measured time between the trigger and the first sampling point. This approach does not give uniform sampling.

Traveling Wave Cathode Ray Tube

The cathode ray oscilloscope has been one of the highest bandwidth recording devices for decades and remains so today. Modern recorders that use a cathode ray tube (CRT) as the recording device have bandwidths in excess of 5 GHz. An advantage of CRT recorders, besides the very high bandwidth, is their ability to withstand input signals hundreds of times their full scale signal range without damage. Historically, the cathode ray oscilloscope has been converted from a display device to a recording device by attaching a camera to record the display on the face of the CRT on film. Film recording was then replaced by an electronic camera whose output was digitized to form a digital recording of the two dimensional image of the CRT. In some modern CRT recorders the phosphorous face, which converts the electron beam to light, is omitted. Instead, the electron beam writes directly onto a CCD array. The CCD array is read out and the image digitized for analysis. The image is analyzed to produce a record of time-volts pairs.

A traveling wave deflection structure is used on the vertical axis to obtain the extremely high bandwidths that give the CRT an advantage over an ADC. In a traveling wave deflection structure the potential difference to be recorded travels as a wave along the deflection structure at the same speed and in the same direction as the electron beam to be deflected. The speed of the electron beam is typically around one-tenth the speed of light. Why use a traveling wave structure? The angle of deflection of the electron beam is proportional to the time an individual electron in the beam remains in the deflection structure. This time must be several nanoseconds to obtain adequate deflection. With a conventional deflection structure, the transition duration of a recorded step signal will be, approximately, the time it takes an electron to traverse the deflection plate. This limits the bandwidth to 100 MHz or so. With a traveling wave structure the transition duration can be reduced by a factor of 100.

Figure 7. Each circle represents the electron beam striking the face of the CRT corresponding to one time point on the signal. The vertical line represents the scan line of the read out for the time corresponding to the shaded circle. It passes through several circles causing the y-coordinate of the output to be an average of the beam from different times. This results in an effective bandwidth reduction due to the beam size. This phenomenon is not taken into account when reporting the bandwidth of the recorder.

The errors produced by CRT recorders are generally much larger than one might predict from the published specifications. This is because of limitations inherent in the use of electron beams. Typical specifications might be: bandwidth, 5 GHz; vertical resolution, 11 bits; sweep lengths, from 1 ns to 1 ms; number of data points per record, 1000.

With a record length of 1000 samples, the sampling rate = $1000/(\text{sweep length})$. The useful sampling rate is typically an order of magnitude or more lower than this, because of the nonzero spot size of the electron beam. The useful sampling rate is obtained by replacing the number 1000 with the number of electron beam radii that fit along the time axis of the writing area of the CRT. This is because signal samples taken at a higher rate than this will interfere with each other, as illustrated in Fig. 7. The figure understates the magnitude of the problem, because the density of sample points per beam radius is likely larger than shown. Figure 8 illustrates the distortion that occurs because of the nonzero beam size. The peak of the pulse is recorded lower than the true value, because points more than one beam radius below the peak are written on by the beam on the rising and falling edges of the pulse. In the illustration it is assumed that the recorded signal will be halfway between the lower and upper edge of the trace; in actual practice the situation is usually worse than this. The trace will be more intense below the peak than above it, because the beam hits points below the peak twice—once on its way up, and once on its way down. This causes the recorded signal to be even lower than in the figure.

Another type of distortion peculiar to CRT recorders is called *wide-narrow distortion*, which is illustrated in Fig. 9. The input signal is a pure sine-wave. The recorded signal at the left of the display is wider than it should be at the positive peaks and narrower than it should be at the negative peaks. This gradually shifts to the opposite, narrow at positive peaks and wide at negative peaks, on the right side. This problem is inherent in the traveling wave structure. When the signal increases

Figure 8. Illustration of the signal distortion which can be caused by the nonzero size of the electron beam in a CRT based recorder. The upper and lower envelopes are determined by having a perfectly circular beam traverse the signal. The read out is taken by scanning the beam vertically and calculating an estimate of the center of the trace. When the display has significant curvature, the center of the trace does not coincide with the signal.

rapidly with time, the voltage across the deflection structure decreases rapidly in the direction of beam travel. This decelerates the electron beam, which effects its deflection in the time direction.

The amplitude resolution of 11 or more bits typically advertised for CRT recorders is misleading. Amplitude values are typically obtained by analyzing the recorded beam intensity profile along a vertical slice (constant time) and calculating the

Figure 9. A display demonstrating “wide-narrow” distortion of traveling wave CRTs. The applied sine wave has wide positive peaks and narrow negative peaks on the left, wide negative peaks and narrow positive ones on the right and is relatively undistorted in the center. This phenomenon distorts the recorded width of narrow pulses.

Figure 10. Top view illustration of a streak camera based recorder. Each channel is a dot of light on the photo cathode. The dots are arranged in straight line vertically. Electrons are emitted from each location on the photo cathode in a number proportional to the instantaneous light intensity. After multiplication the electron stream is deflected on the horizontal axis and recorded in the same manner as in a CRT.

centroid (or some closely related measure of the center of the trace) and relating this to a voltage value. The precision specified is usually the precision to which this calculation is rounded. The actual precision of the resulting data is close to seven bits in current commercially available recorders.

Streak Camera

A streak camera has several similarities to a CRT. Information is recorded by an electron beam striking a phosphor face. The image on the face is digitized and analyzed to determine the amplitude versus time of the recorded signal(s). The time information is obtained, as with a CRT, by sweeping the beam across the face of the *streak tube*. The amplitude information, however, is encoded in the intensity of the beam. The signals to be recorded must be converted to light whose intensity is proportional to the amplitude of the signal. The light strikes a photo-cathode that emits a number of electrons proportional to its intensity. The electron beam is amplified and swept across the face of the tube; see Fig. 10. About 20 channels can be recorded simultaneously on a streak camera. The light for each channel is placed at a different location along the vertical axis of the photo-cathode. The data for each channel is one horizontal streak across the face of the tube.

The conversion of light to electrons at the photo-cathode is nearly instantaneous, yielding potential bandwidths in excess of 20 GHz. It is often the case in making very high bandwidth recordings that the signals to be recorded are converted to light to be transmitted to the recording station by fiber-optic cable, thus eliminating the high frequency skin effect loss of coaxial cable. In such situations the streak camera is an especially suitable recorder.

RECORDER ERROR MEASURES

One of the most important features of a recorder is the accuracy with which it records. This is a complex subject, because the errors are usually signal dependent. A number of measures of recorder accuracy and test methods for determining them have been established over the years and are described in this article. Most of those described are covered in Refs. 5 and 6; others are covered in Ref. 7.

The errors made by a recorder are often classified as either *static errors* or *dynamic errors*. Static errors are those that are

evident in recording DC or very slowly varying signals; dynamic errors are those that are frequency dependent and typically disappear at low frequencies. Sometimes the classification is not clear and is made somewhat arbitrarily. Static errors will be covered first, followed by dynamic errors.

Sine Wave Tests

Sine wave tests are among the most useful tools for evaluating recorder errors. A sinusoidal signal of specified amplitude and frequency is recorded yielding a sequence (t_i, y_i) of time-amplitude pairs. One then performs a least squares fit to the data by determining values of A_0 , B_0 , C_0 , and ω_0 that minimize

$$\sum_{i=1}^M [y_i - A_0 \cos(\omega_0 t_i) - B_0 \sin(\omega_0 t_i) - C_0]^2 \quad (2)$$

where M is the number of data values used in the analysis. Details on the calculation of the unknown parameters can be found in Ref. 5. Once the coefficients are determined the *residuals* are given by

$$r_i = y_i - A_0 \cos(\omega_0 t_i) - B_0 \sin(\omega_0 t_i) - C_0 \quad (3)$$

The residuals are a good approximation to a significant portion of the errors in the recording process. They can be analyzed in either the time domain or the frequency domain (Refs. (5,6,7,8) and the following sections of this article) to give useful information. Of particular interest is the rms value of the residuals, σ_r , given by

$$\sigma_r^2 = \frac{1}{M} \sum_{i=1}^M r_i^2 \quad (4)$$

Since the amplitude, phase, frequency, and dc offset of the input signal are estimated from the data, they don't have to be accurately known to perform sine wave tests. For the same reason, the frequency response of the cabling connecting the sinusoidal signal source to the recorder, and of the recorder itself, is not an important factor in sine wave tests.

If the frequency of the test signal is chosen so that an integer number of cycles occur in one record length, that is,

$$f = \frac{J}{M} f_s \quad (5)$$

where f is the frequency of the test signal, f_s is the sampling rate, and J is an integer, then the least squares Eq. (2) can be solved by taking the discrete Fourier transform of the data. The constant C_0 is the 0 frequency term in the DFT; A_0 and B_0 can be derived from the two terms at the frequency, f , and all other terms in the DFT represent the residuals.

There are two main reasons for the prevalence of the use of sine waves in evaluating recorder errors. The first is that sine waves can be produced with very high accuracy; their purity can be measured to even higher accuracy with a spectrum analyzer, and their purity can be improved on by the use of filters. Current technology doesn't permit the economic production of signals of other shapes that are known to the accuracy we expect of many recorders. The second reason for the prevalence of sine waves in this application is they allow one to ignore the frequency response effects of the recorder and the test setup.

Quantization Error

Quantization error is an attribute of analog to digital converters. It arises from the finite number of output values that can be produced by an ADC. Figure 11 is a plot of the output of an ADC versus the input voltage. Each interval of input voltages over which the output code remains constant is called a *code bin*. The difference between the voltage at the right edge of a code bin and the voltage at the left edge is called the *code bin width*. Ideally, the code bin width is a constant, Q . The voltage value assigned to a particular output code is assumed to be the value at the center of the code bin. The difference between the input voltage and the assigned voltage is called the *quantization error*. If the input voltage is equally likely to be any value in the range of the ADC, then the quantization error is equally likely to be any value between $-Q/2$ and $+Q/2$. In this case the average quantization error is zero and the rms quantization error is given by

$$\text{rms quantization error} = \sqrt{\int_{-Q/2}^{+Q/2} \frac{x^2 dx}{Q}} = \frac{Q}{\sqrt{12}} \quad (6)$$

Although the quantization error is a deterministic nonlinearity in the transfer function, it is frequently referred to as

Figure 11. The stair step transfer function of an ADC.

quantization noise. In many cases the sequence of values of the quantization error is most practically analyzed as white noise with an rms value given by (6).

Gain and Offset Errors

If one thinks of a recorder as an amplifier followed by an ideal recorder, then the gain and offset errors are the deviations of the amplifier gain and offset from their nominal values. There are different means of measuring these errors that yield slightly different results. For a sequence of ordered pairs (v_i, v_r) , where v_i is an input voltage and v_r is the corresponding recorded voltage, the gain and offset are defined by the following relation,

$$v_i = Gv_r + v_0 + \epsilon \quad (7)$$

where G is the gain, v_0 is the offset error, and ϵ is the error (different for each value of v_i). The values for v_r in this equation are already corrected for the nominal gain and offset of the recorder; thus, if the recorder were ideal, we would have $G = 1$ and $v_0 = 0$. Values of G and v_0 are determined by fitting a straight line to the (v_i, v_r) pairs. Different means of fitting the line will yield different values. Values for v_i should be selected so that quantization error has negligible effect on the results. Values of v_r should be obtained by averaging so that random noise has negligible effect on the results. The *gain error* is $G - 1$ and is usually expressed as a percentage. The offset error is expressed in input units (e.g., volts).

The gain and offset errors are treated separately from other errors, because they are often larger than other errors. If necessary, the gain and offset errors can be corrected for by using the results of recording two known voltages.

Dynamic Range and Noise

The use of the terms dynamic range and noise is not totally consistent in the industry, reference (9). The most commonly used definition for dynamic range for recorders is

$$\text{dynamic range} = 20 \log \frac{\text{maximum rms signal}}{\text{rms noise}} \text{ dB} \quad (8)$$

Both the numerator and denominator in Eq. (8) are subject to multiple interpretations. The numerator is usually taken to mean the maximum rms sine wave which, for a recorder that covers the voltage range of from $-A$ to A , is $A/\sqrt{2}$. The denominator is usually taken to be the sum (in quadrature) of the noise present with no signal and the quantization noise. This quadrature combination is accurately approximated by the rms residuals from a sine wave test with a low amplitude ($5Q$ to $20Q$) input signal. For audio recorders the rms noise is often calculated with a frequency domain weighting (A weighting) based on the sensitivity of human hearing to low level sounds (11). For an ideal N bit digital recorder, one in which the only source of noise is quantization noise, the dynamic range is given by

$$\text{maximum dynamic range} = 6.02N + 1.76 \text{ dB} \quad (9)$$

Table 1 gives the dynamic range from Eq. (9) for typical values of N .

Table 1. Maximum Attainable Dynamic Range as a Function of Number of Bits

Number of Bits	Maximum Dynamic Range (dB)
6	38
8	50
10	62
12	74

Integral Nonlinearity

The concept of integral nonlinearity (INL), as it has been used for decades, is illustrated in Fig. 12. The curve represents the voltage reported by the recorder as a function of the applied voltage. The straight line represents a best fit to this curve. The INL is the maximum difference between the curve and the straight line. The difference is typically expressed as a percentage of full scale for analog instruments.

For recorders that use an ADC the situation is a little more complicated. As seen in Fig. 11, the ideal curve for an ADC is a stair step rather than a straight line. The stair step necessarily differs from the straight line by $\pm Q/2$. This difference is not considered part of the integral non linearity. For an ADC only the values of the transition levels, the values of input signal for which the output jumps from one code to the next, are considered. The INL is the maximum difference between any transition level and its ideal value. Determining the INL for an ADC based recorder requires determining the transition levels. This is a lengthy process covered in Refs. (5,6,7). If the recorder has a noise level significantly larger than the quantization noise, the INL can be estimated without determining the transition levels. Points on the curve of Fig. 12 can be measured by recording the average outputs to known arbitrary inputs. This works,

Figure 12. Illustration of INL as defined for analog instruments. The curved line is the dc transfer function of the instrument. Its maximum deviation from a straight line (occurring at four different places in this figure) is the integral nonlinearity.

Table 2. Improvement in Analog INL Due to Noise

σ/Q	INL
0	.5
.01	.48
.02	.47
.05	.38
.1	.29
.2	.14
.3	.054
.5	2.2×10^{-3}
.6	2.5×10^{-4}
.7	2.0×10^{-5}

because the noise straightens out the stair step in the average measurements. Table 2 gives the amount of apparent INL caused by the stair step as a function of the rms noise divided by Q .

Differential Nonlinearity

The concept of differential nonlinearity (DNL), like integral nonlinearity, has been used for decades in analog instrumentation. It is defined in terms of the derivative of the recorded voltage with respect to the input voltage, and is a measure of how much this derivative deviates from a constant. Letting

$$S_M = \max \left[\frac{dv_r}{dv_i} \right], \quad \text{and } S_m = \min \left[\frac{dv_r}{dv_i} \right]$$

DNL is defined as

$$\text{DNL} = 200 \frac{S_M - S_m}{S_M + S_m} \% \quad (10)$$

This is illustrated in Fig. 13, which is the derivative of the transfer function in Fig. 12.

For ADC based recorders the derivative of the stair step like ideal transfer function jumps between zero and infinity, and Eq. (10) is not appropriate. A perfectly linear ADC is one for which all code bin widths are constant. DNL for an ADC is the following measure of the maximum deviation of any code bin

Figure 13. Illustration of DNL for an analog instrument. The curve is the derivative of that in Fig. 12.

width from a constant

$$\text{DNL} = \max \left| \frac{W(k) - Q'}{Q'} \right| \quad (11)$$

where $W(k)$ is the width of the k th code bin, and Q' is the average code bin width. The unit typically supplied with this measure is lsb (for least significant bit), while “code bin width” would be a more grammatically correct unit. For ADCs whose noise level is larger than their code bin width, DNL is not a very useful specification.

Frequency Response

The frequency response characterizes the error that is usually the dominant dynamic error of a recorder. Use of a frequency response to characterize a system is only valid if the system is linear and time invariant (2). This is a good approximation for most high quality recorders. One can imagine the recorder as a linear time invariant filter followed by blocks that produce all of the other sources of error of the recorder. For signals for which the errors are small ($<10\%$), the order of the blocks has a second order effect on the overall error. The error produced by the equivalent filter at the input of the recorder is the *frequency response error*. Keep in mind that the frequency response error may actually be caused by limitations in several parts of the recorder; placing the problem in a single filter is just a mathematical convenience.

The quantity of most interest is actually the *impulse response*, $h(t)$, of the recorder. If $x(t)$ is the input signal to be recorded, the recorded signal (accounting only for frequency response errors) is given by

$$r(t) = \int_{-\infty}^{\infty} x(t-t')h(t') dt' \quad (12)$$

The integral in Eq. (12) is called the *convolution integral*. It allows one to calculate the recorded signal for any input signal, and thus estimate the frequency response error—the difference between $r(t)$ and $x(t)$. This error depends on the signal being recorded.

The frequency response is the Fourier transform of the impulse response,

$$H(f) = \int_{-\infty}^{\infty} h(t) \exp(-j2\pi ft) dt \quad (13)$$

The complex frequency response is usually expressed as a gain, $G(f)$, and a phase shift, $\phi(f)$, both of which are real valued and are related to $H(f)$ by

$$H(f) = G(f) \exp[j\phi(f)] \quad (14)$$

These are the gain and phase shift observed when recording a sinusoidal signal of frequency, f . In both Eqs. (13) and (14) j is the imaginary unit. For an ideal recorder (one with no frequency response error) $G(f)$ will be unity for all f , and $\phi(f)$ will be a linear function of f .

Typically the specifications for a recorder will give a lower and upper frequency between which $G(f)$ is within a certain tolerance of unity. This tolerance is usually 3 dB, but sometimes 1 dB is used. One should bear in mind that with a tolerance of 3 dB (1 dB) this specification only gives a range of frequencies

for which the gain error is less than 30% (11%), and tells nothing about phase shift errors. If one needs to record signals to better accuracy than these tolerances, more detail concerning the frequency response error is required. A convenient approach (5) is to determine the gain error and non-linear phase error as a function of frequency. The gain error is $|1 - G(f)|$, and is expressed as a percentage. The nonlinear phase error is the phase shift with a straight line subtracted, usually the line that passes through the origin and passes through the phase shift curve at a phase of $\pi/2$ rad (45°).

Measuring the Frequency Response. The most common method for measuring the frequency response of a recorder is to record the step response, numerically differentiate it (using a simple first difference) to determine the impulse response, and calculate the frequency response by taking the discrete Fourier transform of the result. The step response is recorded rather than the impulse response for a number of reasons. It gives more accurate results at low frequencies at which accuracy is most desired; it is less subject to aliasing errors than the impulse response (12), and the amplitude of the recorded step response is more easily predictable. Other types of signals are used to determine the frequency responses of systems (13), but they have not found wide acceptance in recorders.

If one only wants crude information about the frequency response, the results of sine wave tests can be used. This can determine if the gain error at certain frequencies is less some tolerance. The ratio of the fitted amplitude of the sine wave to the known input amplitude is the gain at the frequency of the test signal.

Step Response

Frequently, characteristics of the step response of a recorder are used as quality measures. These include the settling time, the amount of overshoot and the 10 to 90% transition duration (or rise time). The *settling time* is the amount of time it takes the step response to stabilize to within a certain tolerance of its final value. For example, a specification that the settling time is $5 \mu\text{s}$ to 0.1% means that for any time later than $5 \mu\text{s}$ after the onset of the step, the recorded value stays within 0.1% of its final value. Settling time is frequently the only dynamic specification that relates to precision measurements. The amount of overshoot is zero unless the value of the step response exceeds its final value at some time. Otherwise, the overshoot is the difference between the peak value of the step response and the final value, expressed as a percentage of the final value. Sometimes an overshoot specification will be contingent on the 10 to 90% transition duration of the input signal being longer than some specified value. The settling time and overshoot are illustrated in Fig. 14.

The 10 to 90% transition duration is a crude measure, as is the 3 dB bandwidth, of the response time of the recorder. Two step responses can have the same rise time and have much different distorting effects on a signal. To seriously estimate dynamic errors one should have a complete step response record and use the convolution integral to estimate distortion. Software to do the calculation is readily available.

Noise and Distortion

The sine wave tests described earlier can be used to measure the combined effect of many error sources. The error sources

Figure 14. An pictorial example illustrating the definitions of settling time and overshoot.

left out are gain and offset errors, frequency response errors, and errors associated with uncertainties in trigger delay. Most other sources of error will show up in sine wave tests. In fact, one of the advantages of these tests is that they expose sources of error that aren't even known to the tester.

Signal to Noise Ratio, Effective Bits and Dynamic Range. Of greatest utility is the rms value of the residuals, given by Eq. (4). This is referred to as the total *noise and distortion*, and will usually depend of both the amplitude and frequency of the applied signal. The noise and distortion is often referred to as simply the noise. A related quantity is the *signal to noise ratio* (SNR), given by

$$\text{SNR} = 20 \log \left(\frac{A}{\sigma_r} \right) \text{ dB} \quad (15)$$

where A is the rms amplitude of the applied signal, and σ_r is the rms value of the residuals. The amplitude is selected so that the signal covers nearly the entire range of the recorder. Such signals are called *large amplitude* signals. The SNR looks very much like the dynamic range, given by Eq. (8). They are both the ratios (in decibels) of the rms amplitude of a large sine wave divided by the rms value of the noise. There is, however, a significant difference. For SNR, the noise used in the ratio is the noise that occurs in the presence of the large signal. For dynamic range it is the noise in the presence of a small signal.

Another commonly used related quantity is the *effective bits*, E , given by

$$E = \log_2 \left(\frac{V}{\sqrt{12}\sigma_r} \right) \text{ bits} \quad (16)$$

where V is the full scale range of the recorder (maximum recordable voltage minus minimum recordable voltage). If the only source of noise were quantization noise, then $E = N$, the number of bits. The number of effective bits is reduced by one for each doubling of the rms noise. The SNR and the effective bits are related by,

$$\text{SNR} = 6.02E + 1.76 + 20 \log \left(\frac{2A}{V} \right) \text{ dB} \quad (17)$$

For large amplitude signals (>90 % of full scale) the last term

is between -0.9 and 0 . If E_0 is the effective bits measured for a very small input signal, the dynamic range is given by (see Eq. 9)

$$\text{dynamic range} = 6.02E_0 + 1.76 \text{ dB} \quad (18)$$

Time Errors Versus Amplitude Errors

One can separate errors on the time axis from errors on the voltage axis by examining the variation in effective bits with frequency. If one assumes errors τ_i on the time axis and e_i on the voltage axis that are independent of each other and independent of the signal, then the recorded signal for sinusoidal input is

$$\begin{aligned} y(t_i) &= A \sin(2\pi f t_i + \tau_i) + e_i \\ &\cong A \sin(2\pi f t_i) + e_i + 2\pi A f \tau_i \cos(2\pi f t_i) \end{aligned} \quad (19)$$

where τ_i is the i th discrete sampling time, and the error induced on the voltage axis by that on the time axis is estimated using a first order Taylor expansion of the sin function. The second and third terms are a very good approximation to the residuals. This gives for the rms residuals

$$\sigma_r^2 = \sigma_e^2 + 2\pi^2 f^2 A^2 \sigma_\tau^2 \quad (20)$$

where σ_e and σ_τ are the rms values of e_i and t_i . The first term dominates at low frequencies, the second term at high frequencies. Figure 15 shows this converted to effective bits and plotted against frequency on a logarithmic scale. At low frequencies this is constant; at high frequencies it has a slope of -1 bit per octave. The time component of the error can be determined from the frequency f_B at which the two lines intersect by the relation

$$\sigma_\tau = \frac{\sigma_e}{\sqrt{2\pi} f_B A} \quad (21)$$

where σ_e is the rms value of the residuals at low frequency.

Figure 15. Effective bits versus frequency for a combination of amplitude errors and time errors. The time errors cause the 1 bit per octave roll off at high frequency. The frequency, f_B of the intersection of the two straight lines can be used in equation 21 to estimate the rms value of the time errors.

Harmonic Distortion. If the recorded signal resulting from an applied sine wave contains frequencies that are multiples of the applied frequency, the recorder is said to have harmonic distortion. Harmonic distortion is a consequence of nonlinearity. For a static nonlinearity for which the recorded signal, $v_r(t)$, is given by $v_r(t) = f(v_i(t))$, there is a direct relation between the function, f , and the harmonic distortion. If f is a polynomial of degree n , then there will be harmonic distortion up to order n . If a signal of the form $v_i(t) = A \cos(\omega t)$ is applied, and we let $f_A(x) = f(x/A)$ and expand $f_A(x)$ as

$$f_A(x) = \sum_{k=0}^n a_k T_k(x) \quad (22)$$

where the $T_k(x)$ are the Chebychev polynomials (13,14), then the recorded signal has the form

$$v_r(t) = A \sum_{k=0}^n a_k \cos(k\omega t) \quad (23)$$

Harmonic distortion is specified as a ratio of the combined rms value of the harmonics to the rms value at the signal frequency. The ratio is expressed either as a percentage or in dB. The units used when expressing it in dB are dBc, meaning decibels relative to the carrier. For the example of Eq. (23) we have

$$\text{harmonic distortion} = 10 \log \left[\frac{\sum_{k=2}^n a_k^2}{a_1^2} \right] \text{ dBc} \quad (24)$$

Harmonic distortion typically increases with amplitude and is usually measured with large amplitude signals.

The source of harmonic distortion described previously is closely related to INL, a static nonlinearity, and is, therefore, independent of the frequency of the applied signal. Harmonic distortion can result from dynamic nonlinearity and be frequency dependent. A typical example of a dynamic nonlinearity is a time delay that is proportional to the slew rate of the signal, that is, $v_r(t) = v_i(t - \tau)$, where $\tau = \epsilon(dv_i/dt)$. Estimating the time delay effect by first order expansion as for Eq. (19) gives

$$v_r(t) = v_i(t) - \epsilon(dv_i/dt)^2 \quad (25)$$

Substituting a sinusoidal signal for $v_i(t)$, one obtains second harmonic distortion which is proportional to the signal's amplitude squared and to its frequency squared.

Harmonic distortion is most conveniently measured by performing a sine wave test and calculating the DFT of the recorded signal. The record length must be an integer number of cycles of the applied signal (see Eq. 5) and a large signal should be used. The DFT values are converted to decibels and the dB value for the applied frequency is subtracted from all of the values. This gives harmonic distortion readings directly in dBc. Figure 16 shows a simulated example result. The recorder sampling rate is 2 units, and the record length for the DFT is 1024 points. The input signal was full scale in amplitude with a frequency of 0.2012. The recorded signal has harmonic distortion given in Fig. 16 and had eight bit quantization noise applied.

Interleaving Errors and Noise Spectrum. The methods used to measure harmonic distortion can be used to quantify

Figure 16. DFT of sine wave test results showing 1% second 0.5% third and 0.25% fourth harmonic distortion. A record length of 1024 points was used. The points below -60 dBc are the result of 8 bit quantization noise. This noise floor can be made as low as desired by using a sufficiently long record length.

interleaving errors. When a number of recording channels is interleaved to increase the sampling rate (see section titled “Interleaved ADCs”), errors result from the various channels not being perfectly matched. These are called interleaving errors. The interleaving factor, n , is the number of recorders interleaved. The sampling rate for each recorder is f_s/n , where f_s is the sampling rate of the recorder. When a sine wave of frequency f is recorded, interleaving errors produce additional signals at frequencies

$$\text{interleave error frequencies} = kf_s/n \pm f \quad (26)$$

for integer values of k . When these frequencies are larger than the Nyquist frequency, $f_s/2$, they get aliased down to frequencies in the Nyquist band. However, at most $n - 1$ distinct frequencies below the Nyquist frequency are produced.

The measurements and data reduction for examining interleaving errors are identical to those for harmonic distortion. There is, however, an additional restriction on the input frequency, f . The frequency should satisfy

$$f = \frac{Kn}{M} f_s \quad (27)$$

where K is an integer, and M is the record length. This causes all of the frequencies created by the interleaving errors to be DFT frequency values. Figure 17 shows results with $f_s = 2$, $n = 4$ and $f = 0.297$. All of parameters are the same as for Fig. 16 except that the harmonic distortion has been replaced by distortion due to the four interleaved channels having different gain errors. The gain errors for the channels are (in succession) 3%, 1%, -1% and -3% .

Spurious Signals—Spurious Free Dynamic Range. Spurious signals are any frequencies, other than harmonics of the applied signal, that occur in the recorded signal. The frequencies generated by interleaving errors are just one example. The spectral lines related to the spurious signals are called *spurs*. The test methods used to determine the magnitudes of the spurs are identical to that of the last two sections.

The negative of magnitude of the largest spur (in dBc) is called the *spurious free dynamic range* (SFDR) of the recorder. This specification is much more common for ADCs themselves

than recorders in which they are used. Note that the SFDR can be much larger than the previously defined dynamic range, which was based on the noise level in the time domain. The observed noise floor (due to random noise, quantization noise, and various other sources) is much smaller in the frequency domain than in the time domain, and it can be made as small as desired by increasing the record length. Therefore, the SFDR is unaffected by this noise. SFDR is only meaningful if the recorder is going to be used in narrow band applications, such as communications or spectrum analysis.

Intermodulation Distortion. When two sine waves of different frequencies, f_1 and f_2 , are passed through a nonlinear system, new signals are produced with frequencies $k_1 f_1 \pm k_2 f_2$, for integer values of k_1 and k_2 . This is referred to as *intermodulation distortion* (IMD). The phenomena in the recorder that are responsible for IMD are the same as those responsible for harmonic distortion. However, there are situations in which harmonic distortion measurements will lead one to believe that the recorder is more accurate than it actually is. When input frequencies are above one-half of the bandwidth of the recorder,

Figure 17. DFT of sine wave test results showing the results of the interleaving errors for the example given in the text. The interleave error frequencies given by Eq. (26) are 0.203, 0.703, and 0.797.

harmonics can be attenuated. This can hide some of the high frequency errors. If two high frequency signals are summed, the nonlinearities will cause a number of spectral lines that are well within the bandwidth of the recorder to be produced, making the errors easier to detect and quantify.

There is another situation in which IMD measurements have an advantage over harmonic distortion measurements. One can use test signals with harmonic distortion larger than the distortions one wishes to measure, because the harmonics will be at different frequencies than the IMD products.

Noise Spectrum for Cathode Ray Tube Based Recorders. Sine wave tests and frequency domain analysis of the residuals are also useful for recorders that use a CRT as the recording device. However, because the error phenomena are different some changes in approach have to be made. Two potentially substantial sources of error in a CRT, distortion of the image due to misalignment and time base nonlinearity, produce errors at the same frequency as the applied sinusoidal signal. The spectrum of the errors is spread out over a frequency range on the order of the reciprocal of the record length. This causes two difficulties when one attempts to use data displays such as those of Figs. 16 and 17. First, since the errors are at the same frequency as the signal, they become masked by the signal. Second, since the errors are spread out over a frequency band, their rms value isn't related to the peak value in the spectrum but to an integral. The first problem can be eliminated by performing the DFT on the residuals rather than on the recorded signal, the second by displaying the integral of the power spectrum (8).

The types of distortion shown in Figs. 8 and 9 also have particular signature in the frequency domain. The distortion at the signal peaks due to the spot size exhibits itself as odd order harmonic distortion, which is independent of amplitude and increases rapidly with frequency. The wide-narrow distortion has the same form as Eq. (25) with ϵ a linear function of t that passes through 0 near the mid point in time of the record. This produces second harmonic distortion and a zero frequency distortion proportional to $(Af)^2$, where A is the amplitude and f is the frequency of the input signal. The distortions at these two frequencies are also spread out over a frequency ranges on the order of the reciprocal of the record length.

The random noise and the quantization noise of ADC based recorders are typically white, having nearly constant power spectrum amplitude up to the Nyquist frequency. This is not true for CRT based recorders. The random noise for CRT recorders begins rolling off with increasing frequency at a cut-off frequency related to the spot size of the CRT beam. This limits the SNR enhancement that can be attained through low pass filtering.

Time Base Errors

The two types of time base errors are long term stability and aperture errors. The long term stability is a measure of the long term drift of the sampling rate from its nominal value. This was covered in the earlier *Time base accuracy* section. This error shows up in sine wave tests as a deviation between the fitted frequency and the actual frequency of the input signal. This error doesn't show up in the residuals.

Aperture errors do show up in the residuals of sine wave tests. In the *Noise and distortion* section various sources of

aperture error were related to distortions that appear in sine wave tests and whose magnitudes increase with the frequency of the input signal.

OTHER RECORDER QUALITY ATTRIBUTES

There are some other recorder attributes that frequently appear in specifications that don't quite fit into the previous categories.

Cross Talk

Cross talk is the phenomenon, in multichannel recorders, of a small part of the signal into one channel appearing in other channels. The cross talk for any pair of channels, numbered i and j , is defined as

$$c_{ij} = \frac{\text{rms signal recorded on channel } i}{\text{rms signal applied to channel } j} \quad (28)$$

This is measured with all channels terminated in their usual source impedance and with a sinusoidal input signal applied only to channel j . The cross talk typically increases with frequency. The cross talk in practice is the sum of the values from all channels.

Overvoltage Recovery Time

The situation in which the input signal to a recorder exceeds the recording range for a period of time but doesn't exceed the maximum safe input voltage of the recorder is called an overvoltage. The *overvoltage recovery time* is the length of time, after the overvoltage has been removed, for recording at the specified accuracy to resume. The recovery time may depend on the magnitude and duration of the overvoltage.

Trigger Delay and Trigger Jitter

Most high speed (above audio frequency) recorders begin recording upon the receipt of a trigger signal. The *trigger delay* is the length of time between the trigger signal and the first time in the recorded signal. This time can be negative for recorders with pretrigger capability. The trigger jitter is (with the exception given shortly) the standard deviation of the trigger delay. For recorders with a continuously running clock signal, there is an inherent jitter of $1/f_s \sqrt{12}$, where f_s is the sampling rate. Some recorders provide a measurement of the time between the trigger signal and the first clock signal. For these recorders the trigger jitter is the standard deviation of the error in this measurement.

Common Mode Rejection Ratio

Common mode rejection ratio (CMMR) applies to recorders with differential amplifiers at the input. The meaning of CMMR for recorders is the same for amplifiers (15), the ratio of the output for differential signals to that for common mode signals of the same amplitude. The CMMR is especially easy to measure for recorders, because a DFT can be performed on the recorded data to more accurately determine the magnitude of a small common mode signal that is below the noise level. The CMMR is usually frequency dependent, generally increasing with increasing frequency.

RECORDER APPLICATION COMMENTS

Determining Recorder Sampling Rate and Bandwidth Requirements

The cost of recorders can increase drastically as sampling rate and bandwidth increase. Furthermore, the amount of data that must be stored increases linearly with sampling rate for a fixed record length (measured in time units). Hence, overestimating the bandwidth and sampling rate requirement for a recording system can drastically increase its cost, while underestimating them can lead to complete loss of the information that one desires to record. Thus, proper estimation of these requirements is an important part of recorder selection. The author has frequently seen errors of a factor of ten in estimated sampling rate requirements and has found errors by a factor of one hundred not to be uncommon.

The Sampling Theorem and Its Misuses. The sampling theorem (1,2) states that a signal of bandwidth f_B Hz can be exactly reconstructed from samples taken at a rate of $2f_B$ Sa/s. There is a common folklore that says that, to be safe, one should record a signal at a rate of ten times its bandwidth. These concepts lead people to ask "What is the bandwidth of the signal to be recorded?" as the first step in determining sampling rate requirements. This is, in most practical situations, a fruitless approach. The bandwidth in the sampling theorem refers to a frequency above which the Fourier transform of the input signal is exactly zero; real signals never have this property for any frequency upper limit. So for real signals the "bandwidth" is not a well-defined quantity. Often people will use the -3 dB bandwidth of a signal as an approximation. This, coupled with the five times over sampling by sampling at ten times the bandwidth rather than two times, seems reasonable. The error in this will be illustrated with a brief example.

Consider the signal of Eq. (1) which is shown in Fig. 1. Figure 18 shows the magnitude of the Fourier transform of this signal; the -3 dB point is at 83 Hz. However, from Fig. 1 one can see that sampling the signal at 1 kHz (more than ten times the 3 dB bandwidth) can completely miss the peak that occurs early in the signal. Figure 2 shows that passing the signal through a system with a 500 Hz bandwidth removes the peak. Thus, if one wishes to record the first peak, the common rules of thumb

Figure 18. The magnitude of the Fourier transform for the signal in Fig. 1. The shelf at -46 dB is from the narrow pulse at -10 ms.

completely fail. However, if the first peak (and any other narrow peaks) were noise, then it would be desirable to use a lower bandwidth and sampling rate to reduce the cost of the recording system.

Use of the Convolution Integral. The best way to determine the bandwidth requirement of a recorder is through simulation. One obtains sample input signals, simulates passing them through filters of various bandwidths, examines the result at each bandwidth and determines the smallest bandwidth that produces acceptable distortion. Simulations are done by evaluating the convolution integral, Eq. (12). To do this one must have sample input signals, $x(t)$, and estimates of an impulse response, $h_B(t)$, parameterized by the bandwidth. The exact form of $h_B(t)$ is seldom critical. A particularly convenient form to use in simulations is

$$h_B(t) = (t/\tau^2) \exp(-t/\tau), \text{ with } \tau = 0.102/B \quad (29)$$

where B is the -3 dB bandwidth of the filter. With this impulse response the convolution can be rapidly carried out using an IIR filter (1,2,3). These filters are available in many software packages. Another useful impulse response model is the Gaussian,

$$g_B(t) = (1/\sqrt{2\pi}\sigma) \exp(-t^2/2\sigma^2), \text{ with } \sigma = 0.133/B \quad (30)$$

Which of these one uses makes little difference. Of course, if one is interested in the adequacy of a particular recorder for which the impulse response has been measured, the known impulse response could be used.

There are situations in which estimates can be made with very simple calculations. Often the requirement is that pulses with widths exceeding a certain value have their peak values recorded to a certain tolerance. Assuming both the pulse to be recorded and the impulse response of the recorder to be Gaussian, one can use the relation

$$e = \frac{4.9}{(BW)^2} \% \quad (31)$$

where B is the -3 dB bandwidth of the recorder, W is the width (full width at half maximum), and e is the error in the peak amplitude of the pulse. This relation is valid for $e \leq 20\%$. For the example used previously of Eq. 1 and Fig. 1, the width of the first peak is $W = .24$; to obtain an error in the peak of less than 4.9% requires that $B \geq 1/W = 4.2$ kHz.

Use of Antialiasing Filters

An antialiasing filter is a low-pass filter applied to a signal before it reaches the recorder. The cut-off frequency of the filter is at (or slightly higher than) half the sampling rate (the Nyquist frequency) to be used in recording. When a recorder's bandwidth greatly exceeds half of its sampling rate, antialiasing filters should be employed. If not, both noise and signal components at higher than the Nyquist frequency will be aliased down to lower frequencies where they can't be filtered out. This problem is greatest when recorders with variable sampling rate are used at much lower than their maximum rate, because the bandwidth of the recorder will typically be suitable for the highest sampling rate.

Table 3. Extra Bits of Precision Attainable by Oversampling

Oversampling Ratio	Extra Bits of Precision
4	1
16	2
64	3
256	4
1024	5
4096	6
16384	7
65536	8

If the noise in the signal source is white, the antialiasing filter will reduce the noise by a factor of $10 \log(B_f/B_r)$ dB, where B_f and B_r are the bandwidths of the filter and the recorder. The bandwidths in the preceding are the *equivalent noise bandwidths*, rather than the -3 dB bandwidths, but the difference in these is less than 11% for filters of second order or higher. Note that the antialiasing filter does not reduce noise that is produced within the recorder (often a major source) only the external noise.

Noise Reduction through Oversampling

Noise can be reduced and accuracy and dynamic range improved by sampling the signal at a higher sampling rate than required followed by digital filtering of the recorded signal. This process, called *oversampling*, reduces the effect of noise produced within the recorder. If B is the bandwidth required to record the signal, then recording it at a sampling rate of $nB/2$ and filtering the recorded signal to a bandwidth of B reduces the noise level by $10 \log(n)$ dB for the case of white noise. The factor, n , is called the oversampling ratio. To gain a precision of k bits requires an oversampling ratio of $n = 4^k$. The value of n required for a given value of k is shown in Table 3.

Buying a recorder with much higher sampling rate than required in order to apply this technique is usually not cost effective. A 256 MSa/s 8 bit recorder can emulate the accuracy of a 1 MSa/s 12 bit recorder with this technique. The 1 MSa/s 12 bit recorder would probably be cheaper to buy and would require much less (a factor of 170) storage capacity. The oversampling approach is, however, cost effective when the higher sampling rate recorder is already available.

The success of oversampling to reduce noise requires that the noise not be concentrated at frequencies lower than B , the bandwidth of the digital filter. This low frequency concentration of the noise can occur when the primary error source is quantization noise (when the number of effective bits is approximately equal to the number of bits) and the signal is nearly constant. In this situation performance can be significantly improved by adding noise or dither to the signal.

Increasing Dynamic Range with Multiple Recorders

In many applications the average signal level varies with time, and the precision required during a particular time interval is a fixed percentage of the average signal level in the interval. In some cases the dynamic range of expected signal levels exceeds that which can be accurately recorded with a single recorder. In these situations the dynamic range can be increased by using multiple recorders as in Fig. 19. The signal is sent to several

Figure 19. Four recorders used to record 1 signal. Each is A dB more sensitive than the one above it. The signals recorded by the four units are assembled together as described in the text to construct one record.

recorders, and each recorder is set for its full scale voltage to be reduced by A dB with respect to the previous recorder. The data from the three recorders is assembled into a single record after recording is completed by using, for each data point, the largest value from the various recorders that isn't off scale. One must make gain and offset corrections for each recorder to avoid discontinuities in the data.

The optimum value for A and the required number, N , of recorders can be calculated in a straightforward manner. Let $V_{\max}$ be the largest signal to be recorded, D be the dynamic range of the recorder (Eq. 8) in dB and S be the required signal to noise ratio for the signal recording in dB. To use the recorders for this application at all we must have $D > S$. If $V_{\min}$ is the smallest signal level that must be recorded with signal to noise ratio, S , we define the signal dynamic range, $R = 20 \log(V_{\max}/V_{\min})$. The number of recorders required is then $N = R/S$, and the ratio in dB between the ranges of successive recorders is $D - S$.

FUTURE DIRECTIONS

The art and technology of recording have changed drastically in the last decade or so as digital recording has virtually supplanted analog recording. There are several factors that have driven this. One is the rapid decrease in cost and increase in speed and capacity of digital recording media. Another is the advancement of analog to digital converter technology. A third factor is the use of computers within the recorder to control the generation of calibration signals and analyze the recorded results. Future progress is expected to occur along the same lines and is probably more controlled by demand than by technology.

One would expect to see an increase in the bandwidth and sampling rate of ADCs. As the bandwidth moves from its

present limit of 1 to 2 GHz to the 5 to 10 GHz range, the more limited technologies of traveling wave CRTs and streak cameras will probably disappear. One could expect over the next decade to see ADC based recorders reach the same 20 to 30 GHz bandwidth range that sampling oscilloscopes now have.

Increased precision is another area for which there is steady progress. ADCs can be roughly grouped into the 8, 12, 16, and 20 bit classes. Each class has an upper sampling rate limit that can be economically accomplished. These upper frequency limits steadily increase. The increased sampling frequency at a fixed precision of ADCs translates directly into the same improvements for recorders. However, recorders improve at an even faster rate. As the cost, size, and power consumption of ADCs go down it becomes practical to interleave more of them into a single recorder channel—increasing the sampling rate more than that of the ADCs.

An area ripe for improvement at lower sampling rates (10 MSa/s and less) is increased capacity through real time data compression. This involves analyzing and compressing the data between the time it is digitized and the time it is written to disk, so that the disk can hold much longer records. Very specialized computing hardware and algorithms are already in use to accomplish this for audio and video recording. This could be extended to more general situations.

Many users would like to be able to predict a recorder's performance in hypothetical applications based on various recorder specifications. Some work has been done in this area (5) but this is far from straightforward. More research into modeling recorders with sufficient precision to predict performance in a wide range of practical applications is desirable.

A related situation is the current lack of precisely known test signals other than sine waves. One can't test a recorder's performance in a hypothetical situation by generating the hypothetical test signal, recording it, and examining the errors, because the art of accurately generating arbitrary test signals is lagging behind the art of recording them.

TESTING METHODS

EDDY CURRENT TESTING

Eddy current testing is a nondestructive evaluation method that is based on the principle of electromagnetic induction. While an alternating current passes through a coil, an alternating magnetic field is produced that is oriented perpendicularly to the direction of the current and parallel to the axis of the coil. If a conductive object is located in proximity to the coil, circular eddy currents will be induced within its surface layer normal to the magnetic field. Eddy currents in turn generate a secondary magnetic field that is in opposition to the primary coil field. The interaction between the two fields causes a partial decreasing of the primary field, hence a change in coil impedance or coil voltage. Therefore, a coil and a conductive object close to each other couple into a unified system through the interaction of alternating current in the coil and the induced eddy current in the body. A schematic representation of the system is shown in Fig. 1. Essentially, the eddy current testing means to measure the change of coil impedance (1). The magnitude of the coil impedance is related to either the coil construction or the coupling strength between the coil and tested object. The coupling strength is affected by a number of factors, such as electrical conductivity σ , magnetic permeability, μ of the object (target) material, size, shape, and the distance (or clearance) x between the coil and object. Coil construction parameters include outer diameter D , inner diameter d , thickness b , and the number of turns w , and are designed according to particular testing requirements. They are all the factors that affect the magnitude of coil impedance, but they are always kept constant after the coil, the eddy current probe, is built up.

When the object is machined of homogeneous metallic material, and the conductivity σ , permeability μ , and its shape and dimensions are all fixed, then changes in magnitude of the coil impedance vary with changes in the distance x . This phenomenon is called *lift-off effect* (2). Based on lift-off effect, an eddy current transducer provides displacement measurement; hence, we can measure vibration, motion trace, metal foil and sheet thickness, and thickness of cladding material, either for nonmetal plating on metal material or for a nonmagnetic layer on magnetic material.

Figure 1. Eddy current principle. I_1 is the exciting ac current; x the distance between coil and tested object; σ , μ are the conductivity and magnetic permeability of the object material, respectively.

If the distance x is kept stationary, the magnitude and changes in coil impedance indicate the combined influences of conductivity σ and permeability μ of the object material, upon which flaw detections are possible. When the permeability μ is also fixed, the coil impedance becomes a function of the conductivity σ . Thus one could determine the impurity content of pure metal, heat treatment condition of an alloy, concentration of dielectric medium, etc. But otherwise, with conductivity σ fixed, impedance will vary with permeabilities, and one could inspect grain-size metallic materials, thermal related strain, hardness, and so on. Therefore eddy current testing is a multivariable detecting technology and has extensive usage. Some major applications will be stated later.

Eddy current was discovered in 1824 when Gambery (3) noted the eddy current damping phenomenon when the oscillations of a suspended bar magnet rapidly stopped whenever a copper plate was held under it. Subsequently, many scientists dedicated themselves to the study of eddy current theory and its practical use; however, progress was very slow. Förestier first investigated the influence of radial cracks in a metal bar on coil impedance in 1954 (10). Dodd and Deeds (11) in 1968 and Libby (4) in 1971 successfully put forward a theory for analytically calculating the induced eddy current within the cross section of a metal bar in an ac magnetic field, eddy current technology has developed rapidly. Now, numerous versions of eddy current test equipment as nondestructive measurement tools have been successfully developed and are commercially available (2).

Eddy current testing has many advantages, such as the following:

1. A probe coil need not contact the tested object (specimen).
2. It has high sensitivity for measuring the surface or sub-surface of conductive materials.
3. It has a fast response—can be used for either static or high-speed dynamic testing.
4. It is unnecessary to have some actuating medium between probe and specimen. Neither is there a problem even if dust, oil, or any other nonmagnetic and primarily non-conductive medium gets between them. Therefore, eddy current testing can be done in unsatisfactory conditions.
5. A variety of testing circuits, such as bridge circuits, resonant circuits, feedback circuits, and phase discriminators are available to generate corresponding outputs of voltage, current, phase, or frequency to reflect coil impedance and its changes.

Just as everything has strengths and weaknesses, however, the eddy current testing method does have inherent limitations (12), as follows:

1. It is applicable only for testing of conductive materials.
2. It detects flaws mainly for surfaces or surface layers, but cannot determine the shape and types of flaws.
3. It is difficult to inspect specimens with complex shape.

4. Eddy current testing can be used to deal with multiple variables; however, this very advantage can bring about interference signals in the results, so that special signal processing is often necessary.

PRINCIPLES OF EDDY CURRENT TESTING

The impedance of an eddy current coil can be analyzed under three distinct conditions (5).

Idling Impedance

This is the coil impedance with tested object very far from the coil, thus not influencing its impedance. Idling impedance Z_0 is

$$Z_0 = R_1 + j\omega L_1 \quad (1)$$

where R_1 , L_1 are the resistance and inductance of the coil, respectively (Fig. 2), and ω is the angular frequency ($\omega = 2\pi f$).

First-Stage Impedance

The impedance of a coil coupled with an object of known physical properties is defined as *first-stage impedance*. It indicates the characteristics of a coil impedance that varies with the distance between coil and object, such as lift-off effect. As mentioned previously, when a metal specimen is placed adjacent to a coil carrying an alternating current, secondary or eddy current will be induced within the surface layer of the specimen. Figure 2 shows the equivalent circuit. According to Kirchhoff's voltage law, a set of equations can be written:

$$(R_1 + j\omega L_1)I_1 - j\omega MI_2 = U \quad (2)$$

$$-j\omega MI_1 + (R_2 + j\omega L_2)I_2 = 0 \quad (3)$$

where R_2 , L_2 are resistance and inductance of eddy current loop in tested specimen. M is the mutual inductance between the coil and the tested specimen. From Eqs. (2) and (3), the first-stage impedance Z of the coil can be derived:

$$Z = \left[R_1 + \frac{\omega^2 M^2 R_2}{R_2^2 + (\omega L_2)^2} \right] + j\omega \left[L_1 - \frac{\omega^2 M^2 L_2}{R_2^2 + (\omega L_2)^2} \right] \quad (4)$$

The equivalent resistance R of the coil is a function of the mutual inductance M :

$$R = R_1 + \frac{\omega^2 M^2 R_2}{R_2^2 + (\omega L_2)^2} \quad (5)$$

Obviously, R increases with the decreasing distance between coil and object. Note that this variation is independent of

Figure 2. Equivalent circuit of the coil coupled with a conducting object.

material characteristics (magnetic or nonmagnetic). From the second term of Eq. (4), the equivalent inductance L of the coil is

$$L = L_1 - \frac{\omega^2 M^2 L_2}{R_2^2 + (\omega L_2)^2} \quad (6)$$

L is influenced by two physical effects. The first term L_1 is related to magnetostatic effects, so that it is dependent on whether the material is magnetic or nonmagnetic. The second term $\omega^2 M^2 L_2 / [R_2^2 + (\omega L_2)^2]$ is generally considered as a reflected inductance caused by eddy current effect. The result of these two effects on equivalent inductance L is opposite. When the distance between coil and specimen decreases, coil inductance L increases as a consequence of magnetostatic effect, but it decreases, because of eddy current effect. Based on the analysis above, we can relate the variation in distance between coil and specimen to the variation of impedance.

Secondary Stage Impedance

Here we define the impedance of a coil adjacent to an object of unknown physical properties as *secondary stage impedance*. It demonstrates characteristics of coil impedances as related to tested objects that have different physical properties. In non-destructive testing, it is necessary to gain information about conductivity, permeability, and various flaws, so the concept of secondary stage impedance was born at the right moment. From Eq. (5), the resistance increment ΔR of equivalent resistance of a coil is

$$\Delta R = \frac{\omega^2 M^2 R_2}{R_2^2 + (\omega L_2)^2} \quad (7)$$

And from Eqs.(4) and (6), the reactance increment $\omega \Delta L$ of equivalent reactance of the coil is

$$\omega \Delta L = \omega \frac{\omega^2 M^2 L_2}{R_2^2 + (\omega L_2)^2} \quad (8)$$

When we divide Eq. (7) by Eq. (8), we obtain

$$\frac{\Delta R}{\omega \Delta L} = \frac{R_2}{\omega L_2} \quad (9)$$

The resistance increment ΔR and inductance increment ΔL of the eddy current coil generally depend upon metal conductivity. When the mutual inductance M is selected as a fixed value and ωL_2 is assumed as a constant, Eq. (9) tells us that there are different ratios of $\Delta R / \omega \Delta L$ for different metals. This is the theoretical basis of measuring metal conductivities. If we take the increments ΔR and $\omega \Delta L$ as horizontal and vertical axes, respectively, an impedance information graph (showing the relationships of $\omega \Delta L$ and ΔR in impedance Z) can be drawn by plotting $\omega \Delta L$ against ΔR (5). The slope of the plotted straight line is $\omega L_2 / R_2$. Figure 3 shows that different conductivities of tested objects have different lines. Here we see that the particular exciting angular frequency ω is very critical. Too high a frequency is unsuitable for measuring metallic conductivity. Using Eqs. (7) and (8), we can eliminate R_2 ; then we have

$$(\Delta R)^2 + \left(\omega \Delta L - \frac{M^2 \omega}{2L_2} \right)^2 = \left(\frac{M^2 \omega}{2L_2} \right)^2 \quad (10)$$

Figure 3. Relationships between metallic conductivity and information impedance.

Equation (10) shows that when the angular frequency ω and mutual inductance M are fixed at certain values, the impedance information graph follows semicircle law. The center of the semicircle sits in the vertical axis of $\omega\Delta L$, its radius is $M_2\omega/2L_2$. Different semicircles can be plotted for different M . Each semicircle passes through the origin of the coordinates and is tangential with the horizontal axis (ΔR axis). For a particular metal conductivity and mutual inductance, the intersecting point of the above straight line and the circle shows the value of the coil impedance information precisely.

The impedance diagram is the basis of eddy current testing. The relationship between coil impedance and flaws, cracks, lift-off, conductivity, permeability, and frequency, as well as the degree of filling, can be clearly known from the impedance diagram (2). Now, we let R be the horizontal axis and ωL the vertical axis, resulting in a complex impedance plane in which the terminal locus of impedance Z becomes the impedance diagram (6). It is the advantage of the complex plane diagram that the locus is rather clear and readily perceived, as shown in Fig. 4(a). We find that the shapes of loci are similar to each

other, but their magnitudes and positions are much different, being affected by different radii of coils and exciting frequencies. Therefore this kind of impedance diagram is difficult to study and utilize. In order to overcome this limitation, a normalized impedance diagram is usually used. As shown in Fig. 4(a), this normalization is achieved first by moving the vertical axis right to the idling coil resistance R_1 , eliminating the left part of the information impedance with the tested object free. Then the two coordinate axes are divided by the idling coil reactance ωL_1 . Through this modification, the normalized impedance diagrams are the same no matter what the exciting frequency and radii of coils are changed to (5), as shown in Fig. 4(b). The fractional resistance $\Delta R/\omega L_1$ and reactance $\omega L/\omega L_1$ are all dimensionless and all less than 1. Therefore normalized diagrams have identical forms and are extensively comparable.

In eddy current testing, there are many variables that cause changes in coil impedance, and so it is very complicated to analyze their influence. For simplification, Förestor proposed a conception of *effective permeability*. He assumed an ideal model in which a cylindrical tested object is placed in an infinitely long solenoid coil that carries ac current. A constant field exists at any cross section of the cylinder, but magnetic permeability changes in the section along its radial direction. However, the related magnetic flux equals that in the real cylinder. Under these assumptions, he came to a conclusion that the real alternating magnetic intensity and constant permeability could be replaced by a constant magnetic intensity and an alternating permeability. This assumed altering permeability is called *effective permeability*, symbolized as μ_{eff} , and is defined by the equation

$$\mu_{\text{eff}} = \frac{2}{\sqrt{-j}} \cdot \frac{J_1(\sqrt{-j}kr108108)}{J_0(\sqrt{-j}kr108108)} \quad (11)$$

where $K = \sqrt{\omega\mu\sigma}$, r is the radius of the cylinder, $J_0(\sqrt{-j}kr)$ is a zero-order Bessel function, and $J_1(\sqrt{-j}kr)$ is a first-order Bessel function. After introducing the concept of effective permeability, Förestor defined the frequency at which the modulus of the Bessel function argument (kr) equals 1 as the *character frequency* f_g and called it the *limiting frequency* (2):

$$f_g = \frac{1}{2\pi\mu\sigma r^2} \quad (12)$$

Obviously, for a common testing frequency f , the following equation is valid:

$$kr = \sqrt{2\pi f\mu\sigma r^2} = \sqrt{f/f_g} \quad (13)$$

Effective permeability μ_{eff} changes with variable (kr), so μ_{eff} can be calculated as long as the ratio of f/f_g is known. Conventionally, f/f_g is taken as a parameter for the analysis of coil impedance.

In practical eddy current testing, a tested cylinder with diameter d usually cannot fully fill the testing coil, which has an inner diameter D , because a gap between coil and tested object is needed for relative movement. Here we define the fill factor η (1) as

$$\eta = (d/D)^2 \quad (14)$$

Figure 4. Impedance diagram of aluminum. (a) Impedance changes with variables. (b) Normalized impedance diagram. (1): Conductivity σ . (2): Thickness t . (3): Clearance (lift-off distance) x .

Figure 5. Several designs of eddy current probes. (a) Solenoid-type coil (or single coil) around cylindrical specimen, absolute measurement. (b) Pancake-type coil (or surface-mounted type probe) for testing planar objects. (c) Double coils for comparison measurement. (d) Multi-solenoid coils for differential measurement. (e) Bobbin probe (double or multiple coils) for use in tubular specimen. (f) Pancake-type coils with ferrite cores, the front coil used as a sensing coil, the rear for temperature compensating.

Undoubtedly, the influence of a tested object with different η on coil impedance is different.

From the analysis above, the effect on coil impedance of the opposing magnetic field produced by eddy currents in tested objects is completely determined by the fill factor η and effective magnetic permeability μ_{eff} . On the other hand, we can see from Eqs. (11) and (13) that μ_{eff} is determined by the ratio of f/f_g . Therefore the variation of coil impedance is actually determined by factors η and f/f_g . Thus, for a constant value of η , the distribution of eddy current and magnetic flux density in tested objects is a function of f/f_g . This result leads to a new conclusion: For two different tested objects, if η is kept constant and the corresponding frequency ratios f/f_g are the same, then the geometric distribution of effective permeability, eddy current density, and magnetic flux density are also the same, respectively. This is the so-called *law of similitude* of eddy current testing (5). From Eq. (13) the similitude condition can be written as

$$f_1 \mu_1 \sigma_1 r_1^2 = f_2 \mu_2 \sigma_2 r_2^2 \quad (15)$$

where the subscripts 1 and 2 describe the physical parameters and geometric sizes of tested bodies 1 and 2, correspondingly.

The law of similitude is a theoretical basis for proper simulation experiment. When problems that are solved neither by mathematical method nor settled by direct measurement are encountered in eddy current testing, we can have reasonable results according to the law by simulation experiment. For example, the law of similitude is applied to detect discontinuity flaws of materials, as long as the frequency ratios f/f_g are equal, and discontinuity flaws with geometric similarity (such as flaws having definite depths and widths that are all described as percentages of the cylinder diameter) will cause equal eddy current effect and equal variation of effective magnetic permeability. So, by means of a simulation test model with artificial flaws, the relationship between the variation $\Delta\mu_{\text{eff}}$ of

effective permeability and the depth, width, and location of the flaw can be demonstrated. According to the similitude law, we can take these well-established results as a valid basis for practical evaluation of existing flaws. Thus, in testing of metal wires and small-size tubes, the influences of cracks on the probe coil's parameters may be understood by study of a test model with a magnified cross section and artificial flaws. Fortunately, in the testing of large tubes with eccentricities, nonuniform wall thickness, as well as other flaws, simulation testing makes the evaluation much easier. For particular applications, impedance plane diagrams are usually drawn with selected f/f_g as a parameter. Experimental results indicate that frequency ratios f/f_g within the range of 5 to 150 are of high sensitivity and practical significance.

Eddy Current Probe

The eddy current probe is one of the key components in eddy current testing equipment (2). It consists of a sensing coil, a coil frame, and connecting cables. Performance of the coil directly affects testing accuracy and data reliability. Figure 5 shows several types of eddy current probes for testing metallic tubes, cylinders (wire), and planar objects.

APPLICATIONS OF EDDY CURRENT TESTING

Applications of eddy current testing are generally classified into three main kinds: nondestructive flaw detection, material examination, and displacement and vibration measurement.

Nondestructive Flaw Detection

Flaw Detection in Metallic Tubes. The main purpose of tube flaw detection is to understand flaw kinds, their geometric shapes, and their locations. However, it is difficult to calculate theoretically the sites and shapes of flaws (13). Simulation

Figure 6. Several types of artificial defects. (a) Rectangle slot. (b) V-type slot. (c) Hole (or blind hole). (d) "Wire cutting" gap.

tests, as pointed out before, are available to acquire knowledge about various flaws (such as shapes, sizes, and locations) within different materials under different ac exciting frequencies. The resulting data, tables, and curves can provide reference criteria for other practical testing (14). For that reason, reference specimens with standard artificial flaws, called *standard scars*, are necessary. Figure 6 shows four types of artificial flaws.

With wide use of eddy current testing, standardization of artificial flaws in many countries is increasingly accurate (8). A number of symbols, shapes, and sizes of standard flaws has been clearly designated today, making the selection, application, and reproduction of artificial flaws much easier. For the testing of tubular materials, single-coil solenoids are often employed. With reference to wall thickness, tubular materials can be put into two categories: thin-walled tubes and thick-walled tubes. The influence of tubular material on coil impedance is determined by the conductivity σ , relative permeability μ_r , outer and inner diameters d_2 and d_1 , and wall thickness w . Of course, flaws within the outer and/or inner surface of a tube and eccentricity are also factors that affect coil impedances. Figure 7(a) shows that impedance varies with outer diameter d_2 (η is altered), whereas the ratio of d_2/d_1 is kept constant and the impedance diagram presents a set of semicircular curves in the case of $\eta = 1, 0.75, 0.5$, respectively. Each of the curves indicates coil impedance changes with conductivity σ , inner diameter d_1 , and wall thickness w ; and with frequency ratio of f/f_g under the condition of outer diameter $d_2 = \text{constant}$ (η is fixed). The crosswise-oriented curves indicate direction of the variation in coil impedance with outer diameter d_2 .

If the inner diameter d_1 of the tubular material is fixed, variation of outer diameter d_2 may cause two types of effects: One is outer diameter effect, where the crosswise curve in Fig. 7(a) shows the changes of impedance. The second is wall thickness effect, which makes f/f_g change greatly while the impedance value reaches to a new place corresponding to the new point of f/f_g . Because these two effects happen at the same time, impedance variation along with the crosswise curve caused by outer diameter effect is not very obvious, but it changes clearly along the semicircular curve symbolized as f/f_g . So the "total effect" makes impedance vary along the curve labeled, "varying d_2 and w " as shown in Fig. 7(b).

The eddy current effect of cracks in thin-wall tubes is the same as that of decreasing w of wall thickness. Therefore the

Figure 7. Impedance diagram for nonmagnetic thin wall tubes. (a) Coil impedance changes with d_2 as $d_1/d_2 = \text{const.}$ (b) Coil impedance changes with d_2 as $d_1 = \text{const.}$ (c) Coil impedance changes with d_2 as $d_1/d_2 = 80\%$.

Figure 8. Coil impedance affected by cracks in nonmagnetic metal tube. Numbers on curves represent the depth of cracks as percent of wall thickness W .

effect owing to the existence of cracks in the outer surface layer is identical to that caused by altering outer diameter d_2 while inner diameter d_1 remains fixed—see Fig. 7(b). Similarly, the effect caused by cracks in the inner surface layer is identical to that caused by altering inner diameter d_1 while outer diameter d_2 is kept constant (wall thickness w varies), as shown in Fig. 7(a).

A frequency range corresponding to $f/f_g = 0.2 \sim 2.4$ is usually selected as the exciting frequency because there is greatest sensitivity at the point of $f/f_g = 1$.

Impedance curves of single coil testing of thick-walled tube are located, in the impedance diagram, between curves tested from cylinders and thin-walled tubes. If the ratio of d_1/d_2 of a thick-walled tube holds constant, whereas the outer diameter d_2 changes, we will obtain the impedance diagram shown in Fig. 7(c). Figure 7(c) also shows a set of curves for coil impedance that varies with frequency ratio f/f_g under the condition of $d_1/d_2 = 80\%$ and η (or d_2) as a parameter. As the outer diameter changes, the coil impedance changes chordwise.

For understanding of interior flaws, a great amount of model testing is necessary (5). Figure 8 shows the effects of cracks in nonmagnetic tubes, localized at different sites and depths, on coil impedance at frequency ratios $f/f_g = 5$ and 15. We can see from the diagram that there is a phase shift between impedance curves of cracks in inner and outer walls and the impedances increase with f/f_g and w/r_2 . The effect of cracks within the material on the coil impedance is slightly less than that of cracks having the same depths in the inner or outer surface layer.

In practical applications, single coil testing is generally employed for tubes with diameters smaller than 75 mm, whereas the bobbin-type coil is suitable for tubes with diameters larger than 75 mm. Usually, a single-pancake coil or surface-mounted probe is preferable for tubes with very large diameters.

Flaw Detection in Metallic Rods and Wires. Even though eddy current testing can only detect flaws in the surface or surface layers, it is widely used in the area of surface quality evaluation for some metallic rods and wires. For flaw detection of the batch process rods and wires, a similar way to detect flaws in metal tubes is available. However, eddy current penetration

is smaller in rods and wires than in tubes, and its distribution is also different. In order to raise eddy current sensitivity, a much lower test frequency should be selected than that used for tube testing (5). For these applications, single coil may often be used as the detecting coil.

As mentioned in the last section, the conductivity σ , magnetic permeability μ , dimensions and flaws of tested materials, and testing frequency are the major factors that influence coil impedances. The effect of flaws on coil impedance can be considered as the combined result of conductivity and dimensions. Flaws that are characterized by such qualities as their shape, depth, and location are very difficult to calculate theoretically. Hence flaw detections currently have to be achieved by means of model testing.

Figure 9 shows the effects of flaws on coil impedance and the curves resulting from model tests at frequency ratios of $f/f_g = 5$ and 15 for nonmagnetic cylinders (rods) with flaws of various locations, shapes, depths, and widths. The zero points of all these curves relative to flaw-free objects are located at the point that is determined by the frequency-dependent effective permeability μ_{eff} .

With $f/f_g = 15$, for example, one line segment marked Δd on Fig. 9(b) expresses the “diameter effect” relative to variation of diameter, and the numbers on it indicate percent decrease in diameter. Another line segment marked $\Delta\sigma$ expresses the “conductivity effect,” and the numbers indicate percent increase in conductivity. Other line segments marked 10, 15, 20, and 30 show the regularity of coil impedance variation in the case of a tested cylinder with narrow cracks and width-to-depth ratio of 1:100 and when depths equal 10%, 15%, 20%, and 30% of diameter, respectively. The numbers 3.3, 2, and 1 at the right-hand side express the distance of upper terminals of internal cracks to the object (cylinder) surface as being 3.3%, 2%, and 1% of diameter. The numbers 4:1, 2:1, 1:1 express width-to-depth ratios of cracks. We also can see from the diagram that, for a subsurface crack with a depth of 30% diameter, as its upper terminal gets farther from the surface, the coil impedance will vary along the curve marked with the numbers 1, 2, and 3.3. When the depth of a “V-type” crack varies, the coil impedance will vary along the curve marked with the ratios 4:1, 2:1, and 1:1. Furthermore, with the increasing width-top-depth ratio, the orientation of crack effect becomes that of diameter effect.

Figure 9. Cracks' effect on solenoid coil impedances. (a) $f/f_g = 5$. (b) $f/f_g = 15$.

According to the analysis above, the danger of cracks can be evaluated. For instance, the larger the angle included between the directions of crack effect and diameter effect, the deeper the crack. A harmful "sharp crack" is often the case. Otherwise, the heavy scratch mark usually has a large width-to-depth ratio, but the included angle between crack and diameter effect is very small or near zero, so it does not cause any danger.

In practical eddy current nondestructive crack detections, a frequency ratio f/f_g ranging from 5 to 150 is valuable. The optimum ratio for searching surface cracks is within 10 to 50. And a ratio of 4 to 20 is the best range for searching for subsurface cracks, whereas a ratio of 5 to 10 is useful for detecting both surface and subsurface cracks (5).

Material Examination

Eddy current testing of materials is achieved by measuring the variations of electrical conductivity and magnetic permeability of tested objects (9). Usually, material quality condition such as chemical constitution and impurity content affect conductivity and permeability.

Determining Chemical Composition and Impurity Content of Nonmagnetic Metals. The relative permeability μ_r for nonmagnetic metallic material is $\mu_r = 1$, approximately that of air, and it is generally taken as constant. Therefore, the problem is simplified because only conductivity need be measured by the eddy current method.

The purity of metallic materials is closely related to their conductivities. If a small amount of impurities is melted into the materials, their conductivities will be decreased rapidly. Figure 10 shows the variation of electrical conductivity of metallic copper with different impurities and different content amounts. We can see from the diagram that even if the impurity contents in copper are 0.1% to 0.2% Fe, Si, or P, and so on, the conductivity decreases dramatically. Furthermore, the

variation of conductivity is roughly proportional to the impurity content. Here unit IACS in diagram is the international annealed copper standard (6). Conductivity of copper according to it is defined as 100% IACS. In the copper industry, the amount of impurity is evaluated by its conductivity.

In brief, once we obtain the definite relationships between conductivities and impurity content, we can easily conclude what impurities and how much of them the material contains.

Determining Chemical Composition of Magnetic Materials.

Relative permeabilities μ_r of magnetic materials are very much larger than that of nonmagnetic ones, usually in the order of 10^2 to 10^4 . Therefore, the magnetic parameter becomes the major factor in eddy current testing for magnetic materials.

Magnetization (B - H) curves of magnetic materials are chemical composite dependent (15). For example, the curve of

Figure 10. Effect of impurity content on copper conductivity.

Figure 11. Effect of carbon content in carbon steel on magnetization curves (annealed condition).

carbon steel changes with different carbon content in it, as shown in Fig. 11. Generally, magnetic permeability, residual magnetization, and saturation flux density will all decrease with increasing carbon content. We can use these relationships between magnetic parameters and chemical composites and their contents to evaluate qualities of materials.

Displacement and Vibration Measurement

Displacement Measurement. Generally, the surface-mounted probe, or pancake-type coil, is acceptable for displacement measurement. Parameters of the coil such as diameters, turns, and thickness are required for test range and accuracy. For instance, in order to measure large displacement, a coil with the necessary axial uniform distribution of magnetic field is needed to form a large linear range. If high sensitivity is needed, the variation of eddy current dissipations with the relative movement of coil and testpiece along the coil axis should be large enough, thus a little bit thicker coil is suitable.

Once the conductivity σ , permeability μ , and exciting frequency f have been selected, coil impedance is only the function of distance x between coil and testpiece, as per the lift-off (or "clearance") effect stated earlier. In flaw detecting, however, lift-off effect is an interference factor and needs to be avoided. Curves of lift-off effect are expressed as impedance variation with spacing under conditions of specific materials measured and constant testing frequency, whereas the impedance of a surface-mounted coil is of great significance to lift-off effect. Figure 12 shows an impedance diagram of surface-mounted coils.

Here we should point out that the curves in Fig. 12 were obtained with testing frequency equal to 60 kHz and validated with the test coil only. Coil impedance diagrams will differ when using different coils, different exciting frequencies, and different materials. Thus, these diagrams cannot be for common use but rather for reference. Because the scope of a magnetic field generated by a coil carrying ac current is limited and only its uniform range is usable, linear range of displacement conventionally takes $\frac{1}{3}$ to $\frac{1}{5}$ of the outer diameter of the coil.

Vibration Measurement. Vibration problems are always present in operations of rotational machinery. Serious vibrations will affect normal operations, so that vibration measurement becomes an important aspect of engineering. The eddy current method serves as a noncontact detecting technique for testing various vibrations.

Figure 12. Normalized impedance diagram for surface-mounted coil (or pancake coil).

The testing process is very simple. As long as we place a surface-mounted coil facing the vibrating body within a certain distance from the body, while the vibrating body has reciprocating movements in repeating patterns, the distance between them will be altered periodically, and so will the magnitude of the coil impedance. Testable range of vibration magnitude is generally within several millimeters. The vibration signal can usually be input to an oscilloscope so that its waveshape can be observed directly. Figure 13 shows radial and axial vibration measurements for a turning shaft.

Eddy current methods based on the lift-off effect also have wide use in research activities and industrial processes such as thickness measurement, rotatory angle and rotatory speed measurement, and counting of products.

PROSPECTIVE DEVELOPMENT OF EDDY CURRENT TESTING

In the early 1950s, Förster put forward an "impedance analysis method"—a new way to discriminate various factors that affect eddy current signals. Since then, eddy current testing technology has achieved an essential breakthrough and has come into a new period of practical applications. After the 1970s, the rapid advances in integrating electronics, computer science, and signal processing encouraged the development of

Figure 13. Vibration measurement of rotating shaft.

eddy current testing and pushed forward theoretical study, practical research, and new equipment production (2). Its application is constantly growing.

Multifrequency Eddy Current Technology

The application of multifrequency eddy current testing is relatively new. After thorough analysis of electric magnetic theory, Libby pointed out that a variety of interference signals can be significantly rejected and valuable signals more easily acquired by means of multifrequency eddy current testing methods. Now, multifrequency technology has been applied to tube flaw detecting, graphic display of tube cross sections, thickness measurement of multilayer metal film, and more (16), even though it isn't widely used yet owing to limitations of component performance, analytical methods for particular problems, complicated circuits, and so on. However, with the development of eddy current theory and computer-based signal processing, the multifrequency method will certainly play an important part in eddy current testing because of its attractive advantages.

Remote Field Eddy Current Testing Technology

The *remote field* method is a low-frequency eddy current technology (17) with which magnetic flux is able to penetrate metallic plates or tubular walls. The eddy current probe for tube flaw detecting works with an exciting coil and a relatively small searching coil that is installed apart about twice that of inner diameter from the exciting coil. The search coil can pick up the magnetic flux that comes from the exciting coil penetrating the tube wall and then returning into the tube. Thus flaws within the inner walls of tubes and decreasing thicknesses of tubular walls can be effectively detected. Because remote field technology has high sensitivity to metal tubes (especially to ferromagnetic tubes), it has become a practical way to inspect various flaws in tubes having long lengths. For that reason, remote field technology has been widely applied to tubes for petroleum, natural gas, and municipal coal gas transporting.

Evaluation of Surface Quality of Metallic Materials

As mentioned before, the eddy current effect is very sensitive to electromagnetic conditions in surface layers of metallic materials. Through the study of relationships between eddy current effects and surface layer performances, the evaluations of surface qualities of metallic materials can be fairly well achieved (9). Therefore we expect that the extensive studies of eddy current testing for residual stress, fatigue cracks, and crack extension and initiation will advance at a great pace.

Computer-Aided Eddy Current Testing

In order to raise reliability and automation of eddy current testing, digital and intelligent instruments have been developed. Numerical calculation for complicated theory problems of eddy current testing will be realized with the most advanced computer technology. Computer technology will be widely used for automatic control and data processing of eddy current testing (18). Microprocessor-based intelligent testing apparatuses

that are portable, multifunctional, and easily operated will be emerging.

Signal Image Processing and Discrimination

In eddy current testing, the eddy current information caused by flaws can be extracted by multifrequency technology, after which a variety of images relative to eddy current data can be analyzed by means of computer image processing. Once the images reflecting flaws of tested objects are displayed on screen, the flaws are shown visibly and can be quantitatively analyzed.

Probe Research

The eddy current probe, as pointed out earlier, plays an important role in eddy current testing activities. Its performance mainly comprises linearity, sensitivity, resolution, range, copper resistance, temperature stability, reliability, and probe dimensions. Most of these are connected with probe construction parameters such as coil turns, inner and outer diameters, coil thickness or length, whether air-cored or ferrite-cored, stranded wire-wound coil or metal film-type coil, and the combined use of multiple coils. Consequently, optimum design of probe parameters has become an important project (19). However, there is still a lack of theoretical analysis for probe design. The design is frequently carried out by means of experiment and experience. Optimum design is important, since, for example, a well-built stranded wire-wound coil can reject or reduce temperature drift over a wide temperature range if it is made with the proper diameter of single wire, the correct number of wire strands, and the proper choice of ac current frequency (20).

In short, with the development of science and industrial technology, the theoretical study of eddy current testing and improvement of testing equipment will certainly advance to a new stage. Eddy current testing technology has splendid applications in the fields of aircraft (21), navigation, metallurgy, machinery, electric energy production, chemistry, nuclear power generation, and more.

EDDY CURRENT NONDESTRUCTIVE EVALUATION

Eddy current methods of nondestructive testing (NDT) (1,2) are one of the most commonly used methods for evaluating the integrity of materials in industry. Although there are several different eddy current methods, they all rely on the principles of electromagnetic induction to ascertain the condition of a given test specimen. The basic principle underlying such methods can be illustrated with a simple arrangement shown in Fig. 1.

Consider a coil placed over an electrically conducting, non-ferromagnetic test specimen. If the coil is excited by an alternating-current source, an alternating magnetic field is established. The alternating magnetic field causes currents to be induced in the conducting test specimen in accordance with the Maxwell-Faraday law. The induced currents are called eddy

Figure 1. Eddy current probe over a conducting test specimen.

Figure 2. Exaggerated view of the impedance-plane trajectory of a coil over a conducting nonferromagnetic test specimen.

currents since they follow closed circulatory patterns that are similar to eddies found in bodies of water. The alternating eddy current, in turn, establishes a field whose direction is opposite to that of the original or primary field. Consequently, the net flux linkages associated with the coil decreases. Since the inductance of a coil is defined as the number of flux linkages per ampere, the effective inductance of the coil decreases relative to its value if it were to be suspended in air. The presence of eddy currents in the test specimen also results in a resistive power loss. The effect of this power loss manifests in the form of a small increase in the effective resistance of the coil. An exaggerated view of the changes in the terminal characteristics of the coil is shown in Fig. 2, where the variation in resistance and inductance is plotted in the impedance plane. When a flaw or inhomogeneity whose conductivity differs from that of the host specimen is present, the current distribution is altered. Consequently, the impedance of the coil changes relative to its value obtained with an unflawed specimen, as shown in Fig. 2. A system that is capable of monitoring the changes in impedance can, therefore, be used to detect flaws in a specimen that is scanned by a coil. It is not necessary to rely on impedance measurements to detect the presence of flaws. Systems that rely on the measurement of the coil currents and voltages have also been used for detecting flaws. A more detailed discussion relating to variations of the method as well as some simple transducer configurations follows after a brief introduction to the underlying theory.

MATHEMATICAL MODEL

The eddy current nondestructive evaluation phenomena, in common with all electromagnetic phenomena, are governed by Maxwell's equations (3). Three of these equations that are pertinent to eddy current testing are

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \quad (1)$$

$$\nabla \times \mathbf{H} = \mathbf{J} + \frac{\partial \mathbf{D}}{\partial t} \quad (2)$$

$$\nabla \cdot \mathbf{B} = 0 \quad (3)$$

where $\mathbf{E}$ is the electric field intensity (V/m), $\mathbf{H}$ is the magnetic field intensity (A/m), $\mathbf{B}$ is the magnetic flux density (Wb/m²) and $\mathbf{J}$ is the current density (A/m²). The coil excitation frequencies are typically very low (<10 MHz) and consequently the

displacement current term ($\partial \mathbf{D}/\partial t$) in Eq. (2) can be neglected. Equation (2), therefore, reduces to

$$\nabla \times \mathbf{H} = \mathbf{J} \quad (4)$$

Since $\mathbf{B}$ is divergence free, it can be expressed as

$$\mathbf{B} = \nabla \times \mathbf{A} \quad (5)$$

where $\mathbf{A}$ is called the vector magnetic potential. Substituting Eq. (5) in Eq. (1) and using Eq. (4) as well as the constitutive relationships $\mathbf{B} = \mu \mathbf{H}$ and $\mathbf{J} = \sigma \mathbf{E}$, the following result can be derived:

$$\nabla \times \frac{1}{\mu} \nabla \times \mathbf{A} = \mathbf{J}_s + \sigma \frac{\partial \mathbf{A}}{\partial t} \quad (6)$$

where $\mathbf{J}_s$ is the applied or impressed current density. Equation (6) is a parabolic partial differential equation that governs the physical process underlying eddy current phenomena and is applicable for situations involving both sinusoidal as well as nonsinusoidal excitation. If the coil is excited by a sinusoidal source, then, the governing equation can be simplified, assuming steady state conditions to the elliptic equation,

$$\nabla \times \left(\frac{1}{\mu} \nabla \times \mathbf{A} \right) = \mathbf{J}_s - j\omega\sigma \mathbf{A} \quad (7)$$

where $\omega = 2\pi f$ is the angular excitation frequency (rad/s) and $j = \sqrt{-1}$. The partial differential equation represented by Eqs. (6) or (7) can be solved with appropriate boundary conditions to obtain the vector magnetic potential A in the region of interest.

Other measurement quantities of interest, such as the coil impedance Z , induced coil voltage V_i , and eddy current density $\mathbf{J}_e$ can be derived using

$$Z = \left(\frac{j\omega}{I_s} \right) \int_c \mathbf{A} \cdot d\mathbf{l} \quad (8)$$

$$V_i = (j\omega) \int_c \mathbf{A} \cdot d\mathbf{l} \quad (9)$$

$$\mathbf{J}_e = -j\omega\sigma \mathbf{A} \quad (10)$$

The solution of the underlying partial differential equation is fraught with several challenges due to the awkward boundary conditions. Analytical as well as numerical approaches to addressing the problem are discussed in a later section.

The electromagnetic field decays exponentially as a function of depth within the test specimen. Eddy current methods, as a general rule, are not very effective for detecting defects that lie deep in the material. The rate of decay is a function of the excitation frequency f , as well as the conductivity and permeability of the test specimen. A useful index that is often employed in industry is called the skin depth. The skin depth δ is defined as the depth at which the eddy current decays to $1/e$ or 36.8% of the value at the surface. If an infinite sheet of current is induced at the surface of a conducting half-plane, the current decays to $1/e$ of the value at the surface, at a depth δ

given by

$$\delta = \frac{1}{(\pi f \mu \sigma)^{1/2}} \quad (11)$$

Although the value of the skin depth as given by Eq. (11) is applicable for the theoretical case of a half-plane specimen, it is nevertheless often used as a guide for choosing the excitation frequency for a given test specimen. Lower excitation frequencies have to be employed for detecting flaws that are located deep in the specimen. Likewise, the skin depth “rule” dictates that, other factors being equal, lower excitation frequencies have to be used when the specimen conductivity is high.

Eddy Current Probes

A variety of eddy current probes are in use today, and a full discussion relating to their type and characteristics is beyond the scope of this short article. The eddy current probe described in the introductory section is an absolute probe. In practice the change in the impedance of the coil due to a defect is very small relative to its quiescent value. The challenges associated with the measurement of these small perturbations in the presence of variations contributed by changes in the environment (temperature, noise, etc.) can be formidable. Differential probes (1,4) are often used to overcome some of these problems. Figure 3 shows a simple differential eddy current probe that is used for inspecting tubes. The probe consists of two identical coils that are spaced apart by a small distance. Consider a situation in which the probe is moved past a small defect such as a crack. When the probe is positioned in a defect-free region of the tube, the impedances of the two coils are identical. Consequently the differential impedance is zero. As the leading

Figure 3. (a) Differential eddy current probe used for inspecting tubes; (b) Impedance-plane trajectory traced for an OD slot on the tube.

Figure 4. High-resolution eddy current probe.

coil moves past the defect, the change in its impedance causes the differential impedance to trace one of the lobes (lobe A) shown in Fig. 3. When the defect lies between the two coils, the impedances of the both coils are equal and hence the differential impedance is zero. When the trailing coil moves past the defect the second lobe (B) in the impedance plane trajectory is traced. After the trailing coil has moved past the defect, the differential impedance reduces to zero. The shape of the impedance plane trajectory is a function of the shape of the defect, excitation frequency, and probe design. Defect characterization usually involves analysis of the impedance plane trajectory. The differential nature of the probe makes it relatively insensitive to effects of temperature and variations in the spacing between the specimen and the probe (often called the lift-off). The probe is also, unfortunately, less sensitive to long axial cracks. Several variations of the basic design have been proposed in recent years to overcome this deficiency. Commercial absolute probes often use a differential arrangement in which the reference coil is located away from the specimen. The difference in the impedances of the two coils is measured.

The electromagnetic "footprint" of most eddy current probes is large. This contributes to poor resolution and the need for using deconvolution procedures. One of the most commonly used techniques is to employ a ferrite core with a small tip to improve resolution. The ferrite core concentrates the field, thereby improving the resolution. Other methods include the use of copper shielding (4) as well as active compensation methods (through the use of auxiliary coils) (5). Figure 4 shows an alternative approach involving the use of a large excitation coil combined with a very small sensor or pickup coil. The small size of the sensor coil improves the resolution. Other probe designs include those that rely on the establishment of a uniform field and the detection of small perturbations in the field. Nuclear utilities also employ probes that rotate for inspecting tubes (4).

A number of new field sensors have emerged in recent years. High-sensitivity Hall sensors and magnetodiodes as well as self-contained sensors that include amplifiers and temperature compensation circuits are increasingly being used as sensors instead of coils. Another exciting development is related to the availability of relatively low-cost superconducting quantum interference devices (SQUIDS) (6), which are capable of measuring extremely low fields. Several researchers are investigating the feasibility of using such sensors for detecting extremely small and deeply embedded defects.

EDDY CURRENT TECHNIQUES

The test setup used in the introductory section to explain the concept of eddy current testing involved the use of a single coil

excited by an alternating current source. Several variations of this basic scheme are used in industry.

A simple extension of the concept is to employ multiple excitation frequencies to exploit the fact that the depth of penetration is a function of the excitation frequency. Defects and artifacts that are close to the surface can be detected with greater levels of sensitivity using high-frequency excitation signals. Low excitation frequencies can be used to detect defects that lie in the recesses of the material. The responses obtained at the two excitation frequencies can be combined appropriately to suppress contributions selectively from extraneous artifacts that are present in the vicinity of the defect and prevent direct observation of the defect signal. The excitation signals can be applied to the eddy coil either sequentially in a time division or simultaneously in a frequency-division multiplexed manner.

As an example, multifrequency methods are used extensively in nuclear utilities for extracting defect signals that are masked by unwanted signals from artifacts such as support plates. Consider a case where a small defect exists in a tube, which is anchored and held in place by a support plate as shown in Fig. 5. If the tube is inspected using a differential eddy current probe, the signals due to the defect and the support plate would overlap, particularly if the flaw were to be close to the plate. This is evident from Fig. 6(a), which shows a composite impedance-plane trajectory. The defect signal is clearly corrupted by the larger support-plate signal. Multifrequency methods involve measurement of the eddy current signal at two different excitation frequencies. The first signal is captured using a high excitation frequency so as to obtain a response that is relatively more sensitive to the defect. The second signal is captured using a low excitation frequency to obtain a relatively high level of sensitivity to the support plate. Figures 6(a) and 6(b) represent impedance-plane trajectories obtained at high and low excitation frequencies, respectively. The two signals are then "mixed" to suppress the support-plate signal. Mixing is performed by first transforming (rotating, scaling, and translating) the second impedance-plane trajectory. The

(a)

(b)

(c)

Figure 6. (a) Composite impedance-plane trajectory obtained at 400 kHz excitation frequency; (b) Composite impedance-plane trajectory obtained at 200 kHz; (c) Signal obtained after mixing signals shown in (a) and (b).

transformation parameters are chosen such that the transformed and the second impedance-plane trajectory are as similar as possible to each other. The transformed signal is subtracted from the first signal to obtain the defect signal. Figure 6(c) shows the result of mixing the signals shown in Figs. 6(a) and 6(b). The mixing can be accomplished either manually or automatically (7,8) by estimating the transformation parameters in a manner that minimizes an appropriate cost function. The cost

Figure 7. Typical remote-field eddy current probe arrangement.

function could, for example, be the energy in the error between the transformed and first impedance-plane trajectories. This example shows how a pair of eddy current signals obtained at two different excitation frequencies can be “mixed” to suppress indications from unwanted artifacts. The concept can be easily extended for mixing more than two signals for suppressing one or more artifact indications.

Skin-effect considerations limit the use of conventional eddy current methods to the detection of either surface breaking or shallow defects. Inner-diameter (ID) eddy current probes, for example, are more sensitive to defects that lie on the inner surface of thick-walled tubes. Special techniques that increase the level of penetration or alternatively the use of high-sensitivity sensors such as SQUIDs are required if ID probes are to be used. Recent years have witnessed the growth in popularity of a new technique that exploits the remote-field eddy current phenomenon (9,10). A major advantage lies in the sensitivity of the technique to inner- as well as outer-diameter (OD) defects. Figure 7 shows a typical remote-field eddy current probe used for the inspection of pipes. An excitation coil that is energized by a relatively low-frequency ac source establishes the eddy current field. Remote-field eddy current methods employ measurements taken at a distance from the excitation coil, unlike conventional methods that rely on field measurements in the vicinity of the excitation coil. The sensor coil is typically located two to three pipe diameters away from the excitation coil along the axis of the pipe. The eddy current field distribution can be divided into three regions. The field in the vicinity of the excitation coil (region 1) follows intuition in that the field magnitude decays exponentially with increasing radial distance from ID to OD. In the remote region (region 3), which occurs at a distance two to four pipe diameters away from the excitation coil along the axis of the pipe, the field magnitude decays from the OD to ID. This is in complete contrast to the behavior of the field in the vicinity of the excitation coil. The field distribution in the transition zone between these two regions (region 2) is characterized by very rapid changes. Energy that is directed outward, away from the excitation coil, interacts with the energy that travels close to the outer surface before traveling inward. The interaction causes the eddy current and vector magnetic potential magnitudes to drop to zero (potential valleys) at points in the pipe wall. Similarly, the phase of the eddy current undergoes rapid transitions (phase knots) in the pipe wall. Figure 8 shows the energy-flow pattern in the pipewall. The phenomenon is interesting in that it is characterized by a process wherein the field levels decay both from ID to OD (region 1) as well as from OD to ID (region 3). This renders the method sensitive to both ID as well as OD flaws in contrast to conventional eddy

Figure 8. Energy-flow pattern in the pipewall.

current methods that are sensitive to ID flaws only (for an ID probe).

Unlike conventional eddy current methods, the remote-field methods typically involve the measurement of the phase difference between the excitation signal and the voltage induced in the sensor coil. A lock-in amplifier is typically used since the field values in the remote and transition regions are very low and measurement is difficult due to poor signal-to-noise ratios.

The remote-field eddy current methods are used largely for the inspection of ferromagnetic tubes. Extensions of the method for the inspection of nonferromagnetic pipes as well as flat sheets and plates have been proposed in recent years. The industry has been quick to exploit the phenomena and many commercial systems are now available.

Multifrequency methods use two or more excitation frequencies to exploit the skin-effect phenomenon and to heighten selectively the flaw detection sensitivity at various depths. An alternative is to use a spectrally rich signal such as a pulse to excite the probe (11). Figure 9 shows a typical setup using a pulsed eddy current to inspect spot welds. A relatively high-energy pulse energizes the excitation coil. The energy diffuses through the material and induces a signal in the sensor coil. The sensor coil signal is analyzed to ascertain the condition of the test specimen. Pulsed eddy current methods are used for characterizing thin films, spot welds, and a host of other applications.

Figure 9. Typical pulsed eddy current probe setup for inspecting spot welds.

Instrumentation. The instrumentation used is simple and straightforward. Figure 10 shows a block diagram of a typical eddyscope. The excitation coil is energized by a variable frequency sinusoidal current source. If the impedance of the coil is $Z \angle \theta$ then the voltage across the coil is

$$V = I|Z| \cos(2\pi f_c t + \theta) \quad (12)$$

where f_c is the excitation frequency (Hz), $\theta = \tan^{-1}(2\pi f_c L/R)$ (rad), L is the effective inductance of the coil (H), and R is the effective resistance of the coil (Ω). The signal V is amplified using a low-noise, wideband amplifier.

The real component of the eddy current probe impedance is obtained by demodulating the amplified signal with the in-phase output ($A \cos 2\pi f_c t$) of the variable-frequency oscillator and low-pass filtering the result. The output of the demodulator is

$$\begin{aligned} V_p &= k \cos(2\pi f_c t + \theta) \cos(2\pi f_c t) \\ &= \frac{k}{2} [\cos(4\pi f_c t + \theta) + \cos(\theta)] \end{aligned} \quad (13)$$

where k is related to the magnitude of the eddy current probe impedance Z . The high-frequency component is filtered by a low-pass filter. The output of the low-pass filter is

$$V_r = C_1 |Z| \cos(\theta) \quad (14)$$

where C_1 is a constant.

Similarly, the imaginary component of the eddy current probe impedance is obtained by demodulating the amplified signal with the quadrature output ($A \sin 2\pi f_c t$) of the oscillator and low-pass filtering the output. The output of the demodulator is

$$\begin{aligned} V_q &= k \cos(2\pi f_c t + \theta) \sin(2\pi f_c t) \\ &= \frac{k}{2} [\sin(4\pi f_c t + \theta) + \sin(\theta)] \end{aligned} \quad (15)$$

Figure 10. Block diagram of a single-frequency eddyscope.

The output of the low-pass filter is

$$V_i = C_2 |Z| \sin \theta \quad (16)$$

where C_2 is a constant. V_r and V_i are outputs that are related to the real and imaginary components of the probe impedance. Most commercial instruments allow the signals to be sampled, digitized, and stored in memory. Eddyscopes also offer a feature that permits the impedance-plane trajectories to be rotated through an arbitrary angle θ_r . The output of the rotator is given by

$$x = V_r \cos \theta_r - V_i \sin \theta_r \quad (17)$$

$$y = V_i \cos \theta_r + V_r \sin \theta_r \quad (18)$$

The rotation feature allows the user to rotate the signal and ensure that signal changes due to lift-off (distance between the probe and the test specimen) variations result in a trajectory that is either along the real or imaginary axis. After the rotation angle is adjusted, subsequent measurements are projected along the other axis to obtain relative immunity to the effects of lift-off.

Most eddyscopes are either housed in or interfaced to a personal computer. Highly sophisticated signal-processing algorithms can be implemented on the computer to analyze the signals.

Multifrequency eddy current instruments are similar to single-frequency instruments except that it is possible to apply two or more excitation signals to the eddy current coil either simultaneously or in a time-multiplexed mode. If the excitation signals are applied in a time-multiplexed mode, an appropriate time-windowing scheme is employed to separate the individual eddy current responses at each excitation frequency. If the excitation signals are applied simultaneously, classical frequency-division demultiplexing methods can be used to isolate the individual eddy current responses (12).

FORWARD PROBLEM MODELING

Computational eddy current models are extremely valuable in providing a visualization of the field distribution around the probe coil and the test sample. Such capabilities help not only in understanding the physics of the underlying process but also in optimization of probe design as well as the development of defect characterization schemes for mapping measured eddy current signals onto defect profiles. Eddy current models developed to date fall broadly into two main classes, namely, analytical and numerical.

Analytical Models

One of the earliest analytical results for the eddy current phenomenon was obtained by Dodd and Deeds (13). The governing equation in terms of the vector magnetic potential $\mathbf{A}$ for a linear isotropic, homogeneous media due to applied current density $\mathbf{J}_s$ is

$$\nabla^2 \mathbf{A} = -\mu \mathbf{J}_s + \mu \sigma \frac{\partial \mathbf{A}}{\partial t} \quad (19)$$

In the case of an axisymmetric geometry with only the ϕ component of $\mathbf{J}$ and $\mathbf{A}$, and a sinusoidal excitation, the equation in cylindrical coordinates is

$$\frac{\partial^2 \mathbf{A}}{\partial r^2} + \frac{1}{r} \frac{\partial \mathbf{A}}{\partial r} + \frac{\partial^2 \mathbf{A}}{\partial z^2} - \frac{\mathbf{A}}{r^2} = -\mu \mathbf{J}_s + j\omega \mu \sigma \mathbf{A} \quad (20)$$

Assuming the probe to be a δ -function coil at (r_0, z_0) , the equation becomes

$$\frac{\partial^2 \mathbf{A}}{\partial r^2} + \frac{1}{r} \left(\frac{\partial \mathbf{A}}{\partial r} \right) + \frac{\partial^2 \mathbf{A}}{\partial z^2} - \frac{\mathbf{A}}{r^2} - j\omega \mu \sigma \mathbf{A} = \mu \mathbf{J}_s \delta(r - r_0) \delta(z - z_0) \quad (21)$$

This equation is solved using the separation of variables method for a coil over a planar conductor or a coil inside a cylindrical

tube as shown in Fig. 3(a). The solution for both geometries are given in terms of integrals of Bessel functions. The vector potential due to other coil configurations is then obtained using the superposition principle.

In an attempt to establish a more quantitative interpretation of the eddy current response, Auld et al. (14) formulated a mathematical flaw response model for rectangular surface-breaking defects based on the Lorentz reciprocity relation

$$\nabla \cdot (\mathbf{E}' \times \mathbf{H} - \mathbf{E} \times \mathbf{H}') = 0 \quad (22)$$

where $\mathbf{E}$, $\mathbf{H}$ and $\mathbf{E}'$, $\mathbf{H}'$ are solutions of Maxwell's equations, at any point in the presence and absence of the flaw, respectively.

A third approach for obtaining an analytical solution proposed by Sabbagh et al. (15) uses the volume integral formulation. Based on an algorithm used for simulating the electromagnetic responses of three-dimensional bodies in layered media (16), Sabbagh et al. developed an eddy current NDT model where the inhomogeneities in a conducting specimen are replaced by an equivalent current distribution approximated by pulse basis functions. The current source representing the flaw produces a perturbation field at the probe coil that is then responsible for the eddy current signal. The change in probe impedance due to a flaw is defined as

$$\Delta Z = \frac{(\text{emf induced by the perturbed field at the coil})}{(\text{excitation current})} \quad (23)$$

The conductivity $\sigma_0(\mathbf{r})$ of the test material is expressed as $\sigma_0(\mathbf{r}) = \sigma_f(\mathbf{r}) + \delta\sigma_0(\mathbf{r})$, where $\sigma_f(\mathbf{r})$ is the conductivity of a flaw and $\delta\sigma_0(\mathbf{r})$ is the perturbation in conductivity

$$\delta\sigma_0(\mathbf{r}) = \begin{cases} 0 & \text{outside the defect} \\ \sigma_f(\mathbf{r}) - \sigma_0(\mathbf{r}) & \text{inside the defect} \end{cases} \quad (24)$$

Substituting this conductivity function into the diffusion equation for $\mathbf{E}$, we see that the discontinuity in conductivity introduces a perturbation source term in the equation as

$$\mathbf{J}_f = [\sigma_f(\mathbf{r}) - \sigma_0(\mathbf{r})]\mathbf{E}(\mathbf{r}) \quad (25)$$

$$\nabla^2 \mathbf{E} - j\omega\mu\sigma_0\mathbf{E} = j\omega\mu\mathbf{J}_0 + j\omega\mu[\sigma_f(\mathbf{r}) - \sigma_0(\mathbf{r})]\mathbf{E} \quad (26)$$

The implementation of this method for the axisymmetric geometry consisting of an excitation and pickup coil pair moving in the interior of a tube consists of the following steps.

1. Compute the Green's function for the desired positions of the source. For the given geometry, $G_{ij}(\mathbf{r}, \mathbf{r}')$ corresponds to a field at $\mathbf{r}$ in region i due to a filamentary coil at $\mathbf{r}'$ in region j . The regions are labeled as 1, tube interior; 2, tube wall; 3, tube exterior.
2. Calculate the unperturbed field for the defect-free medium as

$$\mathbf{E}_0(\mathbf{r}) = \int_{\text{coil}} G(\mathbf{r}, \mathbf{r}') \mathbf{J}_0(\mathbf{r}') d\mathbf{r}' \quad (27)$$

3. Calculate the equivalent current source $\mathbf{J}_f(\mathbf{r})$ for the flaw by solving

$$\mathbf{E}_f(\mathbf{r}) = \mathbf{E}_0(\mathbf{r}) + \int_{\text{flaw}} G_{12}(\mathbf{r}, \mathbf{r}') [\sigma_f(\mathbf{r}') - \sigma_0(\mathbf{r}')] \mathbf{E}_f(\mathbf{r}') d\mathbf{r}' \quad (28)$$

4. Compute the perturbation field at the coil using the current source from step 3:

$$\mathbf{E}_f(\mathbf{r}) = \mathbf{E}_0(\mathbf{r})|_{\text{coil}} = \int_{\text{flaw}} G_{12}(\mathbf{r}, \mathbf{r}') \mathbf{J}_f(\mathbf{r}') d\mathbf{r}' \quad (29)$$

5. Compute the emf induced in the coil using

$$\text{emf} = n \int_{\text{coil}} \mathbf{E}_f(\mathbf{r}) \cdot d\mathbf{l} \quad (30)$$

The eddy current probe impedance is then calculated using $Z = \text{emf}/I$.

Numerical Models

Analytical models are desirable because they provide exact closed-form solutions that provide a functional relation between experimental parameters and the measured eddy current signal. However, the relative complexity of such methods and their limitations in terms of their inability to deal with nonlinearities and the restricted classes of problem geometries that can be handled have limited their usefulness. In contrast, numerical solutions are not limited by geometrical complexities or material nonlinearities. The high-speed computational power and storage capabilities of modern-day computers have led to the extensive development and use of numerical techniques for solving and simulating a wide variety of physical situations. The principal numerical methods that are in use in electromagnetic NDT are the finite-difference, finite-element, and hybrid techniques such as boundary-element methods.

Finite-Difference Formulation. The finite-difference method is based on replacing domains and differential operators by a discrete grid of nodes and difference quotients, respectively. Once the difference equations are obtained, the task of solving the problem numerically consists of writing the difference equations for each nodal point in the grid in terms of the values at the appropriate neighboring nodes. This results in a set of linear algebraic equations written in a matrix form. The matrix of coefficients is then inverted to obtain the unknown fields at the nodal points.

Dodd (17) solved the complete, nonlinear eddy current problem for the inhomogeneous material case using finite-difference operators. For axisymmetric geometries such as a coil above a conducting plane or a coil encircling a tube with sinusoidal excitation, the equation can be written as

$$\begin{aligned} \frac{\partial^2 A}{\partial r^2} + \frac{1}{r} \frac{\partial A}{\partial r} + \frac{\partial^2 A}{\partial z^2} - \frac{A}{r^2} \\ = -\mu J_s + j\omega\mu\sigma A - \mu \left[\frac{\partial}{\partial r} \left(\frac{1}{\mu} \right) \left(\frac{1}{r} \frac{\partial r A}{\partial r} \right) + \frac{\partial}{\partial z} \left(\frac{1}{\mu} \right) \frac{\partial A}{\partial z} \right] \end{aligned} \quad (31)$$

Using central difference operators for all differentiations except for permeability variations across interface boundaries where forward difference operators are used, the vector potential at a point (r, z) in terms of four nearest neighbors is

$$A_{r,z} = \left(\frac{1+a}{r} \frac{\mu_{r,z}}{\mu_{r+a,z}} A_{r+a,z} + A_{r-a,z} + \frac{\mu_{r,z}}{\mu_{r,z+a}} A_{r,z+a} + A_{r,z-a} + a^2 \mu_{r,z} J_{r,z} \right) + \left(z + \frac{a}{r} + \frac{a^2}{r^2} + \frac{\mu_{r,z}}{\mu_{r+a,z}} + \frac{\mu_{r,z}}{\mu_{r,z+a}} + ja^2 \omega \mu_{r,z} \sigma_{r,z} \right) \quad (32)$$

where $\mu_{r,z}$, $J_{r,z}$, and $\sigma_{r,z}$ have specified values at each nodal point in the two-dimensional rectangular grid. The nonlinearities associated with medium permeability are also incorporated in the formulation without additional computations.

The major disadvantage of the finite-difference method (17) is one of fitting a regular grid to geometries that have curved boundaries and interfaces. One has to resort to using a mixture of rectangular and cylindrical coordinates, resulting in added complexity of programming and implementation. Also, increasing the mesh density to satisfy the boundary requirements may result in a large grid size and computer requirements without contributing to the accuracy of the final solution.

Finite-Element Formulation. A more widely used numerical model employs finite-element (FE) analysis techniques and has its origin in the fields of solid mechanics, structural analysis, and heat transfer. Finite-element analysis techniques was first applied by Chari to electromagnetics (18) for studying the eddy current problem in magnetic structures and later by Brauer (19) for determining induced fields and currents in transformers. The modeling technique was then used extensively by Lord and associates for the investigation of various problems in electromagnetic NDT. Palanisamy and Lord (20,21) developed a two-dimensional axisymmetric finite-element model for predicting eddy current probe signals from defects in steam generator tubing. Ida (22) developed a three-dimensional finite-element model for eddy current nondestructive evaluation applications.

The finite-element technique is based on principles of variational calculus (23) in which the solution of a differential equation is obtained as the stationary value of a functional. In eddy current problems, the functional represents the energy of the system so that the stationary value is a minimum. The principles of variational calculus can be used to show that the differential equation is satisfied by a function that simultaneously minimizes the appropriate energy functional (24). A brief description of the finite-element formulation for an axisymmetric geometry of a differential coil probe inside a tube follows.

Assuming a linear, isotropic, and homogeneous medium and a sinusoidal excitation source, the governing diffusion Eq. (20) is

$$\frac{1}{\mu} \left(\frac{\partial^2 \mathbf{A}}{\partial r^2} + \frac{1}{r} \frac{\partial \mathbf{A}}{\partial r} + \frac{\partial^2 \mathbf{A}}{\partial z^2} - \frac{\mathbf{A}}{r^2} \right) = j\omega\sigma \mathbf{A} - \mathbf{J}_s \quad (33)$$

The corresponding energy functional obtained from variational principles is

$$F = \iint_R \left[\frac{1}{2\mu} \left(\left| \frac{\partial \mathbf{A}}{\partial r} + \frac{\mathbf{A}}{r} \right|^2 + \left| \frac{\partial \mathbf{A}}{\partial z} \right|^2 \right) + \frac{j\omega\sigma}{2} |\mathbf{A}|^2 - \mathbf{J}_s \times \mathbf{A} \right] r dr dz \quad (34)$$

The terms in Eq. (34) can be recognized as the energy terms due to the magnetic field, eddy currents, and the input source.

The region of interest is discretized using a mesh consisting of triangular elements connected to each other at the nodes. A sample FE mesh for the axisymmetric geometry in Fig. 3 is shown in Fig. 11. Using linear or higher-order interpolation functions $[N]$ to express the magnetic vector potential $\mathbf{A}$ at any point within an element, the energy functional for an element can be written in terms of its unknown nodal values A_i, A_j, A_k as

$$F_e = \int_v \frac{1}{2} \left[\frac{1}{\mu} \left(\frac{\partial N}{\partial y} \right)^2 + \frac{1}{\mu} \left(\frac{\partial N}{\partial x} \right)^2 - 2J[N] \right] \begin{bmatrix} A_i \\ A_j \\ A_k \end{bmatrix} \quad (35)$$

(a)

(b)

Figure 11. (a) Two-dimensional region in the axisymmetric geometry; (b) FE mesh of the region in (a).

Minimizing F_e with respect to the nodal point values gives a set of linear algebraic equations

$$\frac{\partial F_e}{\partial A_l} = 0, \quad l = i, j, k \quad (36)$$

in three unknowns A_i, A_j, A_k . These individual element equations are combined into a single global matrix equation

$$\left[\begin{array}{c} \text{Diagram of a rectangular element} \end{array} \right] \begin{Bmatrix} A_1 \\ A_2 \\ \vdots \\ A_M \end{Bmatrix} = \begin{Bmatrix} Q_1 \\ Q_2 \\ \vdots \\ Q_M \end{Bmatrix} \quad (37)$$

Due to the banded, symmetric, and sparse nature of the matrix, direct inversion techniques such as the Gaussian elimination method can be used to solve for the unknown vector magnetic potentials at the nodal points in the mesh.

Calculation of Eddy Current Probe Impedance

In eddy current NDT, the physical quantity that is usually measured is the impedance of the probe. The eddy current probe impedance is derived from nodal values of magnetic vector potential. The impedance Z of a single-turn coil of radius r carrying an alternating current of I_s amperes is

$$Z = \frac{V}{I_s} \quad (38)$$

where V is the phasor voltage across the coil,

$$V = - \oint_c \mathbf{E} \cdot d\mathbf{l} \quad (39)$$

Using the Maxwell–Faraday law in terms of the vector magnetic potential, $\mathbf{E}$ can be expressed as

$$\mathbf{E} = \frac{-\partial \mathbf{A}}{\partial t} - \nabla \phi \quad (40)$$

which for sinusoidal excitation reduces to

$$\mathbf{E} = -j\omega \mathbf{A} - \nabla \phi \quad (41)$$

Since the induced voltage is independent of the scalar potential, Eq. (41) can be substituted in Eq. (39) to get

$$\mathbf{E} = -j\omega \oint_c \mathbf{A} \cdot d\mathbf{l} \quad (42)$$

The impedance of the coil is

$$Z = -\frac{j\omega}{I_s} \oint_c \mathbf{A} \cdot d\mathbf{l} \quad (43)$$

which for a single-turn coil is

$$Z = j \frac{2\pi r \omega A}{I_s} \quad (44)$$

Model predicted eddy current differential probe signals for both outside-diameter and inside-diameter defects in a steam generator tube compare very well with experimental measurements (20).

The finite-element method is a very powerful tool for analyzing nonlinear, inhomogeneous boundary-value problems. Nonlinearities and inhomogeneous material properties can be incorporated very simply by specifying the material constants appropriately in each element of the discretized domain. A major advantage of the finite-element technique is that irregularly shaped boundaries can be handled easily. It is therefore ideally suited for modeling NDT problems. The boundary conditions are introduced naturally in the process of formulation of the model. Also, since the nodes do not have to be equally spaced, the mesh density can be varied depending on the field gradient in a subdomain, resulting in computational efficiencies. Finally, the implementation is relatively simple and since the matrices involved in finite-element models are sparse, banded, symmetric and diagonally dominant, the inversion process is numerically stable and robust.

The finite-element eddy current model has been extended to simulate the pulsed eddy current phenomenon (25). In this method, the spatial solution of the conventional eddy current model is combined with a finite-difference formulation in the time domain to calculate the transient solution. The model is capable of simulating the diffusion of fields into the test sample, spatial broadening of the eddy current pulse, and a propagation delay time that is proportional to the distance traveled.

EDDY CURRENT INVERSE PROBLEM

The final goal of a nondestructive test is to solve the inverse problem. The complete solution to the inverse problem involves full reconstruction of defect profiles from the sensor measurements. In eddy current testing, the physical process associated with eddy current phenomenon is diffusive in nature. This renders the task of solving the inverse problem relatively difficult. The intractable nature of the inverse problem in eddy current nondestructive evaluation (NDE) has led to the development of several engineering approaches to address the issue. One of the earliest and most widely used approaches is the calibration method, in which features associated with the measured data are compared to those derived from a set of standard signals obtained from known defects. Calibration plots for eddy current probe signals were obtained by Auld et al. (26) in which features derived from an absolute coil probe signal are directly related to defect parameters. For instance, when the flaw dimensions are larger than the coil diameter, the signal exhibits distinct “shoulders” that can be mapped to edges of the defects. The calibration plot using the features in the signal for different defect widths and theoretical inversion charts using magnitude and phase of the signal to predict defect depths are also given in Ref. 26. These procedures characterize defects in terms of an equivalent depth, width, and angle or equivalent volume. It must be mentioned that calibration methods are useful only when the defect shapes are known a priori. The method becomes invalid if the defect shapes are substantially different from the shapes of the calibration defects.

With increasing availability of greater computing resources, more sophisticated approaches to numerical inversion algorithms have been developed. These algorithms can be

Figure 12. Taxonomy of inverse-problem solution methods.

categorized broadly either as phenomenological or model-based and nonphenomenological or signal-classification-based methods, based on the strategy used to arrive at the inverse solution. Phenomenological models are constructed on the basis of the underlying physical process. In contrast, signal classification methods use changes in the signal features to determine the defect class. A taxonomy of inverse problem solution methods in NDE is described in Fig. 12 and an overview of some of the key work in these classes is described.

MODEL-BASED METHODS

In this section, three representative model-based approaches are discussed for finding the inverse-problem solution in terms of the defect profile in a test object. The first method is based on a volume integral formulation. The second approach uses an error minimization approach that involves the use of a neural network for minimizing the quadratic error function. The third approach uses a finite element forward model in an iterative scheme to determine the defect profile.

Volume Integral Approach

This technique belongs to the category of direct approaches for the inverse-problem solution. A seminumerical approach proposed by Sabbagh et al. (15) uses an analytical formulation based on the Green's function where the inverse problem is reduced to solving an integral equation of the type

$$f(r) = \int_{\Omega} G(r, r') g(r') d\gamma' \quad (45)$$

for the source $g(r')$ from measurements $f(r)$, where the kernel $G(r, r')$ is the Green's function. For instance, in eddy current NDE, the volume integral equation for the electric field $\mathbf{E}$ is

$$\mathbf{E}(r) = \int_{\Omega} G(r, r') \mathbf{J}_s(r') dr' \quad (46)$$

A flaw of conductivity $\sigma_f(r)$ is modeled in a host material of conductivity $\sigma_h(r)$ by an equivalent current source

$$\mathbf{J}_s(r) = [\sigma_f(r) - \sigma_h(r)] \mathbf{E}(r) \quad (47)$$

The integral equation for the perturbation field $\mathbf{E}_p(r)$ due to the presence of the flaw is

$$\mathbf{E}_p(r) = \int_{\Omega_f} G(r, r') [\sigma_f(r) - \sigma_h(r)] \mathbf{E}(r') dv' \quad (48)$$

The discretization and the numerical solution of the resulting matrix give a solution of the inverse problem in terms of the conductivity profile $\sigma(r)$ of the test specimen.

Hopfield Network Approach

A novel strategy for solving Fredholm integral equations using the Hopfield neural networks was proposed by Elshafiey et al. (27). The major advantage of this method is the stability of the solution procedure that comes from the high degree of parallelism and interconnectivity used in the Hopfield network architecture.

In this algorithm, the integral in Eq. (45) is discretized using a basis-function expansion as

$$g(r) = \sum_{i=1}^n v_i R_i(r) \quad (49)$$

where $\{v_i\}$ are the expansion coefficients and R_i is a basis function, chosen to be a sine or cosine function. The integral equation is then written in matrix form as

$$FV = m + \eta \quad (50)$$

where $F_{ij} = \int_{\Omega} G(r, r') R_i(r') dr'$, $m_i = f(r_i)$, $i = 1, 2, \dots, n$ are the discrete measurements, and η represents measurement noise.

The solution vector $V = (v_1, v_2, \dots, v_n)$ is obtained by minimizing the cost function E written in matrix form

$$E = \frac{1}{2} (FV - m)^T (FV - m) + \lambda V^T DV + \lambda_1 (\Psi V - z_p)^T (\Psi V - z_p) \quad (51)$$

The first term in the cost function is the model error, the second term is a smoothness constraint included for regularization, and the third term represents the boundary conditions. Ψ is a matrix whose elements are basis functions, z_p is the system state at a given node p , and λ and λ_1 are Lagrange multipliers.

By comparing the error function in Eq. (51) to the energy function of the Hopfield neural network expressed in a similar quadratic form, the circuit parameters of the network are estimated. The network is then simulated for obtaining the solution to the integral equation. Once the Hopfield network converges to the solution vector $\mathbf{v}^* = (v_1^*, v_2^*, \dots, v_n^*)$, the defect profile can be computed using Eq. (49). The two methods just described are based on the solution of the integral equation, which, in turn, relies on the availability of the Green's function for the problem. Very often in many NDE test geometries,

Figure 13. Schematic representation of the solution to the inverse problem.

the computation of Green's function poses a serious challenge, limiting the applicability of the method.

An alternate scheme for eddy current inversion that overcomes this difficulty is to use the finite-element model (FEM) in the iterative scheme shown Fig. 13. In this technique, the defect is parametrized in terms of the depth coordinates at different points in the flaw region and the solution minimizes the mean-square error between the measured signal and model prediction (28).

Figure 13 outlines the procedure employed for solving the inverse problem. The iterative process starts by selecting an initial mesh configuration. The mesh coordinates are then updated until the signal predicted by the finite-element model matches the measured signal in the least-squares sense. Specifically, the coordinates of the defect profile are defined by a vector $D = (d_1, d_2, \dots, d_n)$, which represents the depth values of the defect profile at each position on the defect boundary. The elements above and below the defect boundary are compressed or expanded accordingly. By altering the mesh coordinates, rather than the material properties of the elements, derivatives of the unknown material property values do not have to be taken into account explicitly.

The optimal values of D are determined by minimizing an objective function of the summed square error evaluated at N measurement points:

$$F(D) = \sum_{i=1}^N (Z_i - Z_{mi})^2 \quad (52)$$

where Z_i ($i = 1, \dots, N$) is the calculated coil impedance using the FE method and Z_{mi} ($i = 1, \dots, N$) is the measured eddy current signal.

The error function defined by Eq. (52) is minimized using the sequential quadratic programming (SQP) approach (29). This well-known optimization procedure employs gradient information, which is derived analytically to establish the search direction. Changes in defect geometry are mapped onto a change of stiffness matrix K . The corresponding change in the source vector S is also automatically taken into account.

Model-based methods are, in general, computation intensive and are capable of determining the defect profiles only if the solution space is constrained to a suitable subspace. A different class of inversion techniques that is widely used in practice is the nonphenomenological or signal-classification approach.

SIGNAL-CLASSIFICATION METHODS

In this class of techniques, the continuum of solutions to the inverse problem is quantized into a finite number of known classes of sources or defects. These sources may represent defect classes or benign geometrical sources that also produce an eddy current signal. Examples of the latter class are the eddy current signals from edges or support-plate signals obtained in the inspection of steam-generator tubes in nuclear power plants.

A characteristic feature of all signal-classification or pattern-recognition methods is that they rely on the ability to create a data bank of all expected defect types and the corresponding signatures. This collection of signals is referred to as the training database, which is then used for training an automatic signal-classification algorithm. The classification techniques that have received a lot of attention in this area are (1) matched filters and (2) feature-based pattern-recognition methods.

Matched Filters

The matched filter (30) is a linear filter the transfer function of which is matched to a particular input signal, achieved by selecting the impulse response $h(t)$ of the filter as a reversed, shifted and scaled version of the signal $s(t)$ to which it is matched:

$$h(t) = ks(t_0 - t) \quad (53)$$

where k and t_0 are arbitrary constants. The filter then behaves as a simple correlation detector with transfer function:

$$H(j\omega) = ke^{-j\omega t_0} S^*(j\omega) \quad (54)$$

Mucciardi and Shankar (31) use this technique for the interpretation of steam-generation inspection signals. An array of filters is built in which each one is matched to the signal from a known class of defects. An unknown signal is then automatically classified by observing the response of the filters in the array.

The matched-filter algorithm is simple and easy to implement but is also prone to errors in case of any fluctuations in probe speed. Also, this procedure requires that the entire signal be stored in contrast to feature-based signal-classification methods that store and use only distinguishing features in the signal.

Feature-Based Methods

Feature-based methods form the core of automated signal-classification systems that are becoming increasingly popular in many commercial applications. An overall schematic of this approach is shown in Fig. 14.

The approach consists of two steps:

1. The first step is feature extraction, from which characteristic features in the signal that carry discriminatory information are extracted.
2. The second step is classification of the feature vector via a clustering algorithm or a neural network.

Figure 14. Schematic of the overall signal-classification procedure.

Feature Extraction. Feature extraction serves two major functions, namely, data compression and invariance processing. The vector of signal features referred to as the feature vector is extracted from a typically oversampled set of measurements. The feature extraction procedure is designed to eliminate the redundancy in the impedance plane trajectories. The entire signal is thus represented by a feature vector. The features are evaluated in the second step, called feature reduction, in which the goal is to identify those features containing the most amount of discriminatory information, in order to reduce the dimensions of the feature vector (32). One of the earlier methods used for feature reduction is the adaptive learning network, in which a polynomial representation is built from quadratic elements that use pairwise combinations of the features. The discriminatory performance of each polynomial fit is evaluated at each stage and only the “best” pairs are selected. The adaptive learning network was first introduced by Ivakhenko (33) and was applied for feature selection by Mucciardi and Shankar (31). An alternative method for feature reduction is the Fisher discriminant method (34), which calculates a statistical weight function for each feature as a measure of its ability to classify. The features are often picked from different domains, making it difficult to define a single quantitative measure for evaluating a figure of merit of the features. Furthermore, the time-domain features are sensitive to variations in probe speed and can consequently result in classification errors.

Parameter-Invariant Features. An example of features with invariance properties is obtained using a Fourier descriptor representation of eddy current impedance-plane trajectories. Fourier descriptors have been used for a long time for representing closed contours (35) in a variety of applications. This technique not only represents the signal by a few coefficients that are invariant under rotation, translation, and scaling of the eddy current impedance-plane trajectory, but also allows the resynthesis of the original signal from the stored coefficients. This results in data compression, and the error in the resynthesized signal can be used for a quantitative evaluation of the feature vector. The basic idea underlying the approach is to parametrize the impedance-plane trajectory such that the representation is periodic in the transformed domain. One such

function is the complex contour function (36)

$$u(l) = x(l) + jy(l) \quad (55)$$

where $x(l)$ and $y(l)$ represent the real and imaginary components of the impedance at a distance l arc length units away from an arbitrary starting point P_0 . Then $u(l)$ is periodic in l with period L ,

$$u(l + L) = u(l) \quad (56)$$

Here L represents the total arc length of the curve. The periodic nature of $u(l)$ allows its expansion in a Fourier series, that is,

$$u(l) = \sum_{n=-\infty}^{\infty} c_n e^{j(2\pi/L)nl} \quad (57)$$

where

$$c_n = \frac{1}{L} \int_0^L u(l) \exp\left(-\frac{j2\pi nl}{L}\right) dl \quad (58)$$

In order to obtain descriptors of the curve that are insensitive to drift and gain setting of the eddy current instrument, the coefficients in Eq. (58) are used to compute the descriptors

$$d_n = \frac{c_{l+n}c_{l-n}}{|c_1|^2} \quad (59)$$

The descriptors d_n , $n = 1, 2, \dots, N$ are insensitive to rotation, translation, and scaling of the curve. The implication of this invariance is that changes in the signal due to the instrument gain drift or gain settings will not affect the interpretation of the signal. The parametric representation $u(l)$ also ensures that variations in probe speed will not affect the final result.

The two procedures for feature extraction described previously illustrate the use of appropriate signal features for achieving data compression and invariance to selected experimental parameters. A K -means clustering or a neural network is used to classify the feature vector.

Classification Algorithms

The second step in signal-classification systems is the labeling of the feature vector. Two of the widely used techniques for classifying eddy current signals are (1) clustering algorithms and (2) neural networks.

K-Means Clustering. In a clustering algorithm, a feature vector of length n is treated as a point in an n -dimensional feature space. The set of feature vectors from a similar class of signals are expected to cluster together in the feature space. Clustering algorithms are capable of identifying the clusters in either a supervised (with training data) or unsupervised (without training data) mode. The K -means algorithm (34) partitions the set of feature vectors into K disjoint subsets such that a performance index is minimized. The performance index is typically chosen to be the sum of the squared Euclidean distances between a cluster center and all the points contained within that cluster. The algorithm is iterative in nature and during each cycle the cluster centers are updated. The performance of the algorithm can be improved significantly if the K cluster centers

Figure 15. Multilayer perceptron neural network.

during the first iteration are drawn from K different classes of signals in the training data.

Neural Networks. Neural networks represent an attempt to mimic the biological nervous system with respect to both architecture as well as information-processing strategies (37). These networks consist of simple processing elements that are interconnected via weights. The network is first trained using training data and an appropriate learning algorithm for the estimation of the interconnection weights. Once the network is trained, unknown test signals can be classified. The class of neural networks used most often for classification tasks is the multilayer perceptron (MLP) network (37) shown in Fig. 15.

The multilayer perceptron network generally consists of an input layer of nodes, one or more hidden layers of nodes, and an output layer of nodes. The nodes within the same layer are not connected but each layer of nodes are fully interconnected to the nodes in the next layer. All units within a layer process data in parallel, but the outputs of different layers are calculated sequentially starting from the input layer and moving towards the output layer. Each node j in a layer $k + 1$ performs the following computations.

Step 1. The input to node j , x_j , is

$$x_j = \sum_{i=1}^{N_k} w_{ij} y_i \quad (60)$$

where y_i is the output of node i in layer k , N_k is the number of nodes in layer k , and w_{ij} are the interconnection weights.

Step 2. The output of node j , y_j , is

$$y_j = f(x_j) = \frac{1}{1 + \exp[-(x_j + \theta_j)]} \quad (61)$$

where θ_j is a bias variable. This nonlinear function is primarily used to limit the output of a node between the values of 0 and 1.

One of the most commonly used training algorithms is the backward error propagation algorithm (38) in which training patterns are sequentially applied to the network. The algorithm uses a gradient search technique for minimizing the squared

error between the actual output and the desired output by iteratively adapting the interconnection weights. The algorithm cycles through the training data until the error drops below a specified threshold value. Neural networks have been used with considerable success in the classification of eddy current and ultrasonic NDE signals (39,40). These networks are also capable of learning in an incremental mode and use prior knowledge for improving its performance with time.

PULSED EDDY CURRENT SIGNAL PROCESSING

The processing of pulsed eddy current signals for defect characterization is based on a calibration approach where the features are peak amplitude and zero crossover point of the waveform (41). The peak amplitude is proportional to the amount of metal loss and the zero crossover point, which is proportional to the propagation time, carries information about the depth of the flaw. Time gated images of the peak voltage, called C-scan images, provide information relating to material properties at different depths within the sample. The pulsed eddy current technique has proved to be particularly advantageous in the inspection of multilayer structures encountered in the aerospace industry.

IMPULSE TESTING

All electrical equipment is subjected to voltage surges (impulses) during operation. These surges vary in magnitude and duration depending on their origin and the system parameters in which the equipment is installed. Impulse voltages generated in a piece of equipment or a system are termed overvoltages because they usually exceed the normal operating voltage.

In designing electrical equipment, two main factors are taken into consideration. The first is the insulation, which depends not only on the operating voltage but also on the voltage surges that it may be subjected to during operation. Consequently, the insulation of a piece of electrical equipment should provide complete isolation between electrically live parts and other parts, either live or dead, for the safety of the equipment and personnel. The second factor is the equipment current. It should not produce excessive heating, which may shorten the life of the equipment or damage its conducting and insulating materials.

Overvoltages in a piece of electrical equipment installed in a power system are generated either from external or internal sources. Lightning is an external source of overvoltage to power systems, which is usually characterized by large magnitudes and a short duration. Switching operations in power systems are internal sources of overvoltages and are characterized by lower magnitudes and a longer duration.

Electrical equipment is subjected to impulse testing to verify its ability to withstand surge voltages or currents to which it may be subjected during operation.

LIGHTNING OVERVOLTAGES

Upward humid air drafts from the earth's surface reaching high altitudes are subjected to relatively low temperatures where their moisture content condenses into large water drops. These drops disintegrate into smaller ones. The process of disintegration produces electrification where the small drops carry positive charges and the negative charges are carried by the

Figure 1. Direct lightning strokes. (a) Development of a lightning stroke. (b) Accompanied discharge current.

ambient air. The head of a cloud is positively charged, whereas its lower part is negatively charged (1). The process of water drops disintegration may be repeated, thus creating many charges. These charges produce potentials on the order of millions of volts within the cloud and voltage gradients on the earth surface on the order of a few tens or even hundreds of kilovolts per centimeter, depending on the amount of charge contained in the cloud and its height from ground surface. Under some favorable conditions, a direct lightning stroke may occur between the cloud and the earth's surface, buildings, or electrical installations including power transmission lines. The process of lightning strokes are rather complicated in their growth, and numerous theories are found in the literature (2,3). Direct lightning strokes are characterized by large and fast rising discharge currents. The amplitude of discharge current is on the order of few tens of kiloamperes and in severe cases may reach 200 kA. Its rise time is few microseconds with an average steepness of few kiloamperes per microsecond. The process of developing of lightning stroke is illustrated in Fig. 1. Direct lightning strokes may cause severe damage to buildings and power systems if they are not properly protected. Protection of buildings and similar structures is usually carried out by means of metal masts (Franklin rods). Power transmission lines are protected by earth wires strung between towers above the line conductors.

SWITCHING OVERVOLTAGES

Power systems are subjected to switching overvoltages during their operation. These voltages are classified into two main categories, according to the switching operation and the switched current. Table 1 shows the main switching operations in power systems.

Compared to lightning surges (impulses), switching surges are characterized by their long duration and lower magnitudes. Figure 2 shows the duration of lightning and switching over-

voltages as well as their magnitudes per unit of system working voltage.

GENERATION OF IMPULSE VOLTAGES

For test purposes, impulse voltages, simulating voltage surges from lightning or switching, are generated in high-voltage test laboratories.

An impulse voltage is a unidirectional voltage that rises to peak value in a short time and decays slowly to zero value. For the purpose of standardizing high-voltage tests, the impulse voltage shape should be precisely defined. Figure 3 shows an impulse voltage wave simulating a lightning surge. The wave shape, in general, is defined by its time to crest (wave front T_1) and its decay time to 50% of crest value (wave tail T_2).

Usually generated impulse voltages have a low rate of rise at their initial and final stages of buildup. On the other hand, a considerable percentage of the peak value builds up in a relatively short time compared to the total front time. To overcome this, the wave front and tail times are evaluated, as shown in Fig. 3. Impulse voltage waveshapes are defined by the values T_1 and T_2 in microseconds (T_1/T_2).

Impulse voltage in the range of 100 kV are generated by single-stage impulse generators and higher voltages, up to about 6 MV, are generated by multistage generators.

Figure 3. Lightning impulse voltage wave. Exact evaluation of wave front and tail times are shown.

Single-Stage Impulse Generators

Impulse voltages are simply generated by charging a condenser from a dc source and suddenly discharging it through a resistor by closing a fast-acting switch. In actual impulse generators, this switch is in the form of a sphere gap, controlled to close the circuit and start operation when required. Figure 4 shows a single-stage impulse generator. Construction of the impulse generator's control circuit (trigatron) is not shown; more details are given in Refs. 4 and 5. The voltage E is the input dc voltage usually obtained from a variable step-up high-voltage transformer with full-wave rectifier and smoothing circuit. The resistor R is for charging the stage capacitor C_1 ; R_1 and R_2 control the wave front and tail times, respectively; and C_2 is the test object capacitance. The output voltage $e(t)$ can be obtained by Laplace transform and simple circuit equations, which is in the form

$$e(t) = \frac{E}{R_1 C_2 (\alpha_2 - \alpha_1)} [\exp(-\alpha_1 t) - \exp(-\alpha_2 t)] \quad (1)$$

where

$$\alpha_1, \alpha_2 = \frac{a}{2} \mp \sqrt{\left(\frac{a}{2}\right)^2 - b} \quad (2)$$

$$a = \left(\frac{1}{R_1 C_1} + \frac{1}{R_1 C_2} + \frac{1}{R_2 C_1} \right)$$

$$b = \frac{1}{R_1 R_2 C_1 C_2}$$

Equation (1) is the difference between two exponential voltage waves decreasing with time. The first one decays slowly with

Figure 4. Single-stage impulse generator circuit.

time, and the second decays relatively faster. Examination of the two constants α_1 and α_2 in Eq. (2) shows that the values of R_1 and R_2 control the wave front and tail times. Complete details of other circuits arrangements, calculation of the wave front and tail times, and efficiency of the generator are fully given in Ref. 5.

In calculating the parameters of the impulse wave, no consideration was taken for the inherent inductance of the circuit elements and connecting leads. However, the value of this inductance has a great effect on its shape.

For the purpose of impulse voltage testing, standard impulse waves are recommended by different national and international standards. The most common impulse waves are 1.2/50 in Europe and 1/40 in North America.

Multistage Impulse Generators

For technical reasons, the dc charging voltage is usually limited to voltages around 200 kV. To obtain impulse voltages in the range of 6 MV multistage impulse generators are constructed. The basic idea of these generators is to charge several condensers in parallel from a moderate voltage dc source (say 200 kV) and then simultaneously discharging them in series through resistors. Figure 5 shows the circuit of a multistage generator in which an impulse voltage of approximately ten times the charging voltage is obtained. Full details of multistage impulse generators circuit, operation, and control are given in several high-voltage engineering textbooks (4–6).

Figure 5. Multistage impulse generator circuit. Charging voltage = 200 kV, number of stages = 10, output impulse voltage $\approx$ 2 MV.

Figure 6. Switching impulse voltage generation by Tesla coil.

GENERATION OF SWITCHING SURGES

Switching voltage surges are characterized by their long front and tail times and high energy. The definition of the wave front and tail times is more or less similar to that of lightning impulse voltages (7). Switching impulse voltage wave shapes in common use for testing purposes have wave front and tail times on the order of several hundred microseconds (250/2500 and 500/2500 μ s). These voltages can be generated from normal impulse generators with some modifications in their circuit elements to control the wave front and tail times to the required values. Alternative methods for generating such voltages are by producing voltage oscillations in the low-voltage winding of a step-up transformer or coil (Tesla coil). These oscillations are then transferred to the high-voltage side. Adjustment of the low- and high-voltage side parameters (inductance and capacitance) of the transformer or coil circuit and the instant of switching operation on the low-voltage side control the generated voltage shape. Figure 6 shows the well-known circuit of a Tesla coil. Interested readers may refer to Refs. 4 and 5 for more details on circuit construction, operation, and merits and demerits of different systems.

IMPULSE VOLTAGE MEASUREMENT

Impulse voltage measurement needs special measuring equipment and techniques to give true measure of the peak value and wave shape. When measuring high-impulse voltages on the order of megavolts and high rising rates, the measuring process becomes rather complicated, and the accuracy is highly reduced. Whatever the method used to measure impulse voltages, tedious precautions should be taken to reduce measuring errors. These errors are mainly introduced by external interference and response of the measuring system to such single-event voltages.

The main measuring methods used in impulse testing and research work are (1) sphere gaps and (2) resistive or capacitive voltage dividers.

Sphere Gaps

Measurement of the peak value of impulse voltages by means of sphere gaps, especially at extra high voltages, is very common in impulse testing. They consist of two identical metallic spheres separated by an air gap. The basic principle of measurement by sphere gaps is that the air in the separating gap breaks

down in response to the peak value of the applied voltage, provided that its rise time is not less than 1 μ s. To obtain accurate measurement by sphere gaps, several precautions should be taken. These precautions include sphere diameter selection, separation, and mounting; surface conditions; and connection to the measured voltage and nearby objects. Standard sphere diameters in common use range between 6.25 cm and 200 cm.

Measurement of impulse voltages by sphere gaps is the simplest method, with an accuracy of $\pm 3\%$, provided all recommendations given by IEC (8) are strictly followed. In laboratory testing work, it is difficult to control the temperature and pressure to standard values (20°C and 101 kPa) because of the large space and size of equipment. A correction factor k is used to obtain actual values corresponding to ambient conditions. This factor depends on the relative air density δ , which is given by

$$\delta = \frac{P}{760} \frac{(273 + 20)}{(273 + t)} = \frac{0.386P}{273 + t} \quad (3)$$

where t and P are the ambient temperature and pressure in degrees Celsius and millimeters of mercury, respectively. If V_s is the breakdown voltage at standard conditions given in IEC (8), then the actual voltage measured is kV_s . The values of δ and k are very close to each other (8).

Resistive Dividers

Resistive voltage dividers are commonly used in measuring ac and dc high voltages, and their construction is relatively simple. When measuring high-impulse voltages on the order of megavolts having short rise time, these dividers need special construction to give a true picture of the measured signal in magnitude and shape. Theoretically, resistive dividers consist of a high resistance in series with a low-value resistor. The combination is connected directly on the test object with the low-voltage terminal earthed. The division of voltage between the high- and low-resistance sections of the divider is not simply in the ratio of their values. In ac and dc measurement by resistive dividers, the error is usually much less than when measuring impulse voltages. The difficulty with impulse voltage dividers is that their transfer characteristics introduce large errors in both magnitude and shape if they are not properly constructed and sized. More details on the transfer characteristics of voltage dividers will be presented later. The sample voltage signal on the low-voltage section of the divider can be measured and recorded by oscilloscopes, analog/digital conversion circuits, attenuators, or high-voltage probes. The accuracy of voltage measurement, of course, depends on the divider construction, electromagnetic interference from test equipment, connection leads, and effectiveness of the grounding system.

Capacitive Dividers

Similar to resistive dividers, capacitive dividers are constructed from a single capacitor unit or several units in series and connected across the test object. Construction of high-voltage capacitors needs high technical measures and experience. However, compressed gas (sulfur hexafluoride, SF₆) capacitors are now available with good performance characteristics. Again, the main difficulty with capacitive dividers is their transfer characteristics and electromagnetic interference. It is obvious that the measured voltage signal across the low-voltage section

of the divider is not simply proportional to the inverse ratio of the divider capacitances. This is true because the equivalent circuit of the divider involves stray capacitances, inherent inductances, and resistors either actual or representing losses in the capacitors dielectric.

Impulse Currents

Lightning and voltage surges (impulses) are often accompanied by current surges that flow in a piece of equipment or a system subjected to such surges. Thus, impulse currents are generated in high-voltage laboratories for testing purposes. Surge arresters, used for protecting high-voltage equipment, are tested with impulse currents to verify their performance characteristics.

Similar to lightning and switching voltage impulses, two current wave shapes are used for testing electrical equipments. Figure 7(a) shows the wave shape recommended by IEC for testing under lightning impulse currents. Again, the wave shape is defined by the wave front and tail times in microseconds (T_1/T_2). The standard lightning impulse currents used in testing purposes are 1/20, 4/10, 8/20, and 30/80. Figure 7(b) shows the wave shape, recommended by IEC, for testing under switching impulse current. The wave shape is nearly rectangular in shape. The two time parameters defining the current wave T_d and T_t are shown in Fig. 7(b). Standard rectangular impulse currents have a time duration T_d of 500, 1000, or 2000 μ s.

Figure 7. Impulse current wave shapes: (a) exponential and (b) rectangular.

Measurement of Impulse Current

Fast-rising high-impulse currents up to few hundreds kiloamperes (200 kA) are usually encountered in testing surge arresters and lightning discharges. The main requirements from the measuring system are: (1) accuracy, (2) fast response, (3) simple construction, and (4) size.

Measurement of impulse currents relies on its basic effects; voltage drops when passing in a resistive element, associated magnetic field, and optical phenomenon. Resistive shunts are commonly used for high-impulse current measurement having ohmic resistance on the order of few milliohms. The voltage drop across the shunt (a few hundred volts) is measured by any voltage-measuring device such as a cathode-ray oscilloscope (CRO). The difficulties in designing resistive shunts are their inherent inductance, which should be minimal; the voltage across the shunts, which should be on the order of few hundreds volts; and their volume, which should be capable of absorbing the energy associated with the measured current without the temperature exceeding a permissible rise (20°C). Different designs and performance characteristics are given in Refs. 9 and 10. Methods based on the magnetic effect of electric currents use a single-turn coil placed perpendicular to the magnetic field. The induced voltage in the coil is a function of the measured current in magnitude and shape. The basic equations governing the measured current and induced voltage in the coil are

$$\oint_c H dl = I \quad (4)$$

$$\int \int B ds = \phi \quad (5)$$

$$e = -\frac{d\phi}{dt} \quad (6)$$

$$e = -\mu \frac{r^2}{R_o} \frac{di(t)}{dt} \quad (7)$$

where H is the magnetic field, ϕ is the flux linking the coil, r is the radius of the coil, and R_o is the distance between the coil center and the current-carrying conductor.

Pulse current transformers are sometimes used to measure impulse currents. However, their accuracy, lowpass band (a few kilohertz), and saturation problems limited their applications.

Optical methods used to measure impulse currents are based on two facts. The first is that, when a current flows through a light emitting diode, it generates light that depends on the current shape and magnitude. This light can be detected and transformed by photodetectors to an electrical signal, which is taken as a measure of the current (11). The second is that light beams show rotation when subjected to magnetic fields. Again, photodetectors are used to transfer this rotation to an electrical signal (12) proportional to the measured current.

ELECTRICAL DISCHARGE

Insulation media in electrical equipments may be a liquid, solid, gas, or combination of them. Gases are used to insulate electrical equipments such as circuit breakers, high-voltage capacitors, and other equipment. Gases, when compressed, are

excellent insulants and superior to other media. Under natural conditions, a gas constitutes neutral molecules and few free electrons (negative charge carriers) produced by natural sources such as cosmic rays. When this gas is subjected to a uniform electric field between two electrodes, the free electrons gain energy and move toward the positive electrode (anode). On their way to the anode, they collide randomly with the neutral gas molecules. If they have enough energy, they may ionize these molecules, thus producing new electrons and positive ions. The new electrons and the initiatory ones in their way to the anode may produce additional electrons. This process is a cumulative one, and a large number of electrons form an "electron avalanche" heading toward the anode. In the mean time, positive ions travel slowly (because of their relative large mass) toward the cathode. This process of ionization is called the Townsend primary ionization process. The flow of electrons between the electrodes is a flow of charge or a current. This current increases with the increase of electric field between the electrodes. Many other ionization and de-ionization processes are involved in gaseous discharge. How these processes occur, the factors governing their contribution to the electrical discharge, and the equations quantifying their contribution is a very broad subject, which is covered in a huge number of articles and reference books (2,4,5,13). The basic equation for current growth is

$$i = i_0 \frac{e^{\alpha d}}{1 - \beta(e^{\alpha d} - 1)} \quad (8)$$

where i is the current flowing between the electrodes, i_0 is the initiatory primary current, α is Townsend first ionization coefficient, β is Townsend secondary ionization coefficient, and d is the electrode spacing. Equation (8) does not take into consideration all secondary ionization and deionization processes such as photoionization in the gas and at the cathode surface, ionization by metastable atoms, thermal ionization, diffusion, and attachment. However, Eq. (8) was modified to be in the form

$$i = i_0 \frac{\frac{\alpha}{(\alpha - \eta)} e^{(\alpha - \eta)d} - \frac{\eta}{\alpha - \eta}}{1 - \frac{\gamma\alpha}{(\alpha - \eta)} [e^{(\alpha - \eta)d} - 1]} \quad (9)$$

where γ is the secondary ionization coefficient and may involve more than one secondary process and η is the attachment coefficient.

The coefficients α , η , and γ in Eq. (9) are functions of more than one of the parameters evolved in gaseous discharges (electric field, gas, electrode geometry, cathode material, and gas pressure and temperature).

The condition of breakdown in the gas is assumed when the current flowing between the electrodes is theoretically equal to infinity. This occurs when

$$\frac{\gamma\alpha}{\alpha - \eta} \{ \exp[(\alpha - \eta)d_s] - 1 \} = 1 \quad (10)$$

where d_s is the electrode separation at breakdown.

Electric discharge leading to breakdown as given by Townsend's equations has many limitations in explaining how breakdown occurs in long gaps and nonuniform field gaps resulting from the very short time observed during their breakdown. The streamer theory was then developed to account for

such limitations. In brief, the streamer theory is based on the fact that for breakdown to occur in a time on the order of 10^{-6} s to 10^{-8} s, there must be a buildup of a high electric field in the gap to accelerate the breakdown process. This field was attributed to the accumulation of the slow moving positive ions in the gap, thus leading to an external space charge field. Photoionization in the gas was also considered as an additional accelerating factor for breakdown. Several explanations and equations have been developed by Meek, Loeb, and Raether on the theory of streamer breakdown (2,3).

In nonuniform field electrode geometries (e.g., point to plane, parallel wires, and coaxial wire-cylinder), the electric field is highly localized at the point or the wires while it is relatively low at other places. This high field may start discharge at and around these electrodes while the rest of the gap is not. This phenomenon is known as Corona discharge, and it is characterized by its pale violet light, smell of ozone, and hissing noise. Corona represent continuous power losses on transmission lines, and its presence in electrical equipment should be avoided because it may lead to their failure.

IMPULSE BREAKDOWN

Breakdown under impulse voltages is different from those under ac and dc because of their short duration time. For breakdown to start, at least one electron should exist in the gap at a favorable location and time. Alternating (60 Hz or 50 Hz) and direct voltages can be considered constant during the buildup of the breakdown process. The probability of the appearance of an electron or electrons in the gap is high, and that explains the small scatter in the breakdown voltages under ac and dc. On the other hand, the appearance of an electron away from the peak of the impulse voltage has very low probability to initiate breakdown. Figure 8 shows how breakdown occurs under impulse voltages. If an electron appears at time t_1 or t_4 corresponding to voltages V_1 and V_4 on the wave front and tail, respectively, no breakdown can occur because the voltages at these instants are less than the static breakdown voltage V_s . For discharge to start and develop to breakdown, the initiatory electron should appear within a time between t_2 and t_3 , where the impulse voltage exceed V_s . The time interval between t_2 and t_b is divided into two time intervals:

1. Statistical time lag T_s , which is defined as the time that elapses from the instant the impulse voltage reaches the

Figure 8. Breakdown under impulse voltage.

static breakdown value until an initiatory electron appears at a suitable location in the gap to start discharge.

2. Formative time lag T_f , which is defined as the time that elapses between discharge initiation until breakdown develops.

The statistical time lag is relatively long and is in the range of 10 s to 10^{-3} s. Short formative time lags in the 10^{-9} s range were recorded (5).

IMPULSE BREAKDOWN STRENGTH

When testing an insulation system under impulse voltage, large scatter in the results is usually observed. The probability of breakdown under impulse voltage depends on its peak value and duration time. A probability breakdown curve is usually drawn to define the impulse breakdown. Figure 9 shows the breakdown probability characteristics of a test object (e.g., an insulator string). This curve can be obtained by applying a certain number of shots for each voltage level and determining the ratio between the number of breakdowns and the total shots. This ratio is the probability of breakdown for a specified impulse voltage. It is clear that the breakdown probability increases with the increase of the applied voltage relative to the static breakdown voltage of the test object. To obtain representative values of the breakdown probability, large number of voltage shots (say 100 shots) at each voltage level are applied. In practical testing, this number is limited to 15 or 20 shots. Figure 9 shows two distinct voltages V_0 and V_{100} corresponding to zero and 100% breakdown probability. The question now arises which value is taken to represent the impulse breakdown voltage? The answer to this question is that it is the voltage corresponding to 50% breakdown probability and it is termed critical flash over voltage (CFO). The value of V_0 and V_{100} are of importance to the insulation design and insulation coordination, respectively. Exact determination of V_0 and V_{100} from Fig. 9 needs the application of large number of shots, which is time-consuming. In practice, more realistic procedures are used. These procedures depend on the fact that the breakdown probability function is Gaussian; interested readers may refer to Refs. 4 and 5.

TRANSFER CHARACTERISTICS

In measuring and recording impulse voltages by means of voltage dividers and CRO, errors as high as 10% or even higher are usually observed. The errors are not only in magnitude but

Figure 9. Impulse voltage breakdown probability.

Figure 10. Response of voltage dividers to unit step function voltage.

also in phase. Whatever the equivalent circuit of voltage dividers is, they can be represented by a four-terminal network, and their transfer characteristics (output voltage/input voltage, v_o/v_i) can be evaluated. Practical impulse voltage shapes are the difference between two exponential voltages. The mathematical analysis for such waves is very lengthy and tedious. Checking the response of voltage dividers by applying a unit step function is recommended by IEC (14). If a unit step function in the form

$$v_i(t) = \begin{cases} 0 & t < 0 \\ 1 & t > 0 \end{cases} \quad (11)$$

is applied to a voltage divider, the output response will be $v_o(t)$. The response to another input voltage can be derived by Laplace transform, and hence the output in the time domain is obtained (4). Figure 10 illustrates how the output voltage of a divider can differ from the input in magnitude and shape. Good design of voltage dividers should provide (1) short delay time T_d , (2) low overshoot, and (3) short time to steady state.

In recording impulse voltage waves, the output of the divider is taken via coaxial cables to a CRO. Unless proper matching is provided, errors resulting from voltage reflections are introduced.

MEASUREMENT STANDARDS

All standard specifications for impulse voltage and current limit measurement accuracy. Table 2 shows the standard accuracy limits for impulse voltage and current measurement as well as acceptable tolerances in their generation (7).

Table 2. Standard Impulse Voltage and Current Tolerances and Measurement Accuracy

Quantity	Lightning Voltage (%)		Switching Voltage (%)		Impulse Current (%)	
	Tol.	Accu.	Tol.	Accu.	Tol.	Accu.
Peak value (full impulse)	±3	±3	±3	±3	±10	±3
Peak value (chopped)						
on front		≤±5				
on tail		≤±3				
Front time	±30	±10	±20	±10	±10	±10
Tail time	±20	±10	±60	±10	±10	±10

CALIBRATION

Regular calibration of the measuring system against a standard measuring device is a common practice in impulse testing and research work. The sphere gap is an acceptable standard measuring device for measuring the peak value of an impulse voltage with an accuracy of $\pm 3\%$. When recording an impulse wave, the recording system should be calibrated against a reference measuring system. The accuracy of the reference system ranges between ± 1 and $\pm 3\%$ for measuring the peak voltage or current and $\pm 5\%$ for measuring the time parameters (14).

APPLICATIONS

Electrical equipment is subjected to voltage and current surges during operation, and impulse testing is one of the main tests specified by all standard specifications. Circuit breakers, cables, transformers, high-voltage capacitors, switchboards, transmission line insulators, surge arresters, and other kinds of equipment are tested under impulse voltages and/or current. The main purpose of impulse tests is to validate the performance characteristics, proper design, and manufacture quality. Impulse voltages and currents have several applications other than for testing. They can be used for triggering electronic circuits and components. Electrostatic precipitators, used to collect dust particles from the exhaust of chimneys, use high-impulse voltages in their operation. The basic construction of such devices consists of a thin wire concentric with a metallic cylinder. When a high voltage is applied between the wire and the cylinder, corona discharge starts at and around the wire. The flow of charges between the wire and cylinder charges the particles, and they move toward the cylinder wall where they are collected. It is claimed that using impulse voltages instead of dc is more effective in collecting dust particles. In cars, an inductive electric circuit, supplied from a 12 V battery, is regularly switched off and on to produce impulse voltages of several kilovolts. This voltage is applied to the car's plugs to produce sparks, thus igniting the fuel.

Low-voltage impulse signals are used for fault detection and location in underground cables. This is based on the fact that when a voltage surge is applied at one end of a long conductor in air it travels to the other end with light velocity ($c = 3 \times 10^8$ m/s). In the case of underground cables, it travels with velocity $c/\sqrt{\epsilon_r}$, where ϵ_r is the relative permittivity of the cable insulating material. If there is a fault in the cable, between its ends, the voltage signal is reflected at the fault. The reflected signal is received at the voltage source on a recording device, such as a CRO. Knowing the velocity of the voltage signal and the time taken to reach the fault and return back to the source, one can then estimate distance. The reflected voltage signal may be positive or negative depending on whether the fault resides in an open cable's conductor or insulation. By this method fault location is determined with high accuracy and the type of fault is known, thus reducing the effort and time of digging and repairing the fault. Cable's fault detectors are now available in the marketplace and can detect and locate faults without any human calculations.

Fast-rising impulse voltages of a few tens of kilovolts are used to generate ozone for water treatment. Ozone generators are similar to electrostatic precipitators in their basic construction. Corona discharge is initiated by applying a repetitive voltage pulse to a thin wire in a duct where air flows axially or radially. Corona discharge starts at and around the wire surface, due to the high electric field therein, and consequently ozone is formed. The amount of generated ozone depends on the magnitude of the applied impulse voltage, its repetition rate, duration, wire diameter, and rate of air flow.

Lightning protection from thunderstorms is usually carried out by means of metallic rods (Franklin rods) installed on or around the protected objects. These rods have a protection zone where they are highly effective, and beyond it the degree of protection is reduced. To increase the protection zone and degree of protection and to decrease the height of the rod, the electric field at the tip of the protecting rod should be increased to help direct the lightning stroke to it. The field at the tip of the rod can be increased by applying to it a repetitive impulse voltage of a few tens of kilovolts from an external source.
