Eddy Current Nondestructive Evaluation	1062
Impulse Testing	1075

INDEX 1083

PREFACE

“Measurement is the heart of all science, engineering, and technology.” Thus wrote Peter K. Stein, a measurement engineer and educator, several decades ago.

And it is true. Beginning some 5000 years ago with the establishment of measurement standards—important to trade, government, work, and religion—and continuing past the last few centuries B.C.E., when primitive instruments were developed for measuring time, this now vast and all-important field of instrumentation and measurement (I&M) got its kickstart during the sixteenth century with what can be considered the birth of experimental science. The eighteenth and following centuries have seen great progress in science and engineering in general and I&M in particular. The development of electronics and computers has allowed very sophisticated—and relatively easy-to-use—instruments to be designed. These instruments, when coupled with the ingenuity of careful and clever investigators, have in turn led to the ability to make very accurate, precise, important measurements of sometimes-very-hard-to-access quantities, both macroscopic and microscopic.

What do I&M systems do? They measure physical quantities, such as temperature, pressure, voltage, and current. They locate events and objects. They count things. They discriminate based on one or more parameters. The need for I&M is everywhere. Everyone uses it.

Indeed, the number and sheer breadth of applications make it challenging to give coverage to such a field within a single

volume. The 97 articles appearing herein are drawn from the *Wiley Encyclopedia of Electrical and Electronics Engineering*. They are chosen to give a broad representation of I&M, but with the realization that most of the other topics in the full encyclopedia remain in some relationship with I&M, either affected by it or having some important contribution to this fascinating field.

The articles contained within are grouped into topical categories selected to help you navigate this volume. Of course, there are some articles that might comfortably fit within more than one category, and, likewise, there are occasions in which articles from two or more categories are closely related. We hope that, given the table of contents, the index, and your own curiosity, it will be reasonably easy to make the appropriate connections.

Physicists, chemists, mathematicians, statisticians, computer scientists, a variety of scientists from other disciplines, engineers of various types, talented technicians, and others—many have, either directly or indirectly, made contributions to I&M. It is our hope that this survey volume will indeed prove a significant aid as you make use of—and perhaps your own contributions to—this diverse, exciting, and continually growing field.

STEPHEN A. DYER

INTRODUCTION

Instrumentation and Measurement—Introductory

Kelvin's first rule of instrumentation states, in essence, that the measuring instrument should not alter the event being measured. That rule impacts the design of any instrument.

In broad terms, we can view a measuring instrument or instrument subsystem as comprising an input transducer followed by a signal-conditioning section, which in turn drives a data-processing and display section.

The instrument or piece of test equipment may be completely manual, requiring (sometimes significant) tending by its operator, or it may be automated to one extent or another. The increasing availability of inexpensive computing power, beginning in the early 1970s, has encouraged the design of instrumentation capable of being controlled by computer, with all but the simplest of instruments today having interfaces built in.

Sensors and Transducers

Transducers are energy-conversion devices and are the “molecule” of a measurement system (i.e., the smallest unit from which measurement systems are constructed). Some transducers, such as thermocouples, are active (or self-generating); i.e., they are such that the input energy in one form directly produces another form of energy at its output. Other transducers, such as resistance thermometers, require two forms of input energy to produce some form of output energy; they are termed passive, or non-self-generating.

Traditionally, sensors have been taken to be the passive portions of non-self-generating transducers. They are usually elements which have one or more physical properties affected by some physical quantity.

In today's literature there is often a lack of distinction between “sensor” and “transducer.” The terms are often used interchangeably. Furthermore, integrated-circuit technology has led to the inclusion of signal conditioning circuitry and data-acquisition-and-communication interfaces on the same chip as the sensor or transducer. While the entire package is typically referred to as a sensor, in reality it is an instrumentation subsystem, or perhaps a complete instrument, on a chip.

While the need for traditional, discrete sensors and transducers will certainly continue, present research and development of integrated sensors, intelligent sensors, and integrated systems on a chip will result in an expanding offering

of compact, rugged, relatively inexpensive, and easy-to-apply measurement front ends and systems based on one or more sensors or transducers.

Signal Conditioning

It is the task of the signal conditioner to accept the signal output from the transducer and produce from it a signal acceptable for introduction to the remainder of the instrument.

Signal conditioning is typically analog in nature, and it can involve strictly linear operations, strictly nonlinear operations, or some combination of the two. Examples of linear operations include amplitude scaling (amplification or attenuation), impedance transformation, linear filtering, and modulation. Some nonlinear operations include obtaining the root-mean-square (rms) value, absolute value, square root or logarithm of the input signal.

The signal conditioning may also provide auxiliary services, such as producing an excitation signal for the transducer, providing a reference signal for the transducer, or introducing electrical isolation.

Building blocks for providing analog signal processing are available in many forms—as modules, as integrated circuits (ICs), and as complete subsystems having universal backplanes and plug-in input and output modules. Operational amplifiers, instrumentation amplifiers, isolation amplifiers, nonlinear processing circuits such as comparators, multiplier/dividers, log/antilog amplifiers, trigonometric-function generators, and rms-to-dc converters are but a few of the building blocks available.

General-Purpose Instrumentation

The electrical quantities most commonly measured include voltage, current, charge, resistance, and impedance. This section surveys general-purpose instrumentation typically used for measurement of such quantities. Many of these instruments can be found on even the most modest of laboratory or test benches.

Electrical Variables

There are a variety of approaches to measuring the electrical variables of charge, current, inductance, capacitance, and quality (Q). This section provides an overview and, in several cases,

acts as supplemental material to the discussions on various general-purpose instruments.

Electromagnetic Variables

The measurement of electromagnetic variables is useful in a wide variety of applications, from determination of the moisture content in grain to satisfying governmental regulations on radiated and conducted emissions associated with electronic equipment. This section provides coverage of a variety of instruments and measurement techniques applicable at frequencies up through the millimeter range of the electromagnetic spectrum.

Mechanical Variables

Linear displacement, velocity, acceleration, and jerk; angular displacement, velocity, and acceleration; length; force; torque; shaft power; pressure; sound; fluid flow; temperature; heat flux; humidity; and liquid level all fall broadly under “mechanical variables.” The fundamental quantities are length, time, mass, and temperature, and there exist independent standards for each. Other quantities such as force, pressure, etc., are derived quantities. This section provides coverage of a breadth of measurement techniques applicable to mechanical variables. The reader should also refer to the “Sensors and Transducers” section, as well as “Time, Frequency and Phase” section for additional and related information.

Time, Frequency, and Phase

Time is one of the fundamental quantities in nature, and it plays a very important role in the vast majority of measurements made, either directly or through its relationship to two other often-measured quantities—frequency and phase. This section presents the important aspects of the measurement of time, frequency and phase. It provides general information on the measurement of time, addresses frequency standards, and discusses time-interval, frequency and phase meters, along with additional topics.

Instrumentation for Chemistry and Physics

There is a vast collection of instruments and instrumental methods used in chemical and physical analysis, and the progress in instrumental methods of analysis over the past few decades can be aptly described as “explosive.” As with many other areas of instrumentation and measurement, the computer has played a significant role.

Even a brief list of instrumental methods would probably include colorimetry; fluorescence; spectrophotometry; flame photometry; spectrometry; turbidimetry; nephelometry; thermal conductivity; X-ray diffraction; radiochemical methods; refractometry; interferometry; pH determination; potentiometric, conductometric and amperometric titrations; electrolytic separations; polarography; chromatography; and nuclear magnetic resonance.

This section gives an introduction to several common instruments and techniques. Coverage of interferometers and

spectrometers is given under a separate section. Likewise, two important types of microscopy—electron and X-ray—have coverage under their own sections.

Interferometers and Spectrometers

Interferometers are nondispersive devices in which patterns of constructive and destructive interference of electromagnetic or mechanical waves can be set up. A. A. Michelson pioneered the use of interferometry in 1880 in making accurate measurements of distance. The invention of the laser and its subsequent application to interferometry have resulted in the commercial practicality of interferometric measurement of distances. Another very important use of interferometers is in obtaining spectral information. Indeed, interferometers form the basis for many types of spectrometers.

Spectrometers are instruments used to provide information about a spectrum associated with a sample. The spectrum, for example, might be of radiation absorbed, emitted, or scattered by the sample over a particular range of wavelengths; it might be a mass spectrum, a record of the relative numbers of the various kinds of ions associated with a molecule, sorted by their charge-to-mass ratio; or it might indicate the characteristic absorption of energy by spinning nuclei in a strong magnetic field.

This section provides an introduction to interferometers and describes the mass spectrometer, one of the most broadly useful of all the tools employed in instrumental analysis.

Data Acquisition and Recording

The “storage and readout” portions of instruments have made tremendous strides over the past decades. The large, analog industrial recorder has been supplanted to a large extent by systems that acquire the analog data, convert it to digital form, and store it on media such as magnetic tape or disk, magneto-optical disk, solid-state memory cards, or compact disc (either CD-R or CD-RW). The “readout”—or display—might be a cathode-ray tube (CRT), a liquid-crystal display (LCD), or something similar. There remain, of course, recorders that produce hard-copy on paper, but most of these are hybrid recorders which are microprocessor-based and which typically expect the data in digital form.

The sophisticated, expensive, analog recorders which relied on frequency-modulation (FM) techniques likewise are hard to find nowadays. Analog-to-digital converters with 16- to 24-bit resolution are inexpensive, and the cost-per-gigabyte of hard-disk storage is measured in tens of dollars (US); CD-RW media are one to two orders of magnitude less expensive yet. Even when considered only from the standpoint of cost, digital has proven itself the route to take for most data-storage applications associated with instrumentation and measurement.

Recording instruments, as more and more computing power is provided them, will continue to be placed in increasingly sophisticated applications. Their use as smart network devices, as data nodes, and even as control elements in fieldbus-based systems are just a few of the uses for some of the newer recording instruments.

INSTRUMENTATION AND MEASUREMENT—INTRODUCTORY

INSTRUMENTS

Measurement is essential for observing and testing scientific and technological investigations. It is so fundamental and important to science and engineering that the whole science can be said to be dependent on it. Instruments are developed for monitoring the conditions of physical variables and converting them into symbolic output forms. They are designed to maintain prescribed relationships between the parameters being measured and the physical variables under investigation. The physical parameter being measured is known as the *measurand*. The sensors and transducers are the primary sensing elements in the measuring systems that sense the physical parameters to produce an output. The output from the sensor is supplied to a transducer, which converts energy from one form to another. Therefore, a transducer is a device capable of transferring energy between two physical systems.

Measurement is a process of gathering information from a physical world and comparing this information with agreed standards. Measurement is carried out with instruments that are designed and manufactured to fulfill given specifications. After the sensor generates the signals, the type of signal processing depends on the information required from it. A diverse range of sensors and transducers may be available to meet the measurement requirements of a physical system. The sensors and transducers can be categorized in a number of ways depending on the energy input and output, input variables, sensing elements, and electrical or physical principles. For example, from an energy input and output point of view, there are three fundamental types of transducers: modifiers, self-generators, and modulators.

In modifiers, a particular form of energy is modified rather than converted; therefore, the same form of energy exists at the input and at the output. In self-generators, electrical signals are produced from nonelectric inputs without the application of external energy. These transducers produce very small signals, which may need additional conditioning. Typical examples are piezoelectric transducers and photovoltaic cells. Modulators, on the other hand, produce electric outputs from non-electric inputs, but they require an external source of energy. Strain gauges are typical examples of such devices.

The functionality of an instrument can be broken into smaller elements, as illustrated in Fig. 1. Most measurement systems have a sensor or transducer stage, a signal-conditioning stage, and an output or termination stage. All

instruments have some or all of these functional blocks. Generally, if the behavior of the physical system under investigation is known, its performance can be assessed by means of a suitable method of sensing, signal conditioning, and termination.

In the applications of instruments, the information about a physical variable is collected, organized, interpreted, and generalized. Experiments are conceived, performed, and repeated; as we acquire confidence in the results, they are expressed as scientific laws. The application of instruments ranges from laboratory conditions to arduous environments such as inside nuclear reactors or remote locations such as satellite systems and spaceships. In order to meet diverse application requirements of high complexity and capability, many manufacturers have developed a large arsenal of instruments. Some of these manufacturers are listed in Table 1.

In recent years, rapid growth of IC electronics and the availability of cheap analog-to-digital and microprocessors have led to rapid progress in the instrumentation field, with the development of instruments, measuring techniques, distributed architectures, and standards aimed to improve performances.

Instruments are applied for static or dynamic measurements. The static measurements are relatively easy since the physical quantity (e.g., fixed dimensions and weights) does not change in time. If the physical quantity is changing in time, which often is the case, the measurement is said to be dynamic. In this case, steady-state and transient behavior of the physical variable must be analyzed so that it can be matched with the dynamic behavior of the instrument.

DESIGN, TESTING, AND THE USE OF INSTRUMENTS

Instruments are designed on the basis of existing knowledge, which is gained either from the experiences of people about the physical process or from the structured understanding of the process. In any case, ideas conceived about an instrument must be translated into hardware and/or software that can perform well within the expected standards and easily be accepted by the end users.

Usually, the design of instruments requires many multidisciplinary activities. In the wake of rapidly changing technology, instruments are upgraded often to meet the demands of the marketplace. Depending on the complexity of the proposed instrument, it may take many years to produce an instrument for a relatively short commercial lifetime. In the design and

Figure 1. An instrument has a number of relatively independent components that can be described as functional elements. These functional elements are the sensors and transducers, signal conditioners, and output or terminations. In general, if the behavior of the physical system is known, its performance is measured by a suitable arrangement and design of these components.

Figure 2. The design process from the conception of ideas to marketing follows carefully considered stages. The proper identification and effective implementation of these stages is important in the success and acceptance of a specific instrument in the marketplace.

production of instruments, one must consider such factors as simplicity, appearance, ease and flexibility of use, maintenance requirements, lower production costs, lead time to product, and positioning strategy in the marketplace.

In order to design and produce instruments, a firm must consider many factors. These include sound business plans, suitable infrastructure, plant, equipment, understanding of technological changes, skilled and trained personnel, adequate finance, marketing and distribution channels, and a clear understanding about worldwide instrument and instrumentation system trends. It is important to choose the right product that is very likely to be in demand in the years to come. Here entrepreneurial management skills may be an important factor.

The design process itself may follow well-ordered procedures from idea to marketing stages. The process may be broken down into smaller tasks such as identifying specifications, developing possible solutions for these specifications, modeling, prototyping, installing and testing, making modifications, manufacturing, planning marketing and distribution, evaluating customer feedback, and making design and technological improvements. Figure 2 illustrates the stages for the design and marketing of an instrument. Each one of these stages can be viewed in detail in the form of subtasks. For example, many different specifications may be considered for particular product. These specifications include but are not limited to operational requirements, functional and technological requirements, quality, installation and maintenance, documentation and servicing, and acceptance level determination by the customers.

In recent years, computers have been used extensively in the instrument manufacturing industry in the form of computer-aided-design (CAD), automated testing, and in other applications. The computer enables rapid access to knowledge-based information and makes design time considerably shorter, thus enabling manufacturers to meet the customer demand. In CAD systems, mechanical drafting software, electronic circuit design tools, control analysis tools, and mathematical and word processing tools are integrated to assist the design procedure.

Design software is available from various manufacturers listed in Table 1.

Testing and Use of Instruments

After the instrument is designed and prototyped, various evaluation tests may be conducted. These tests may be made under reference conditions or under simulated environmental conditions. Some examples of reference condition tests are accuracy, response time, drift, and warm up time. Simulated environmental tests may be compulsory, being regulated by governments and other authorities. Some simulated environment tests include climatic test, drop test, dust test, insulation resistance test, vibration test, electromagnetic compatibility (EMC) tests, and safety and health hazard tests. Many of these tests are strictly regulated by national and international standards.

Adequate testing and proper use of instruments is important to achieve the best results out of them. When the instruments are installed, a regular calibration is necessary to ensure the consistency of the performance over the time period of operation. Incorrect measurements can cost a considerable amount of money or even lead to loss of lives.

For maximum efficiency, appropriate instrument for the measurement must be selected. Users should be fully aware of their application requirements, since instruments that do not fit their purpose will deliver false data thus resulting in wasted time and effort. When selecting the instrument, users must evaluate many factors such as accuracy, frequency response, electrical and physical loading effects, sensitivity, response time, calibration intervals, power supply needs, spare parts, technology, and maintenance requirements. They must ensure compatibility with their existing equipment.

Also, when selecting and implementing instruments, quality becomes an important issue from both quantitative and qualitative perspectives. The quality of an instrument may be viewed differently depending on the people involved. For example, quality as viewed by the designer may be an instrument designed on sound physical principles, whereas from the user's point of view quality may be reliability, maintainability, cost, and availability.

For the accuracy and validity of information collected from the instruments, correct installation and proper use become very important. The instruments must be fully integrated with the overall system. Sufficient background work must be conducted prior to installation to avoid a possible shutdown of the process that is longer than necessary.

Once the system is installed, the reliability of the instrument must be assessed, and its performance must be checked regularly. The *reliability* of the system may be defined as the probability that it will operate at an agreed level of performance for a specified period of time. The reliability of instruments follows a bath tub shape curve against time. Instruments tend to be unreliable in the early and later stages of their lives. During normal operations, if the process conditions change (e.g., installation of large machinery nearby), calibrations must be conducted to avoid possible performance deterioration of the instrument. Therefore, the correct operations of instruments in service must be assured at all times throughout the lifetime of the device.

Once the instruments are installed they may be left alone and expected to operate reliably. In some applications, the instruments may be part of a large instrumentation system, taking a critical role in monitoring and/or controlling the process

and operations. They may be communicating with other devices and their performance may affect the performance of the rest of the system, as in the case of the process industry. However, in many applications, instruments are used on a stand-alone basis for laboratory and experimental work, and the success of the experiments may entirely depend on their correct usage and performance. In these cases, the experiments must be designed and conducted carefully by identifying the primary variables, controlling, selecting the correct instruments, assessing the relative performances, validating the results, and using the data effectively by employing comprehensive data analysis techniques. Set procedures for experimental designs can be found in various sources given in the Bibliography (e.g., Sydenham et al., 1989).

After having performed the experiments, the data must be analyzed appropriately. This can be done at various stages by examining the consistency of the data, performing appropriate statistical analyses, estimating the uncertainties of the results, relating the results to the theory, and correlating the data. Details of statistical data analysis can be found in many books; also many computer software programs are available for the purpose analysis including common packages such as Microsoft Excel.

INSTRUMENT RESPONSE AND DRIFT

Instruments respond to physical phenomena by sensing and generating signals. Depending on the type of instrument used and the physical phenomenon observed, the signals may be either slow or fast to change, and may also contain transients. The response of the instruments to the signals can be analyzed in a number of ways by establishing static and dynamic performance characteristics. Although, the static performances are relatively simple, the dynamic performances may be complex.

Static Response

Instruments are often described by their dynamic ranges and full-scale deflections (span). The *dynamic range* indicates the largest and smallest quantities that can be measured. The *full-scale deflection* of an instrument refers to the maximum permissible value of the input quoted in the units of the particular quantity to be measured.

In instruments, the change in output amplitude resulting from a change in input amplitude is called the *sensitivity*. System sensitivity often is a function of external physical variables such as temperature and humidity. The relative ratio of the output signal to the input signal is the *gain*. Both, the gain and sensitivity are dependent on the amplitude of the signals and the frequency, which will be discussed in the section on dynamic response.

In the design stages or during manufacturing, there might be small differences between the input and output, which is called the *offset*. In other words, when the input is zero the output is not zero or vice versa. The signal output also may change in time, which is known as the *drift*. The drift can occur for many reasons including temperature and aging. Fortunately, drift usually occurs in a predictable manner. A typical drift curve of an instrument against time is illustrated in Fig. 3.

During practical applications, readings taken from an instrument under the same conditions may not be repeatable. In this case, a repeatability test may be conducted, and statistical

Figure 3. Drift in the output of an instrument. The main causes of the drift are aging, temperature, ambient conditions, and component deterioration. The drift in an instrument may be predicted by performance analysis of components, past experience, environmental tests, and so on.

techniques must be employed to evaluate the repeatability characteristics of the instrument.

Dynamic Response

The dynamic responses of an instrument is characterized by its natural frequency, amplitude, frequency response, phase shift, linearity and distortions, rise and settling times, slew rate, and the like. These characteristics are a common theme in many instrumentation, control, and electronics books. Although sufficient analysis will be given here, the detailed treatment of the topic can be very lengthy and complex; hence, the full treatment of this topic is not within the scope of this article. Interested readers should refer to the Bibliography (e.g., Doebelin, 1990).

The dynamic response of an instrument can be linear or nonlinear. Fortunately, most instruments exhibit linear characteristics, leading to simple mathematical models by using differential equations such as

$$a_n \frac{d^n y}{dt^n} + a_{n-1} \frac{d^{n-1} y}{dt^{n-1}} + \cdots + a_0 y = x(t) \quad (1)$$

where x is the input variable or the forcing function, y is the output variable, and $a_n, a_{n-1}, \dots, a_0$ are the coefficients or the constants of the system.

The dynamic response of instruments can be categorized as zero-order, first-order, or second-order responses. Although higher-order instruments may exist, their behaviors can be understood adequately in the form of a second-order system. From Eq. (1)

$$a_0 y = x(t) \quad \text{zero order} \quad (2)$$

$$a_1 \frac{dy}{dt} + a_0 y = x(t) \quad \text{first order} \quad (3)$$

$$a_2 \frac{d^2 y}{dt^2} + a_1 \frac{dy}{dt} + a_0 y = x(t) \quad \text{second order} \quad (4)$$

Equations (2)–(4) can be written as Laplace transforms, thus enabling analysis in the frequency domain,

$$\frac{Y(s)}{X(s)} = 1 \quad (5)$$

$$\frac{Y(s)}{X(s)} = \frac{1}{(\tau_1 s + 1)} \quad (6)$$

$$\frac{Y(s)}{X(s)} = \frac{1}{(\tau_1 s + 1)(\tau_2 s + 1)} \quad (7)$$

Figure 4. A first-order-hold instrument responds to a step input in an exponential form. For a good response the time delay must be small. Drift is usually expressed in percentage of output.

where s is the Laplace operator and τ is the coefficient, also called time constant.

In zero-order instruments, there is no frequency dependence between the input and output. The amplitude change is uniform across the spectrum of all possible frequencies. In practice, such instruments are difficult to obtain, except in a limited range of operations.

In first-order instruments, the relation between the input and the output is frequency dependent. Figure 4 illustrates the response of a first-order instrument for a unit step input in the time domain. Mathematically, the output may be written as

$$y(t) = K e^{-t/\tau} \quad (8)$$

where K and τ are constants determined by the system parameters. In many cases, the input signals may be a complex rather than a simple step input. In the analysis, we need to multiply the transfer function, the second member of Eq. (6), by the Laplace transform of the input signal and then transform it back to the time domain if we are to understand the nature of transient and steady-state responses. Also, if the first-order systems are cascaded, the relative magnitudes of the time constants become important; some may be dominant, and others may be neglected.

Second-order systems exhibit the laws of simple harmonic motion, which can be described by linear wave equations. Equation (7) may be rearranged as

$$\frac{X(s)}{Y(s)} = \frac{1/a_0}{s^2/\omega_n^2 + 2\zeta s/\omega_n + 1} \quad (9)$$

where ω_n is the natural or undamped frequency (rad/s) and ζ is the damping ratio.

As can be seen, the performance of instruments become a function of natural frequency and the damping ratio of the system. The natural frequency and damping ratios are related to the physical parameters of the devices, such as mass and dimensions. In the design stages, these physical parameters may be selected, tested, and modified to obtain a desired response from the system.

Typical time response of a second-order system to unit step inputs is illustrated in Fig. 5. The response here indicates that a second-order system oscillates or it can even be unstable. Furthermore, we can deduce that, since the second-order system is dependent on time, wrong readings can be made depending on the time that the results are taken. Clearly, recording the output when the instrument is still under transient conditions will give an inadequate representation of the physical variable.

Figure 5. Unit step time responses of a second-order system with various damping ratios. The maximum overshoot, delay, rise, settling times and frequency of oscillation depend on the damping ratio. A smaller damping ratio gives a faster response but larger overshoot. In many applications, a damping ratio of 0.707 is preferred.

The frequency compensation, selection of appropriate damping, acceptable time responses, and rise time and settling times of instruments may need careful attention in both the design and application stages. In these systems, system analysis is essential to ensure that they can measure the input measurand adequately.

A typical frequency dependence of gain and phase angle between input and output is illustrated in Fig. 6 in the form of Bode diagrams. Here, the *bandwidth*, which is the frequencies over which the gain is reasonably constant, is also shown. Usually, half power point (3 dB), which symbolizes 70.7% of the maximum value, is taken as the bandwidth.

An important concept in instruments is *response time*, which can be described as the time required for the instrument to respond to an input signal change. For automatic measurements, the response time is an indication of how many readings can be done per second. Response time is affected by many factors such as analog-to-digital (A/D) conversion times, settling times, delays in electronic components, and delays in sensors.

MEASUREMENT ERRORS AND ERROR CONTROL SYSTEMS

The performance of an instrument depends on its static and dynamic characteristics. The performance may be indicated by its *accuracy*, which may be described as the closeness of measured values to the real values of the variable. The total response is a combination of dynamic and static responses. If the signals generated by the physical variable are changing rapidly, then the dynamic properties of the instrument become important. For slowly-varying systems, the dynamic errors may be neglected. In order to describe the full relationships between the inputs and outputs, differential equations can be used, as discussed previously.

The performance of an instrument may also be decided by other factors, such as the magnitudes of errors; the *repeatability*, which indicates the closeness of sets of measurements

made in the short term; and the *reproducibility* of the instrument. The reproducibility is the closeness of sets of measurements when repeated in similar conditions over a longer period of time.

The ideal or perfect instrument would have perfect sensitivity, reliability, and repeatability without any spread of values and would be within the applicable standards. However, in many measurements, there will be imprecise and inaccurate results due to many internal and external factors. The departure from the expected perfection is called the *error*. Often, sensitivity analyses are conducted to evaluate the effect of individual components that are causing these errors. Sensitivity to the affecting parameter can be obtained by varying that one parameter and keeping the others constant. This can be done practically by using the developed instruments or mathematically by means of appropriate models.

When determining the performance of an instrument, it is essential to appreciate how errors arise. There may be many sources of errors; therefore, it is important to identify these sources and draw up an error budget. In the error budget, there may be many factors, such as (1) imperfections in electrical and mechanical components (e.g., high tolerances and noise or offset voltages), (2) changes in component performances (e.g., shift in gains, changes in chemistry, aging, and drifts in offsets), (3) external and ambient influences (e.g., temperature, pressure, and humidity), and (4) inherent physical fundamental laws (e.g., thermal and other electrical noises, Brownian motion in materials, and radiation).

In instrumentation systems, errors can be broadly classified as systematic, random, or gross.

Figure 6. Bode plots of gains and phase angles against frequency of a second-order system. Curves are functions of frequencies as well as damping ratios. These plots can be obtained theoretically or by practical tests conducted in the frequency range of interest.

Systematic Errors

Systematic errors remain constant with repeated measurements. They can be divided into two basic groups: the instrumental errors and the environmental errors. Instrumental errors are inherent within the instrument, arising because of the mechanical structure, electronic design, improper adjustments, wrong applications, and so on. They can also be subclassified as loading error, scale error, zero error, and response time error. The environmental errors are caused by environmental factors such as temperature and humidity. Systematic errors can also be viewed as static or dynamic errors.

Systematic errors can be quantified by mathematical and graphical means. They can be caused by the nonlinear response of the instrument to different inputs as a result of hysteresis. They also emerge from wrong biasing, wear and aging, and other factors such as modifying the effects environment (e.g., interference). Typical systematic error curves are illustrated in Fig. 7.

Because of the predicability of systematic errors, deterministic mathematics can be employed. In the simplest form, the error of a measurement may be expressed as

$$\Delta x(t) = x_m(t) - x_r(t) \quad (10)$$

where $\Delta x(t)$ is the absolute error, $x_r(t)$ is the correct reference value, and $x_m(t)$ is the measured value.

From Eq. (10), the relative error $r_e(t)$ may be calculated as

$$r_e(t) = \frac{\Delta x(t)}{x_r(t)} \quad (11)$$

However, in complex situations, correction curves obtained either empirically or theoretically may be used. Manufacturers usually supply correction curves, especially if their products embrace wide ranging and different applications (e.g., slurries with changing characteristics in time).

In many applications, the measurement system is made up of many components that have errors in their own rights. The

deterministic approach may be adapted to calculate the overall propagated error of the system, as

$$y = f(x_1, x_2, x_3, \dots, x_n) \quad (12)$$

where y is the overall output and $x_1, x_2, \dots$ are the components affecting the output.

Each variable affecting the output will have its own absolute error of Δx_i . The term Δx_i indicates the mathematically or experimentally determined error of each component under specified operating conditions. The performance of the overall system with the errors may be expressed as

$$y \pm \Delta y = f(x_1 \pm \Delta x_1, x_2 \pm \Delta x_2, \dots, x_n \pm \Delta x_n) \quad (13)$$

For an approximate solution, the Taylor series may be applied to Eq. (13). By neglecting the higher-order terms of the series, the total absolute error Δy of the system may be written as

$$\Delta y = |\Delta x_1 \delta y / \delta x_1| + |\Delta x_2 \delta y / \delta x_2| + \dots + |\Delta x_n \delta y / \delta x_n| \quad (14)$$

The absolute error is predicted by measuring or calculating the values of the errors of each contributing component.

Slight modification of Eq. (13) leads to uncertainty analysis, where

$$w_y = [(w_1 \delta y / \delta x_1)^2 + (w_2 \delta y / \delta x_2)^2 + \dots + (w_n \delta y / \delta x_n)^2]^{1/2} \quad (15)$$

where w_y is the uncertainty of the overall system and $w_1, w_2, \dots, w_n$ are the uncertainties of affecting the component.

Uncertainty differs from error in that it involves such human judgemental factors as estimating the possible values of errors. In measurement systems, apart from the uncertainties imposed by the instruments, experimental uncertainties also exist. In evaluating the total uncertainty, several alternative measuring techniques should be considered and assessed, and the estimated accuracies must be worked out with care.

Random and Gross Errors

Random errors appear as a result of rounding of reading, noise and interference, backlash and ambient influences, and so on. In experiments, the random errors vary by small amounts around a mean value. Therefore, the future value of any individual measurement cannot be predicted in a deterministic manner. Random errors may not easily be offset electronically; therefore, in the analysis and compensation, stochastic approaches are adapted by using the laws of probability.

Depending on the system, the random error analysis may be made by applying different probability distribution models. But, most instrumentation systems obey normal distribution laws; therefore, the Gaussian model can broadly be applied enabling the determination of the mean values, standard deviations, confidence intervals, and the like, depending on the number of samples being taken. A typical example of a Gaussian curve is given in Fig. 8. The mean value $\bar{x}$ and the standard deviation σ may be found by

$$\bar{x} = \frac{\sum x_i}{n} \quad (16)$$

Figure 7. Systematic errors are static errors and they can be quantified theoretically or experimentally. There are many different types, including hysteresis, linearity, and offset. They are contained within an error band typical to the particular instrument.

Figure 8. Random errors of instruments can be analyzed by using probability methods. In many instruments, the errors can be described by a Gaussian distribution curve.

and

$$\sigma = \frac{\sum (x_i - \bar{x})^2}{n - 1} \quad (17)$$

Discussions relating to the application of stochastic theory in error analysis are very lengthy and will not be repeated here. Interested readers should refer to the Bibliography (e.g., Holman, 1989).

Gross errors are the result of human mistakes, equipment fault, and the like. Human errors may occur in the process of observations or during the recording and interpretation of experimental results. A large number of errors can be attributed to carelessness, the improper adjustment of instruments, the lack of knowledge about the instrument and the process, and so on. These errors cannot be treated mathematically and cannot be eliminated completely, but they can be minimized by having different observers repeat the experiments.

Error Reduction Techniques

Controlling errors is an essential part of instruments and instrumentation systems. Various techniques are available to achieve this objective. The error control begins in the design stages by choosing the appropriate components, filtering, and bandwidth selection, by reducing the noise, and by eliminating the errors generated by the individual subunits of the complete system. In a good design, the errors of the previous group may be compensated adequately by the following groups.

The accuracy of instruments can be increased by postmeasurement corrections. Various calibration methods may be employed to alter parameters slightly to give correct results. In many cases, calibration graphs, mathematical equations, tables, the experiences of the operators, and the like are used to reduce measurement errors. In recent years, with the application of digital techniques and intelligent instruments, error corrections are made automatically by computers or the devices themselves.

In many instrumentation systems, the application of compensation strategy is used to increase static and dynamic performances. In the case of static characteristics, compensations can be made by many methods including the introducing opposing nonlinear elements in the system, using isolation and

zero environmental sensitivity, opposing compensating environmental inputs, using differential systems, and employing feedback systems. On the other hand, the dynamic compensation can be achieved by applying these techniques as well as by reducing harmonics, using filters, adjusting bandwidths, using feedback compensation techniques, and the like.

Open loop and close loop dynamic compensations are popular methods employed in both static and dynamic error corrections. For example, using high-gain negative feedback can reduce the nonlinearity generated by the system. A recent and fast-developing trend is the use of computers for estimating measured values and providing compensation during the operations if any deviations occur from the estimated values.

STANDARDS AND REFERENCE MATERIALS

Standards of fundamental units of length, time, weight, temperature, and electrical quantities have been developed for measurements to be consistent all over the world. The length and weight standards—the meter and the kilogram—are kept in the International Bureau of Weights and Measures in Sèvres, France. Nevertheless, in 1983 the meter was defined as the length of the path traveled by light in vacuum in the fraction $1/299,792,458$ of a second, which was adopted as the standard meter. The standard unit of time—second—is established in terms of known oscillation frequencies of certain devices, such as the radiation of the cesium-133 atom. The standards of electrical quantities are derived from mechanical units of force, mass, length, and time. Temperature standards are established as international scale by taking eleven primary fixed points. If different units are involved, the relationship between different units are defined in fixed terms. For example, $1 \text{ lb} = 453.59237 \text{ g}$.

Based on these standards, primary international units, SI (Système International d'Unités), are established for mass, length, time, electric current, luminous intensity, and temperature, as illustrated in Table 2. From these units, SI units of all physical quantities can be derived as exemplified in Table 3. The standard multiplier prefixes are illustrated in Table 4.

In addition to primary international standards, standard instruments are available having stable and precisely defined characteristics that are used as references for other instruments that are performing the same function. Hence, the performance of an instrument can be cross-checked against a known device. At a global level, checking is done by using an international network of national and international laboratories,

1. *International standards* represent certain units of measurement with maximum accuracy possible within today's available technology. These standards are under the responsibility of an international advisory committee and are not available to ordinary users for comparison or calibration purposes.
2. *Primary standards* are the national standards maintained by national laboratories in different parts of the world for verification of secondary standards. These standards are independently calibrated by absolute measurements that are periodically made against the international standards. The primary standards are compared against each other.
3. *Secondary standards* are maintained in the laboratories of industry and other organizations. They are periodically checked against primary standards and certified.
4. *Working standards* are used to calibrate general laboratory and field instruments.

Another type of standard is published and maintained by the IEEE in New York. These standards are for test procedures, safety rules, definitions, nomenclature, and so on. The IEEE standards are adopted by many organizations around the world. Many nations also have their own standards for test procedures, instrument usage procedures, safety, and the like.

CALIBRATION, CALIBRATION CONDITIONS, AND THE LINEAR CALIBRATION MODEL

The calibration of all instruments is essential for checking their performances against known standards. This provides consistency in readings and reduces errors, thus validating the measurements universally. After an instrument is calibrated, future operation is deemed to be error-bounded for a given period of time for similar operational conditions. The calibration procedure involves comparison of the instrument against primary or secondary standards. In some cases, it may be sufficient to calibrate a device against another one with a known accuracy.

Many nations and organizations maintain laboratories with the primary functions of calibrating instruments and field measuring systems that are used in everyday operations. Examples of these laboratories are National Association of Testing

Figure 9. Instruments are frequently calibrated sequentially for all inputs. Calibrations are made under static or dynamic conditions, usually keeping all inputs constant and varying only one and observing the output. The calibration continues until all other inputs are covered.

Authorities (NATA) of Australia and the British Calibration Services (BCS).

Calibrations may be made under static or dynamic conditions. A typical calibration procedure of a complex process involving many instruments is illustrated in Fig. 9. In an ideal situation, for instruments that respond to a multitude of physical variables, a commonly employed method is to keep all inputs constant except one. The input is varied in increments in increasing and decreasing directions over a specified range. The observed output then becomes a function of that single input. The calibration is continued in a similar manner until all other inputs are covered. For better results, this procedure may be repeated by varying the sequences of inputs thus developing a family of relationships between the inputs and outputs. As a result of these calibration readings, the input and output relation usually demonstrates statistical characteristics. From these characteristics, appropriate calibration curves can be obtained, and other statistical techniques can be applied.

In many instruments, the effect of a single input may not represent the true output values when one input is varied and all others are kept constant. In these cases, calibration is conducted by varying several inputs simultaneously. Throughout the calibration procedure, the n number of variables of the system are monitored by appropriate standard instruments. The rule of thumb is that each calibrated variable must have a traceable ladder starting from laboratory standards and secondary standards leading to primary standards. This is known as the linear calibration model or traceability.

Most instrument manufacturers supply calibrated instruments and reliable information about their products. But their claims of accuracy and reliability must be taken at face value. Therefore, in many cases, application-specific calibrations must be made periodically within the recommended calibration intervals. Usually, manufacturers supply calibration programs. In the absence of such programs, it is advisable to conduct frequent calibrations in the early stages of installation and lengthen the period between calibrations as the confidence builds based on satisfactory performance. Recently, with the wide applications of digital systems, computers can make au-

tomatic and self calibrations as in the case of many intelligent instruments. In these cases, post measurement corrections are made, and the magnitudes of various errors are stored in the memory to be recalled and used in laboratory and field applications.

ANALOG AND DIGITAL INSTRUMENTS

Instruments can be analog or digital or a combination of the two. Nowadays, most instruments are produced to be digital because of the advantages that they offer. However, the front end of many of instruments are still analog; that is, the majority of sensors and transducers generate analog signals. Initially, the signals are conditioned by analog circuits before they are put into digital form for signal processing. It is important to mention that digital instruments operating purely on digital principles are developing fast. For instance, today's smart sensors contain the complete signal condition circuits in a single chip integrated with the sensor itself. The output of smart sensors can be interfaced directly with other digital devices.

In analog instruments, the useful information is conveyed by changes in amplitudes, phases, or frequencies or a combination of the three. These signals can be deterministic or non-deterministic. In all analog or digital instruments, as in the case with all signal-bearing systems, there are useful signals that respond to the physical phenomena and unwanted signal resulting from various forms of noise. In the case of digital instruments, additional noise is generated in the process of A/D conversion.

Analog signals can also be nondeterministic; that is, the future state of the signal cannot be determined. If the signal varies in a probabilistic manner, its future can be foreseen only by statistical methods. The mathematical and practical treatment of analog and digital signals having deterministic, stochastic, and nondeterministic properties is a very lengthy subject and a vast body of information can be found in literature; therefore, they will not be treated here.

As is true of all instruments, when connecting electronic building blocks, it is necessary to minimize the loading effects of each block by ensuring that the signal is passed without attenuation, loss, or magnitude and phase alterations. It is also important to ensure maximum power transfer between blocks by appropriate impedance-matching techniques. Impedance matching is very important in all instruments but particularly at a frequency of 1 MHz and above. As a rule of thumb, output impedances of the blocks are usually kept low and input impedances are kept high so that the loading effects can be minimized.

Analog Instruments

Analog instruments are characterized by continuous signals. A purely analog system measures, transmits, displays, and stores data in analog form. The signal conditioning is usually made by integrating many functional blocks such as bridges, amplifiers, filters, oscillators, modulators, offsets and level converters, buffers, and the like, as illustrated Fig. 10. Generally, in the initial stages, the signals produced by the sensors and transducers are conditioned mainly by analog electronics, even if they are configured as digital instruments later. Therefore, we pay more attention to analog instruments, keeping in mind that much of the information given here also may be used in various stages of the digital instruments.

Figure 10. Analog instruments measure, transmit, display, and store data in analog form. The signal conditioning usually involves such components as bridges, amplifiers, filters, oscillators, modulators, offsets and level converters, buffers, and so on. These components are designed and tested carefully to suit the characteristics of a particular instrument.

Instrument bridges are commonly used to measure such basic electrical quantities as resistance, capacitance, inductance, impedance, and admittance. Basically, they are two-port networks in which the component to be measured is connected to one of the branches of the network. There are two basic groups, ac and dc bridges. Also, there are many different types in each group, such as Wheatstone and Kelvin dc bridges and Schering, Maxwell, Hay, and Owen ac bridges. In a particular instrument, the selection of the bridge to be employed and the determination of values and tolerances of its components is very important. It is not our intent to cover all bridges here; however, as typical example of an ac bridge, a series RC bridge is given in Fig. 11. We also offer some analysis to illustrate briefly their typical operational principles. At balance,

$$Z_1 Z_3 = Z_x Z_2 \quad (18)$$

Substitution of impedance values gives

$$R_3(R_1 - j/\omega C_1) = (R_x - j/\omega C_x)R_2 \quad (19)$$

Equating the real and imaginary terms gives the values of unknown components as

$$R_x = \frac{R_1 R_3}{R_2} \quad (20)$$

and

$$C_x = \frac{C_1 R_2}{R_3} \quad (21)$$

Figure 11. A series RC bridge wherein the unknown capacitance is compared with a known capacitance. The voltage drop across R_1 balances the resistive voltage drop in branch Z_2 . The bridge balance is achieved relatively easily when capacitive branches have substantial resistive components. The resistors R_1 and either R_2 or R_3 are adjusted alternately to obtain the balance.

In instruments, the selection and use of amplifiers and filters are also very important since many transducers generate extremely weak signals in comparison to the noise existing in the device. Today, operational amplifiers and high-precision instrumentation amplifiers form the building blocks of modern instruments.

The operation amplifiers may be used as inverting and noninverting amplifiers, and by connecting suitable external components, they can be configured to perform many other functions, such as multipliers, adders, limiters, and filters. Instrumentation amplifiers are used in situations where operational amplifiers do not meet the requirements. They are essentially high-performance differential amplifiers consisting of several closed-loop operational amplifiers. The instrumentation amplifiers have improved common mode rejection ratios (CMRR) (up to 160 dB), high input impedances (up to 500 M Ω), low output impedance, low offset currents and voltages and better temperature characteristics. To illustrate amplifiers in instrumentation systems, a typical current amplifier used in charge amplification is illustrated in Fig. 12. In this circuit, if the input impedance of the operational amplifier is high, output is not saturated, and the differential input voltage is small, it is possible to write

$$\frac{1}{C_f} \int i_f dt = e_{ex} - e_{ai} = e_{ex} \quad (22)$$

$$\frac{1}{C_x} \int i_x dt = e_0 - e_{ai} = e_0 \quad (23)$$

$$i_f + i_x - i_{ai} = 0 = i_f + i_x \quad (24)$$

Manipulation of these equations gives

$$e_0 = \frac{-C_f e_{ex}}{C_x} \quad (25)$$

Figure 12. Using an operational amplifier signal processor is useful to eliminate the nonlinearity in the signals generated by capacitive sensors. With this type of arrangement, the output voltage can be made to be directly proportional to variations in the signal representing the nonlinear operation of the device.

Figure 13. Filtering is used in various stages of signal processing to eliminate unwanted components of signals. They can be designed and constructed to eliminate or pass signals at certain frequency ranges. Suitable arrangements of components yield to lowpass, highpass, band-pass, bandstop and notch filters. Filters can be classified as active and passive.

However, a practical circuit requires a resistance across C_f to limit output drift. The value of this resistance must be greater than the impedance of C_f at the lowest frequency of interest.

Filtering is used to reject unwanted components of signals. For example, by using a filter that narrows the bandwidth, the broadband noise energy is reduced, and unwanted signals outside the passband are rejected. Analog filters can be designed by using various techniques, such as Butterworth, Chebyshev, and Bessel-Thomson filters etc. They can be lowpass, highpass, bandpass, bandstop, and notch filters. Filters can be classified as active filters or passive filters. Active filters involve active components such as operational or instrumentation amplifiers, whereas passive filters are configured completely by inductive, capacitive, and resistive components. The choice of active or passive filters depends on the available components, the precision required, and the frequency of operations. A typical filter used in instrument is given in Fig. 13.

Digital Instruments

In modern instruments, the original data acquired from the physical variables are usually in analog form. This analog signal is converted to digital before being passed on to the other parts of the system. For conversion purposes, analog-to-digital converters are used together with appropriate sample-and-hold devices. In addition, analog multiplexers enable the connection of a number of transducers to the same signal-processing media. The typical components of a digital instrument are illustrated in Fig. 14. The digital systems are particularly useful in performing mathematical operations and storing and transmitting data.

Analog-to-digital conversion involves three stages: sampling, quantization, and encoding. The Nyquist sampling theorem must be observed during sampling; that is, “the

Figure 15. Analog-to-digital converters involve three stages: sampling, quantization, and encoding. However, the digitization introduces a number of predictable errors. After the conversion, the data can be processed by techniques such as FFT analysis, DFT analysis, digital filtering, sequential or logical decision making, correlation methods, spectrum analysis, and so on.

number of samples per second must be at least twice the highest frequency present in the continuous signal.” As a rule of thumb, depending on the significance of the high frequencies, the sampling must be about five to ten times of the highest frequency of the signal. The next stage is the quantization, which determines the resolution of the sampled signals. The quantization error decreases as the number of bits increases. In the encoding stage, the quantized values are converted to binary numbers to be processed digitally. Figure 15 illustrates a typical A/D sampling process of an analog signal.

After the signals are converted to digital forms, the data can be further processed by employing various techniques as FFT analysis, digital filtering, sequential or logical decision making, correlation methods, spectrum analysis, and so on.

Virtual Instruments (VIs)

Traditional instruments have three basic components—acquisition and control, data analysis, and data presentation. In VIs, the use of digital techniques, software, and computers replace the display and processing capabilities of most traditional instruments. In this technology, plug-in data acquisition (DAQ) boards, PC cards (PCMCIA), and parallel port I/O devices are used to interface sensors and transducers of the system under investigation to computers. There are standard interface buses such as VXIbus, which stands for VMEbus Extensions for Instrumentation (also known as the IEEE Standard 1155-1992).

Once the system is interfaced, the computer can be programmed to act just like a stand-alone instrument, but offering additional benefits of flexibility of the processing, display, and storage. In VIs, the data can be saved or loaded in memory to

Figure 14. Digital instruments have more signal-processing components than analog instruments. Usually, analog signals are converted to digital form by analog-to-digital (A/D) converters. The digital instruments have the advantage of processing, storing, and transmitting signals more easily than their analog counterparts.

be processed in popular spreadsheet programs and word processors, and a report generation capability complements the raw data storage by adding timestamps, measurements, user names, and comments.

VI technology allows the user to build test systems that fit specific applications. The VI software can be programmed to resemble familiar instrument panels, including buttons and dials. The user interface tools include knobs, meters, gauges, dials, tank displays, thermometers, graphs, strip charts, and the like to simulate the appearance of traditional instruments. Computer displays can show more colors, and allow users to quickly change the way they display test data and controls as required. The software also contains analysis libraries with high-powered statistics, curve fitting, signal processing, and filtering to standard dynamic link libraries (DLLs).

Designing a VI system is similar to designing a test system with stand-alone instruments. The first step is to determine what types of signals are needed to measure, including their frequencies, amplitudes, and other signal characteristics together with the level of accuracy expected from these signals. To develop the software for the test application, a programming language or test-development software package needs to be selected such as C or Microsoft Visual Basic. Since the display is not fixed, as on a stand-alone instrument, it can be as complex or as simple as the application requires.

Nowadays, users can configure their VIs to update front panels and display real-time, animated VIs over the Internet. The toolkits let applications be published over the Web and viewed with a standard Web browser with little additional programming. With these tools, developers can monitor VIs running in remote locations, publish experiment results on the Web, and automatically notify operators of alarm conditions or status information.

CONTROL OF INSTRUMENTS

Instruments can be manual, semiautomatic, or fully automatic. Manual instruments need human intervention for adjustment, parameter setting, and interpreting the readings. Semiautomatic instruments need limited intervention such as the selection of operating conditions and so on. In the fully automatic instruments, however, the variables are measured either periodically or continuously without human intervention. The information is either stored or transmitted to other devices automatically. Some of these instruments can also measure the values of process variables and regulate their deviations from preset points.

It is often necessary to measure many parameters of a process by using two or more instruments. The resulting arrangement for performing the overall measurement function is called the measurement system. In measurement systems, instruments operate in an autonomously but coordinated manner. The information generated by each device is communicated between instruments themselves, or between the instrument and other devices such as recorders, display units, and computers. The coordination of instruments can be done in three ways: analog-to-analog, analog-to-digital, and digital-to-digital.

Analog systems consist of instruments that generate continuous current and voltage waveforms in response to the physical variations. The signals are processed by using analog

electronics; therefore, signal transmission between the instruments and other devices is also done in the analog form. In assembling these devices, the following characteristics must be considered:

- Signal transmission and conditioning
- Loading effects and buffering
- Proper grounding and shielding
- Inherent and imposed noises
- Ambient conditions
- Signal level compatibility
- Impedance matching
- Proper display units
- Proper data storage media

Offset and level conversion is used to convert the output signal of an instrument from one level to another, compatible with the transmission medium in use. In analog systems, signals are usually transmitted at suitable current levels (4–20 mA). In this way, change in impedance does not affect the signal levels, and standard current signal levels can easily be exchanged.

In digital instrumentation systems, analog data are converted and transmitted in digital form. The transmission of data between digital devices can be done relatively easily, by using serial or parallel transmission techniques. However, as the measurement system becomes large by the inclusion of many instruments, the communication becomes complex. To avoid this complexity, message interchange standards are used for digital signal transmission such as RS-232 and IEEE-488, VXIbus.

Many instruments are manufactured with output ports to pass measurement data and various control signals. The IEEE-488 (also known as the GPIB) bus is one of the established industry standard instrumentation interfacing. It enables simultaneous measurements by interfacing up to 15 instruments together at the same time. It has 16 signal lines distributed as 8 data lines, 3 control lines, and 5 general interface management lines. The line configuration of an IEEE-488 bus is given in Fig. 16. Once connected, any one device can transfer data to one or more other devices on the bus. All devices must be able to perform at least one of the following roles: talker, listener, controller. The minimum system consists of one talker and one listener without a controller. The length of cables connected to the bus cannot exceed 20 m, and the maximum data rate is restricted to 250 kilobytes per second.

RS-232 is issued by the Electronic Industries Association (EIA). It uses serial binary data interchange and applies specifically to the interconnection of data communication equipment (DCE) and data terminal equipment (DTM). Data communications equipment may include modems, which are the devices that convert digital signals suitable for transmission through telephone lines. The RS-232 uses standard DB-25 connectors, the pin connection is given in Table 5. Although 25 pins are assigned, a complete data transmission is possible by using only three pins—2, 3 and 7. The transmission speed can be set to certain baud rates such as 19200 bits per second and can be used for synchronous or nonsynchronous communication purposes. The signal voltage levels are very flexible, with any voltage between –3 V to –25 V representing logic 1 and any voltage between +3 V to +25 V representing logic 0.

Figure 16. The IEEE-488 or the GPIB bus is an industry standard for interface medium. It has 8 data lines, 3 control lines, and 5 general interface management lines. In noisy environments the maximum length of cable is recommended to be not more than 20 m.

In many industrial applications, the current loop digital communication is used. This communication is similar to analog current loop systems, but the signal is transmitted in digital form, with 20 mA signifying logic 1 and 0 mA representing logic 0. Depending on the external noise sources in the installation environment, the current loop can be extended up to 2 km.

When data are transmitted distances greater than those permitted by the RS-232 or current loop, the modem, microwave, or radiofrequency (RF) transmissions are used. In this case, various signal modulation techniques are necessary to convert digital signals to suitable formats. For example, most modems, with medium-speed asynchronous data transmission, use frequency-shift keyed (FSK) modulation. The digital interface with modems uses various protocols such as MIL-STD-188C to transmit signals in simplex, half-duplex, or full duplex forms depending on the directions of the data flow. The simplex interface transmits data in one direction, whereas full-duplex transmits it in two directions simultaneously.

As far as industrial applications are concerned, several standards for digital data transmission are available, commonly

known as *fieldbuses* in the engineering literature. For example, WordFIP and Profibus have been developed and Foundation Fieldbus is under development to increase the performance of the 20 mA current loop. New devices allow for an increase in the data rates (e.g., National Instruments chips and boards operating with high-speed protocol HS488 for 8 Mbytes/s transfer rate). A new standard is under discussion at the IEEE by the working group for higher performance IEEE Std. 488.1, with a very high increase in the data rate.

Concerning the design software, there are important tools that help implement control (application) software for automatic measuring equipment, such as LabWindows and LabVIEW from National Instruments and VEE from Hewlett-Packard.

In various applications, many instruments (say over a thousand) may be used to monitor and control the process as in the case of computer integrated manufacturing (CIM). In these cases, instruments are networked either in groups or as whole via a central computer or group of computers. Appropriate network topologies (e.g., star, ring, field bus) may be employed to enable the signal flow between the instruments and computers, among the instruments themselves, or between instruments and control panels.

Table 5. RS-232 Pin Connections

Pin Number	Direction	Function
1	—	Frame ground
2	Out	Transmitted data (–TxD)
3	In	Received data (–RxD)
4	Out	Request to send (RTS)
5	In	Clear to send (CTS)
6	In	Data set ready (DSR)
7	—	Signal ground (SG)
8	In	Received line signal detector (DCD)

18	In	+ Receive current loop data
20	Out	Data terminal ready (DTR)
22	In	Ring indicator (RI)
25	In	– Receive current loop return

INDUSTRIAL MEASURING INSTRUMENTS

In industry, instruments are used to sense and maintain the functions of the process. Because the requirements of diverse industries are different, the instruments are made quite differently to suit applicational differences from one industry to another. Here, instruments specific to some industries will be discussed briefly.

The process industry uses instruments extensively for on-line monitoring and off-line analysis. Specific instruments are used commonly for sensing variables such as temperature, pressure, volumetric and mass flow rate, density, weight, displacement, pH levels, color, absorbency, viscosity, material flow,

dew point, organic and inorganic components, turbidity, solid and liquid level, humidity, and particle size distribution. The selection and use of these instruments constitute an important part of process engineering, which is a discipline in its own right. Additional information can be found in the Bibliography (e.g., Sydenham et al., 1989).

In medical technology, there are three basic types of instruments—imaging, physiological measurements, and laboratory analysis. In imaging and physiological measurements, the instruments are closely linked with patients. Some examples of these instruments are X-ray tomography, nuclear magnetic resonance (NMR) and nuclear spin tomography, ultrasound imaging, thermography, brain and nervous system sensors, and respiratory sensors. Many instruments are based on the radiation and sound, force and tactile sensing, electromagnetic sensing, and chemical and bioanalytical sensors.

Power plants are instrumented for maximum availability, operational safety, and environmental planning. Therefore, their measurements must be as accurate as possible and reliable. Instruments are used for temperature, pressure, flow, level, vibration measurements, and water, steam, and gas analysis. For example, gas analysis requires instruments to measure carbon compounds, sulfur and nitrogen compounds, and dust and ash contents.

Environmental monitoring requires a diverse range of instruments for air, water, and biological monitoring. Instruments are used for measuring various forms of radiation, chemicals hazards, air pollutants, and organic solvents. Many sophisticated instruments are also developed for remote monitoring via satellites, and they operate on optical, microwave, and RF electromagnetic radiation principles.

In automobiles, instruments are used to assist drivers by sensing variables such as cooling, braking, fuel consumption, humidity control, speed, travel route monitoring, and position sensing. Instruments also find applications for safety and security purposes, such as passenger protection and locking and antitheft systems. Recently, with the advent of micromachined sensors, many diverse instruments such as engine control, fuel injection, air regulation, and torque sensing are developed.

The manufacturing industry, especially automated manufacturing, requires a diverse range of instruments. Machine diagnosis and process parameters are made by instruments based on force, torque, pressure, speed, temperature, and electrical parameter-sensing instruments. Optics, tactile arrays, and acoustic scanning instruments are used for pattern recognition. Distance and displacement measurements are made by many methods (e.g., inductive, capacitive, optical, and acoustic techniques).

Aerospace instrumentation requires an accurate indication of physical variables and the changes in these variables. Instruments are designed to suit specific conditions of operations. Some of the measurements are gas temperature and pressure, fluid flow, aircraft velocity, aircraft icing, thrust and acceleration, load, strain and force, position, altitude sensing, and direction finding.

MEASUREMENT ERRORS

In applied science and engineering, it is agreed that all observations contain errors. This article discusses how these errors are described today. It also discusses how this description is used to compute the effect of the errors upon the measurement result, and how this effect is reduced or even minimized by rational use of the observations and by experimental design.

For the description of observations, use is made of a mathematical model. This is a mathematical expression intended to describe the observations fully. It will be supposed throughout this article that the mathematical model is parametric, and that the parameters are the quantities to be measured. For example, the parametric model may be a sinusoidal function of time with unknown amplitude, frequency, and phase. Then, these three quantities are the parameters of this model. Yet the model of the observations is incomplete without including errors. If there is reason to assume that the errors in the observations are nonsystematic and additive, they are taken into consideration by adding a term representing them to the expression for the sinusoidal function. Then, the resulting sum is the mathematical model of the observations. It is supposed to fully describe the observations. Nonsystematic errors may loosely be defined as errors that vary if the experiment is repeated under the same conditions and are equal to zero if averaged over many experiments. They are modeled as stochastic variables with an expectation equal to zero. The term expectation is the abstract mathematical term for the mean value. It will be used throughout to avoid confusion with averages, such as time averages, which are measurements. If, in the example, the errors are stochastic variables, so are the observations. Since each observation is equal to the sum of the sinusoidal function and the stochastic error, the expectation of an observation is the value of the function at the time instant concerned. Therefore, the expectation or, equivalently, the function value represents the hypothetical errorless observation.

Since the observations are stochastic variables, they are described by probability density functions. These define for discrete stochastic variables, such as counting results, the probability of occurrence of a particular discrete outcome. For continuous stochastic variables, the probability density function defines the probability of occurrence of an observation within a particular range of values. The probability density function also determines the expectation of the observations. Since this expectation is equal to the function value, the probability density function of the observations depends on the parameters of the function, and thus, the measurement problem has become

a statistical parameter estimation problem. This observation has important consequences. It implies that for measurement, use can be made of the extensive theory and methods of statistics. It will be seen that this offers a number of exceptional advantages. A description of these advantages requires some familiarity with a number of notions from statistics. Therefore, these will first be introduced. References 1–4 are useful general texts on statistics.

In statistics, the function of the observations with which a parameter is estimated is called an estimator. Using the same observations, for a particular parameter, different estimators can be defined. Since the observations are stochastic variables, so is the estimator. Therefore, the estimator has a probability density function, an expectation, and a standard deviation. If the expectation of the estimator is equal to the hypothetical true value of the parameter to be estimated, the estimator is called unbiased. Otherwise, it is biased. The deviation of the true value from the expectation is called bias.

Bias is the systematic error. It is, therefore, equivalent to the concept accuracy. There are two essentially different sources of bias. In the first place, the expectation of the observations may be different from the function model assumed. In the above mentioned sinusoidal example, a trend may be present in addition to the sinusoid, while the model assumed and fitted to the observations consists of the sinusoidal function only. This will, of course, always result in a systematic deviation of the estimated parameters, even in the hypothetical complete absence of nonsystematic errors. The remedy is to include the trend in the model fitted. The inclusion of the trend has the effect that two additional parameters, the slope and the intercept of the trend, have to be estimated. It will be discussed later that there are various reasons to keep in measurement the number of parameters to be estimated as small as possible. Therefore, classical measurement measures to avoid errors such as trends, day-and-night cycles, and background are always preferable to including these contributions in the model. The second source of bias is of a completely different nature. It is produced by and is characteristic of the estimator, itself. It may, therefore, also occur if the assumed model of the observations and that of the expectations are the same. Two estimators of the same parameters from the same observations may have different bias. If the bias vanishes as the number of observations increases, the estimator is called asymptotically unbiased. An effective method to remove bias of this kind is described by Stuart and Ord (4).

The standard deviation of an estimator represents precision. It is the spread of the measurement result if the experiment is repeated under the same conditions. In the example of the estimation of the parameters of the sinusoid, the amplitude, frequency, and phase have to be estimated simultaneously. This estimator is, therefore, vector valued. A vector estimator has a covariance matrix associated with it. The diagonal elements of this matrix are the variances of the estimators of each of the elements of the vector of parameters. The off-diagonal elements represent the covariances of the estimators of different elements. Bias and standard deviation are statistical key properties of estimators for practical measurement purposes. They demonstrate the practical feasibility, clarity, and generality of the model based statistical parameter estimation approach to the treatment of errors in observations. In addition to these desirable properties, model based parameter

estimation has a number of advantages which will now be discussed.

It has been mentioned earlier that for the measurement of the parameters of the same model from the same set of observations, use may be made of different estimators. These estimators will generally have different standard deviations, that is, have different precision. The question may, therefore, be asked which estimator is most precise? Or put somewhat differently, what precision is attainable if any estimator may be used? The answer to this question may be given using the concept of Fisher information. The Fisher information with respect to the model parameters is computed from the probability density function of the observations. If the model has one parameter, the quantity computed is called the Fisher information amount. If more than one parameter is measured, such as in the sinusoidal example, it assumes the form of a matrix, the Fisher information matrix. This is a symmetrical matrix of the same order as the number of parameters. The elements of the Fisher information matrix are dependent on the probability density of the observations and on the model of the expectations. They are independent of any method of estimation. With any set of observations, considered as stochastic variables, a Fisher information matrix with respect to the unknown parameters is associated. The inverse of the Fisher information matrix is called the Cramér Rao lower bound. It can be shown that the diagonal elements of the covariance matrix of any unbiased vector estimator, the variances of the elements, cannot be smaller than the corresponding diagonal elements of the Cramér Rao lower bound. Therefore, any unbiased estimator is at best as precise as a hypothetical estimator of the same parameters having the Cramér Rao lower bound as its covariance matrix. Thus, the Cramér Rao lower bound is a standard to which the precision of an unbiased estimator may be compared. This is the reason why the ratio of a diagonal element of the Cramér Rao lower bound to the variance of an estimator is called the efficiency of the estimator. Cramér Rao theory also extends to functions of the estimated parameters. For example, suppose that the height, width, and location of a Gaussian pulse or spectral peak are estimated, but that the quantities to be measured ultimately are the location and the area. Then, the Cramér Rao lower bound for the height, width, and location combined with the expression for the area in terms of the width and height may be used to compute the Cramér Rao lower bound for the location and area. The resulting expressions exactly describe the propagation of the Cramér Rao lower bound for the original parameters to that for location and area. Thus, they show exactly the sensitivity of the Cramér Rao lower bound for the area parameter to the various elements of the Cramér Rao lower bound for the original parameters. This means that an instrument has been found to compute the propagation of errors in the observations to errors in the parameters and, subsequently, to errors in functions of the parameters.

For the engineer and applied scientist, an important question is how to make the influence of errors in the observations upon the measurement result as small as possible. This is equivalent to the question of how to find the method that produces the most precise measurement result from the available observations. For calibration purposes, precision itself may be the ultimate purpose. In other applications, precision is often pursued not for its own sake but to make the conclusions drawn from the measurement result more reliable. The extent to which it is possible to find an efficient estimation method

depends on the available a priori knowledge of the probability density function of the observations. As has been discussed earlier, this probability density function is parametric in the hypothetical exact values of the unknown parameters. This dependence of the probability density function of the observations on the parameters may be used to derive a so-called maximum likelihood estimator of the parameters. First, the numerical values of the available observations are substituted for the corresponding independent variables of the probability density function. Next, the true values of the parameters are considered to be variables. The function thus obtained is called the likelihood function of the parameters. Finally, the likelihood function is maximized with respect to the parameters. The values of the parameters at the maximum are the maximum likelihood estimates of the parameters. This procedure shows the first advantage of the maximum likelihood estimator: it is easily found. In addition, the maximum likelihood estimator has a number of favorable statistical properties. The most important of these is that under general conditions, it attains asymptotically the Cramér Rao lower bound. This means that for a large number of observations, it is most precise. The elements of the Cramér Rao lower bound depend on experimental variables. For example, in the estimation of the parameters of the sinusoid and those of the Gaussian pulse, these are the number of observations and their location. If experimental variables such as these may to a certain extent be freely chosen, this freedom may be used to minimize the Cramér Rao lower bound and, thus, the asymptotic variance. This manipulation of the covariance matrix using experimental variables is called experimental design. From a practical point of view, experimental design may be very attractive since it may lead to a more precise measurement result with the same effort or even less. For practical measurement, the invariance property of maximum likelihood estimators is also important: functions of maximum likelihood estimators are maximum likelihood estimators themselves. Generally, maximizing the likelihood function with respect to the parameters is a nonlinear optimization problem which can only be solved using an iterative numerical optimization method. For a long time, this has been a serious impediment to the application of maximum likelihood, but today, excellent optimization methods and software are available which make the method accessible to any user.

If the observations are normally distributed, the maximum likelihood estimator of the parameters can be shown to be the weighted least squares estimator with the inverse of the covariance matrix of the observations as weighting matrix. If the observations are linear in all parameters to be estimated, the least squares estimator is a relatively simple closed form expression linear in the observations. In addition, if the observations are not normally distributed, the weighted least squares method with the inverse covariance matrix as weighting matrix still has the smallest variance among all estimators that are both linear in the observations and unbiased. If the observations are nonlinear in one or more of the parameters to be estimated, the least squares estimator is, as a rule, no longer a closed form and has to be evaluated using an iterative numerical method. However, effective, specialized, and reliable numerical methods and software are available that make the use of nonlinear least squares straightforwardly. As a result, least squares has become a major tool in the handling of observations subject to error in general and not only of normally distributed observations.

EXPECTATIONS OF OBSERVATIONS

The reduction or minimization of the effect of errors in the observations upon the measurement result requires a mathematical model of the observations. In this article, additive nonsystematic errors in the observations will be modeled as stochastic variables with an expectation equal to zero. This implies that the observations are also stochastic variables, and that the expectations of the observations are the hypothetical exact or errorless observations. Thus, these expectations constitute the model underlying the observations. It will be assumed throughout that this model is a parametric function, and that parameters of this model are the quantities to be measured, or that the quantity to be measured can be computed from these parameters.

Example 1. The multiexponential model. Multiexponential observations are observations with expectations

$$y_n(\gamma) = \alpha_1 \exp(-\beta_1 x_n) + \dots + \alpha_L \exp(-\beta_L x_n) \quad (1)$$

with $n = 1, \dots, N$ where N is the number of observations, and the $2L \times 1$ vector γ is defined as $(\alpha_1 \dots \alpha_L \beta_1 \dots \beta_L)^T$, where the amplitudes α_ℓ and the decay constants β_ℓ are the parameters to be measured, and the superscript T denotes transposition. The measurement points x_n , $n = 1, \dots, N$ are supposed known. If, different from Eq. (1), there is a linear trend in the observations, this deterministic contribution has to be included in the model of the expectations of the observations

$$y_n(\eta) = \alpha_1 \exp(-\beta_1 x_n) + \dots + \alpha_L \exp(-\beta_L x_n) + \lambda x_n + \mu$$

where $\eta = (\alpha_1 \dots \alpha_L \beta_1 \dots \beta_L \lambda \mu)^T$. In this expression, λ and μ are the slope and the intercept of the trend, respectively. These parameters have to be estimated along with the parameters α_ℓ and β_ℓ . This means that the number of parameters to be estimated has increased by two. It will be shown below that this is not only disadvantageous from a computational point of view, but it also unfavorably influences the precision with which the α_ℓ and β_ℓ can be measured. Therefore, it is worthwhile to keep the number of parameters as small as possible. As a consequence, changing the experimental conditions to remove the trend is always preferable to including it in the model of the expectations. On the other hand, if trends cannot be avoided, they have to be included since otherwise, the model of the expectations is wrong. Then, values for the amplitudes and decay constants are found systematically deviating from the α_ℓ and β_ℓ , even in the hypothetical case that nonsystematic errors in the observations are absent.

THE DISTRIBUTION OF THE OBSERVATIONS

The mathematical model of the observations is completed by a description of how the observations are distributed about their expectations. This is done in the form of the joint probability density function of the observations. If $w = (w_1 \dots w_N)^T$ is the vector of the N available observations, their probability density function may be described as $p(w)$. Then, the expectation

$E[w] = (E[w_1] \dots E[w_N])^T$ is defined as

$$E[w] = \int \dots \int wp(w)dw \quad (2)$$

where $dw = dw_1 dw_2 \dots dw_N$, and the integrations are carried out over all possible values of w . Then,

$$E[w] = y(\theta) \quad (3)$$

where $y(\theta) = [y_1(\theta) \dots y_N(\theta)]^T$, and $y_n(\theta)$ is the function parametric in the unknown parameters θ defining the errorless observations such as the exponential model described by Eq. (1). For engineering and applied science, two probability density functions are particularly important. These are the normal probability density function and the Poisson probability density function.

Example 2. The normal probability density function. The observations $w_1, \dots, w_N$ are said to be normally distributed if their probability density function is described by

$$p(w) = \frac{1}{(2\pi)^{N/2}(\det W)^{1/2}} \exp \left[-\frac{1}{2}(w - E[w])^T W^{-1}(w - E[w]) \right]$$

where the $N \times N$ matrix W is the covariance matrix of the observations defined by its (i, j) -the element $\text{cov}(w_i, w_j)$ and $\det W$ and W^{-1} are the determinant and the inverse of W , respectively. This probability density function and many others are discussed in Ref. 3. Equation (3) defines the functional dependence of the normal probability density function on the parameters of the function modelling the expectations. For what follows, the logarithm of $p(w)$ as a function of the parameters θ is needed. After substituting $y(\theta)$ for $E[w]$, it is described by

$$-\frac{N}{2} \ln(2\pi) - \frac{1}{2} \ln(\det W) - \frac{1}{2}[w - y(\theta)]^T W^{-1}[w - y(\theta)] \quad (4)$$

Notice that both first terms of this expression are independent of the parameter vector θ , while the last term is a quadratic form in the elements $w_n - y_n(\theta)$ of $w - y(\theta)$. Observations in practice are often, but not always, normally distributed. One of the reasons is that if the nonsystematic errors are the sum of a number of nonsystematic errors from independent sources, their distribution tends to normal as described by the central limit theorem discussed in Ref. 2.

Example 3. The Poisson probability density function. This probability density function concerns counting statistics. It is described in Ref. 3. Examples of Poisson distributed stochastic variables are radioactive particle counts and pixel values in electron microscopes. The number of counts is Poisson distributed if the probability that it is equal to w_n is given by

$$p(w_n) = \exp(-\lambda_n) \frac{\lambda_n^{w_n}}{w_n!} \quad (5)$$

Simple calculations show that $E[w_n] = \lambda_n$, and that the standard deviation of w_n is equal to $\sqrt{\lambda_n}$. If $w_1, \dots, w_N$ are independent, as is often assumed in applications, their joint probability

density function is equal to the product the probabilities described by Eq. (5)

$$p(w) = \prod_n p(w_n) \quad (6)$$

with $n = 1, \dots, N$. Since $E[w] = \lambda$ with $\lambda = (\lambda_1 \dots \lambda_N)^T$ and $\lambda_n = y_n(\theta)$, the logarithm of the probability density function defined by Eq. (6) may be written

$$\sum_n -y_n(\theta) + w_n \ln[y_n(\theta)] - \ln(w_n!) \quad (7)$$

Notice that the last term in this expression is independent of the parameter vector θ .

From Example 2 and Example 3, the general approach to establishing the dependence of the probability density function of the observations on the parameters, that is, the quantities to be measured, is now clear. First, the expectation of the observations w_n is computed. Then, the result is substituted for the relevant quantities in the probability density function. The probability density function thus obtained is parametric in the parameters of the expectations, that is, of the hypothetical errorless observations. This is the form of the probability density function that will be used hereafter for two purposes. First, it will be used for the computation of the highest attainable precision with which the parameters can be measured from the available observations. It will also be used to find the most precise method to estimate the parameters from the observations.

ATTAINABLE MEASUREMENT PRECISION IN THE PRESENCE OF MEASUREMENT ERRORS

Suppose that a number of N observations $w_1, \dots, w_N$ is available and that the expectations of the observations are described by the multiexponential model defined by Eq. (1). If this model is fitted to the observations with respect to its parameters, the amplitudes, and the decay constants, one could choose the sum of the squares of the deviations of the model from the observations as a criterion of goodness of fit. Then, this criterion could be minimized with respect to the parameters, and the parameter values for which the criterion would be minimum would be the solution. This is the well-known ordinary least squares solution. Alternatively, one could have chosen the values of the parameters for which the sum of the absolute values of the deviations would be minimum. This is the least absolute values or least moduli solution. Then, if the experiment could be repeated sufficiently often, the experimenter could compare the results of both methods and could decide which of both would be most precise. Seeing that the one method is more precise than the other, the experimenter might wonder what the highest attainable precision from these observations is with any method. It has been found that under general conditions, this question may be answered using the concept Fisher information. For a discussion of Fisher information, see Ref. 4. For the computation of the Fisher information, the probability density function of the observations $p(w; \theta)$ is used. This is done as follows. First, the logarithm of $p(w; \theta)$ is taken. For the normal probability density function and for the Poisson probability density function, the result of this operation is described by Eqs. (4) and (7), respectively. Next, the gradient vector of $\ln p(w; \theta)$ with respect

to the elements of θ is calculated. It is defined as

$$\frac{\partial \ln p(w; \theta)}{\partial \theta}$$

If θ is a $K \times 1$ vector, so is the gradient vector. Its k -th element is $\partial \ln p(w; \theta) / \partial \theta_k$. Next, the $K \times K$ matrix

$$\frac{\partial \ln p}{\partial \theta} \frac{\partial \ln p}{\partial \theta^T} \quad (8)$$

is computed where, for simplicity, the arguments of $p(w; \theta)$ have been left out, and $\partial \ln p / \partial \theta^T$ is the transpose of $\partial \ln p / \partial \theta$. The $K \times K$ Fisher information matrix is defined as the expectation of Eq. (8)

$$M = E \left[\frac{\partial \ln p}{\partial \theta} \frac{\partial \ln p}{\partial \theta^T} \right] = \int \dots \int \frac{\partial \ln p}{\partial \theta} \frac{\partial \ln p}{\partial \theta^T} p dw$$

It is not difficult to show that M may alternatively be written

$$M = -E \left[\frac{\partial^2 \ln p}{\partial \theta \partial \theta^T} \right] \quad (9)$$

In this expression, $\partial^2 \ln p / \partial \theta \partial \theta^T$ is the Hessian matrix of $\ln p$ defined by its (q, r) -th element $\partial^2 \ln p / \partial \theta_q \partial \theta_r$.

Example 4. The Fisher information matrix for normally distributed observations. If the observations are normally distributed, the logarithm of the probability density function as a function of the parameters is described by Eq. (4). Then, elementary computations making use of the fact that $E[w_n - y_n(\theta)] = 0$ yield

$$M = \frac{\partial y^T}{\partial \theta} W^{-1} \frac{\partial y}{\partial \theta^T} \quad (10)$$

In this expression, the $N \times K$ matrix $\partial y / \partial \theta^T$ is the Jacobian matrix of $y(\theta)$ with respect to θ . Its (n, k) -th element is equal to $\partial y_n(\theta) / \partial \theta_k$. Therefore, for the multiexponential model, the elements of the Jacobian matrix are of the form $\exp(-\beta_\ell x_n)$ or $-\alpha_\ell x_n \exp(-\beta_\ell x_n)$ with $\ell = 1, \dots, L$.

Example 5. The Fisher information matrix for independent Poisson distributed observations. If the observations are independent and Poisson distributed, the logarithm of the probability density function of the observations as a function of the parameters is described by Eq. (7). This expression may be used to show that here, the information matrix is also described by Eq. (10), but with $W = \text{diag}(y_1 \dots y_N)$, where $y_n = y_n(\theta)$.

The importance of the Fisher information matrix is that from it the Cramér Rao lower bound may be computed. This is a lower bound on the variance of all unbiased estimators of parameters or of functions of parameters. An estimator t is said to be unbiased for the parameter θ if its bias, defined as

$$E[t] - \theta$$

is equal to the null vector. Otherwise, it is biased. In measurement terminology: if the model of the expectations of the observations is correctly specified and the estimator used is unbiased

for the parameters, the measurement result has no systematic error.

Next, suppose that $t(w)$ is any unbiased estimator of the vector of parameters θ from the observations w . Then the Cramér Rao inequality states that

$$\text{cov}[t(w), t(w)] \geq M^{-1} \quad (11)$$

In this expression, $\text{cov}[t(w), t(w)]$ is the covariance matrix of the estimator $t(w)$. That is, the (p, q) -th element of this matrix is defined as the covariance of the p -th element $t_p(w)$ and the q -th element $t_q(w)$. Therefore, the diagonal elements are the variances of $t_1(w), \dots, t_K(w)$, respectively. In Eq. (11) expresses that the difference of the matrix $\text{cov}[t(w), t(w)]$ and the matrix M^{-1} is positive semidefinite. A property of positive semidefinite matrices is that their diagonal elements cannot be negative. Therefore, the diagonal elements of $\text{cov}(t(w), t(w))$, that is, the variances of the elements of the estimator $t(w)$, must be larger than or be equal to the corresponding diagonal elements of M^{-1} . Consequently, the latter diagonal elements are a lower bound on the variances of the elements of the estimator $t(w)$. The matrix M^{-1} is called the Cramér Rao lower bound. For normally distributed observations and for Poisson distributed observations, the Cramér Rao lower bound may be computed by inverting the Fisher information matrix defined by Eq. (10) with appropriate matrix W , respectively. Notice that the main ingredients are simply the derivatives of the model $y_n(\theta)$ with respect to the parameters in each measurement point. These are quantities that are usually easy to compute.

The Cramér Rao lower bound would be of theoretical value only if there would not exist estimators attaining it. Later in this article, estimators will be introduced that do so, at least asymptotically. Therefore, the Cramér Rao lower bound may be used as a standard to which the precision of any estimator may be compared. Notice that the Cramér Rao lower bound is not related to a particular estimation method. It depends on the statistical properties of the observations, the measurement points, and in most cases, the hypothetical true values of the parameters. This dependence on the true values looks, at first sight, as a serious impediment to the practical use of the bound. However, the expressions for the bound provide the means to compute numerical values for it using nominal values of the parameters. This provides the experimenter with quantitative insight in what precision may be achieved from the available observations, an insight that without the bound would be absent. Thus, using the bound, the experimenter gets a detailed insight in the sensitivity of the precision to the values of the parameters. The experimenter also gets impression if the experimental design, that is, the values and the number of the measurement points x_n , is adequate for the purposes concerned. This means an impression if the precision is sufficient to make conclusions possible. If not, there is no other choice than to change the experimental design. If this is not possible, it is to be concluded that the observations are not suitable for the purposes of the measurement procedure.

In many applications, some of the quantities to be measured are functions of the parameters and not the individual parameters. A simple example is the following.

Example 6. Measurement of peak area and location. Suppose that a number of error corrupted observations $w_1, \dots, w_N$

has been made on a spectral peak described by

$$\alpha \exp \left[-\frac{1}{2} \left(\frac{x - \beta}{\gamma} \right)^2 \right] \quad (12)$$

where the parameters α , β , and γ are the peak height, location, and half-width, respectively. Suppose that only the peak location and the peak area are of interest. Then these are described by β and $(2\pi)^{1/2}\alpha\gamma$, respectively.

Fortunately, the Cramér Rao lower bound of functions of the parameters follows relatively easily from the Cramér Rao lower bound for the parameters. Let $r = [r_1(w) \dots r_L(w)]^T$ be an unbiased estimator of the vector function $\rho(\theta) = [\rho_1(\theta) \dots \rho_L(\theta)]^T$, that is, $E[r] = \rho(\theta)$. Furthermore, let M be the information matrix for θ . Then it can be shown that

$$\text{cov}[r(w), r(w)] \geq \frac{\partial \rho}{\partial \theta^T} M^{-1} \frac{\partial \rho}{\partial \theta}$$

where $\partial \rho / \partial \theta^T$ is the $L \times K$ Jacobian matrix with (p, q) -th element $\partial \rho_p / \partial \theta_q$. Therefore, the Cramér Rao lower bound for unbiased estimation of ρ is described by

$$\frac{\partial \rho}{\partial \theta^T} M^{-1} \frac{\partial \rho}{\partial \theta} \quad (13)$$

with M^{-1} the Cramér Rao lower bound for α , β , and γ .

Example 7. The Cramér Rao lower bound for peak area and location. The vector $\rho(\theta)$ for Example 6 is described by $\rho(\theta) = [\beta(2\pi)^{1/2}\alpha\gamma]^T$. Then, the Jacobian matrix of $\rho(\theta)$ with respect to $(\alpha \ \beta \ \gamma)^T$ is defined as

$$\frac{\partial \rho}{\partial \theta^T} = \begin{pmatrix} 0 & 1 & 0 \\ (2\pi)^{1/2}\gamma & 0 & (2\pi)^{1/2}\alpha \end{pmatrix}$$

where $\rho = \rho(\theta)$. The Cramér Rao lower bound for unbiased estimation of ρ is then computed from Eq. (13).

The premultiplication and postmultiplication of M^{-1} in Eq. (13) describe what is conventionally called error propagation. To see how this works, suppose that $\rho = [\rho_1(\theta) \ \rho_2(\theta)]^T$, $\theta = (\theta_1 \ \theta_2)^T$, and let the Cramér Rao lower bound for θ be

$$C = \begin{pmatrix} c_{11} & c_{12} \\ c_{12} & c_{22} \end{pmatrix}$$

Then, the diagonal elements of the Cramér Rao lower bound for ρ_1 and ρ_2 are equal to

$$\left(\frac{\partial \rho_i}{\partial \theta_1} \right)^2 c_{11} + 2 \left(\frac{\partial \rho_i}{\partial \theta_1} \right) \left(\frac{\partial \rho_i}{\partial \theta_2} \right) c_{12} + \left(\frac{\partial \rho_i}{\partial \theta_2} \right)^2 c_{22}$$

with $i = 1, 2$, respectively. This expression shows how the variances c_{11} and c_{22} and the covariance c_{12} of a hypothetical estimator that attains the Cramér Rao lower bound for θ propagate to the variances of a hypothetical estimator of ρ_1 and ρ_2 that also attains the Cramér Rao lower bound. Similar error propagation schemes are proposed in the literature for covariance matrices

of functions of estimators in general, for example in reference 5. These schemes are approximations using the linear Taylor polynomial instead of the nonlinear functions. Equation (13), on the other hand, is exact.

Next, suppose that M is the information matrix for the estimation of $\theta = (\theta_1 \dots \theta_K)^T$, and that an additional parameter θ_{K+1} is to be estimated. For example, θ_{K+1} may be a constant term added to the spectroscopic line model described by Eq. (12) to model a constant background contribution. Then, M has to be augmented with one row and one column corresponding to θ_{K+1} . If the augmented information matrix is inverted, all first K diagonal elements can be shown to be larger than or equal to the corresponding diagonal elements of M^{-1} . Equality occurs only if the nondiagonal elements of the $(K+1)$ -th row and $(K+1)$ -th column of the augmented information matrix happen to be equal to zero. Generally, it is not difficult to show that, typically, the first K diagonal elements of M^{-1} are monotonously increasing with the number of parameters in excess of K .

PRECISELY MEASURING FROM ERROR CORRUPTED OBSERVATIONS

The a priori knowledge of the experimenter about the observations and the extent to which this a priori knowledge is used may considerably influence the precision and accuracy of the measurement result. This concerns both systematic and non-systematic errors in the observations. Systematic errors in the observations are deviations of the assumed parametric model of the expectations from the true model of the expectations. Even in the absence of nonsystematic errors, discrepancy between both models produces systematic errors, that is, inaccuracy in the measurement result. Since no model fitted will be perfect, there will always be a certain amount of systematic error. Non-systematic errors are described by their distribution about the expectations of the observations. This distribution is not always known, but if it is, this knowledge may contribute substantially to the reducing of the nonsystematic error in the measurement result, that is, in the parameters estimates.

Suppose that observations $w_1, \dots, w_N$, are available and that their probability density function $f(w_1, \dots, w_N; \theta)$ is known where θ is the vector of unknown parameters and $w_1, \dots, w_N$ are the independent variables corresponding to the observations $w_1, \dots, w_N$, respectively. Assume that $w_1, \dots, w_N$ are substituted for $\omega_1, \dots, \omega_N$ in $f(\omega_1, \dots, \omega_N; \theta)$, respectively, and that the fixed true parameters θ are replaced by the vector of corresponding variables t . Then, the resulting function $f(w_1, \dots, w_N; t)$ of t is called the likelihood function of the parameters t , given the observations $w_1, \dots, w_N$. The maximum likelihood estimate of the parameters θ is defined as the value $\tilde{t}$ of t that maximizes the likelihood function.

The maximum likelihood estimator has a number of very favorable properties. In the first place, its definition shows that it is simple to find from the known probability density function of the observations. Furthermore, it can be shown to converge under general conditions in a statistically well-defined way to the true values of the parameters as the number of observations increases. Moreover, under general conditions, the covariance matrix of the maximum likelihood estimator approaches asymptotically the Cramér Rao lower bound. Then, the maximum likelihood estimator is asymptotically most precise. Also, a function of a maximum likelihood estimator is the maximum

likelihood estimator of the function. This is called the invariance property of maximum likelihood.

Two of these properties are asymptotic; they apply to an infinite number of observations. If they also apply to a finite or even small number of observations can often only be assessed by estimating from artificial, simulated observations. These simulations may reveal that maximum likelihood estimation applied to small numbers of observations may lead to bias, that is, systematic error in the measurement result. This kind of bias, or the major part of it, is usually inversely proportional to the number of observations and may be removed as follows. Let $\tilde{t}_N$ be the biased maximum likelihood estimate of θ obtained from $w_1, \dots, w_N$, and let $\bar{t}_{N-1}$ be the average of the N different maximum likelihood estimates computed from the N different sets of $N - 1$ observations obtained by omitting one observation from the set $w_1, \dots, w_N$. Then, it may be shown that

$$N\tilde{t}_N - (N-1)\bar{t}_{N-1}$$

is an estimator of θ which may only be biased to order $1/N^2$. This is the so-called Quenouille correction, today called jackknife. A favorable property of this correction is that it hardly affects the variance of the estimator.

Example 8. Maximum likelihood estimation of peak height, width and location from Poisson distributed observations. Suppose that observations $w_1, \dots, w_N$ are available made on the spectral peak of Example 6, and that these observations are independent and Poisson distributed. Then it follows from Example 3 that the likelihood function of the parameters is described by

$$\sum_n -y_n(t) + w_n \ln[y_n(t)] - \ln(w_n!) \quad (14)$$

with

$$y_n(t) = a \exp \left[-\frac{1}{2} \left(\frac{x_n - b}{c} \right)^2 \right]$$

where $t = (abc)^T$. To obtain the maximum likelihood estimate of α , β , and γ , Eq. (14) must be maximized with respect to t . This is a nonlinear optimization problem which has to be solved numerically. If the peak area is computed from the maximum likelihood estimates $\tilde{a}$ and $\tilde{c}$ as $(2\pi)^{1/2}\tilde{a}\tilde{c}$ this is, by the invariance property, a maximum likelihood estimate as well.

Example 9. Maximum likelihood estimation from observations disturbed by normally distributed errors. If the errors and, therefore, the observations are normally distributed, Eq. (4) shows that the likelihood function of the parameters is described by

$$-\frac{N}{2} \ln(2\pi) - \frac{1}{2} \ln(\det W) - \frac{1}{2} [w - y(t)]^T W^{-1} [w - y(t)] \quad (15)$$

Since both first terms of this expression do not depend on the vector of parameters t , maximizing Eq. (15) is equivalent to minimizing

$$[w - y(t)]^T W^{-1} [w - y(t)]$$

with respect to t . This shows that with normally distributed observations, maximum likelihood estimation is equivalent to a weighted least squares measurement with W^{-1} as weighting matrix.

Least squares estimation is also often used if the distribution of the observations is not known or is known to be not normal. Then, the general expression for the least squares criterion is

$$[w - y(t)]^T \Omega [w - y(t)] \quad (16)$$

where Ω is a positive definite weighting matrix to be chosen by the experimenter.

Linear Least Squares

First, as an important special case, models linear in the unknown parameters θ are considered. Then

$$E[w] = y(\theta) = X\theta$$

with X a known $N \times K$ matrix, that is,

$$y_n(\theta) = x_{n1}\theta_1 + \dots + x_{nK}\theta_K$$

Notice that

$$x_n = (x_{n1} \dots x_{nK})^T$$

is the vector independent variable corresponding to the n -th observation w_n .

Example 10. Straight line fitting. If the observations w_n are made on a straight line $y = \alpha x + \beta$ at the points $x_{11}, \dots, x_{N1}$, then X and θ are described by

$$\begin{bmatrix} x_{11} & 1 \\ \cdot & \cdot \\ \cdot & \cdot \\ x_{N1} & 1 \end{bmatrix} \quad \text{and} \quad \theta = (\alpha \ \beta)^T$$

respectively.

The least squares solution $\hat{t}_\Omega$ for θ is

$$\hat{t}_\Omega = (X^T \Omega X)^{-1} X^T \Omega w \quad (17)$$

It is observed that this solution is a linear combination of the observations. As a result, the propagation of the errors in the observations to the measurement result is perfectly clear. Furthermore, since $E[w] = X\theta$, $E[\hat{t}_\Omega] = \theta$ and, hence, $\hat{t}_\Omega$ is an unbiased estimator of θ . Notice that $\hat{t}_\Omega$ has these properties for any distribution of the observations w . It is easily shown that the covariance matrix $\text{cov}(\hat{t}_\Omega, \hat{t}_\Omega)$ is equal to

$$(X^T \Omega X)^{-1} X^T \Omega W \Omega X (X^T \Omega X)^{-1} \quad (18)$$

The conclusion from this expression is that this covariance matrix and, therefore, the variances of $\hat{t}_\Omega$ depend on the choice of Ω . The question is then which Ω minimizes the covariance

described by Eq. (18). The answer has been found to be $\Omega = W^{-1}$. For this choice,

$$\text{cov}(\hat{t}_\Omega, \hat{t}_\Omega) \geq \text{cov}(\hat{t}_{W^{-1}}, \hat{t}_{W^{-1}})$$

As a consequence, the variances of the elements of $\hat{t}_\Omega$ for any choice of Ω are never smaller than those of the corresponding elements of $\hat{t}_{W^{-1}}$. The estimator $\hat{t}_{W^{-1}}$ is called the best linear unbiased estimator. Equation (17) shows that it is described by

$$\hat{t}_{W^{-1}} = (X^T W^{-1} X)^{-1} X^T W^{-1} w$$

Among all estimators that are both linear in the observations and unbiased, it is called best since it has smallest variance. Notice that only the expectation and the covariance matrix of the observations are specified, not their probability density function. Also notice that $\hat{t}_{W^{-1}}$ is optimal within the class of estimators that are both linear in the observations and unbiased. Therefore, there may be better, that is, more precise estimators among those that are not linear in the observations or are biased.

The covariance matrix of $\hat{t}_{W^{-1}}$ is equal to

$$(X^T W^{-1} X)^{-1} \quad (19)$$

If for normally distributed observations, the maximum likelihood estimator is computed, it is found to be identical to the best linear unbiased estimator $\hat{t}_{W^{-1}}$ and, consequently, to have a covariance matrix equal to the one given by Eq. (19). If next, the Cramér Rao lower bound is computed for the same observations, it is found to coincide with Eq. (19). The conclusion is that for normally distributed observations, the best linear unbiased estimator is identical with the maximum likelihood estimator and attains the Cramér Rao lower bound for any number of observations.

In measurement practice, the weighting matrix Ω of $\hat{t}_\Omega$ is often taken as the identity matrix. The reason may be that the covariance matrix W is unknown. Another reason may be the amount and the complexity of numerical computation involved since with $\Omega = I$, the estimator simplifies to the ordinary least squares estimator

$$\hat{t}_I = (X^T X)^{-1} X^T w \quad (20)$$

which is clearly easier to compute than $\hat{t}_\Omega$. The corresponding ordinary least squares criterion is described by

$$(w - Xt)^T(w - Xt)$$

which is simply the sum of the squares of the deviations

$$w_n - x_{n1}t_1 - x_{n2}t_2 + \dots - x_{nK}t_K$$

Notice that $\hat{t}_I$ is only the best linear unbiased estimator if the covariance matrix W is equal to $\sigma^2 I$, that is, if the observations are uncorrelated and have equal variance σ^2 . The estimator $\hat{t}_I$ is the maximum likelihood estimator and achieves the Cramér Rao lower bound if, in addition, the observations are normally distributed. Therefore, if these conditions are not met, the use of $\hat{t}_I$ may mean an exchange of precision for simplicity.

Finally, it is emphasized that Eq. (20) is a formal description of the ordinary linear least squares estimator. It is not a recipe for its numerical evaluation. Special numerical methods have been designed taking care of the fact that the set of linear equations described by Eq. (20) may be ill-conditioned. References 6 and 7 provide the details.

Nonlinear Least Squares

Nonlinear least squares is the most frequently used method for estimation of the parameters of nonlinear models. The criterion used is described by

$$[w - y(t)]^T[w - y(t)] = \sum_n [w_n - y(x_n; t)]^2 \quad (21)$$

which is Eq. (16) with weighting matrix $\Omega = I$. Notice that generally, the solution $\hat{t}_I$ for t minimizing the least squares criterion defined by Eq. (21) is only the maximum likelihood estimator if the observations are independent and identically normally distributed. This means normally distributed with covariance matrix $\sigma^2 I$. For other distributions, $\hat{t}_I$ is generally not the maximum likelihood estimate since it does not maximize the pertinent likelihood function. As compared with linear least squares, the amount of theory concerning nonlinear least squares is limited. However, if the observations are independent and identically distributed, then under general conditions, the least squares estimator $\hat{t}_I$ is asymptotically normally distributed with covariance matrix

$$\sigma^2 \left(\frac{\partial y^T}{\partial \theta} \frac{\partial y}{\partial \theta^T} \right)^{-1} \quad (22)$$

where $y = y(\theta)$. This result is due to Jennrich (8). Notice that the computation of this covariance matrix requires the parameters to be known. In practice, this is not the case, and nominal or estimated values are substituted for the exact ones. Also notice that for independent and identically normally distributed observations, Eq. (22) is equal to the Cramér Rao lower bound. The general form of the elements of the matrix $(\partial y^T / \partial \theta)(\partial y / \partial \theta^T)$ is

$$\sum_n \frac{\partial y(x_n; \theta)}{\partial \theta_p} \frac{\partial y(x_n; \theta)}{\partial \theta_q}$$

This expression shows the dependence of the elements of this matrix upon the values of the independent variable x . Therefore, if the experimenter has some freedom in the choice of the measurement points, it may be used to manipulate the covariance matrix described by Eq. (22) in a desired way. This usually concerns the diagonal elements, that is, the variances and is an example of experimental design: the manipulation of the variances by selecting free experimental variables.

The gradient of the nonlinear least squares criterion with respect to the parameter vector t is equal to

$$-2 \sum_n [w_n - y_n(t)] \frac{\partial y_n(t)}{\partial t} \quad (23)$$

A necessary condition for a point to be a minimum is that the gradient is equal to the null vector. If Eq. (23) is equated to the null vector, this produces a set of K nonlinear equations in

K variables. This set must be solved by an iterative numerical method since, typically, it cannot be solved in closed form. For this problem, specialized numerical methods have been developed. Most frequently used are the Gauss–Newton method and the Levenberg–Marquardt method. These are described in references 8 and 6, respectively. Software for their practical implementation is found in references 6 and 7.

Many nonlinear models in engineering practice are linear in some of their parameters. How this special property may be exploited in nonlinear least squares estimation is illustrated in the following example.

Example 11. Least squares estimation of the parameters of a multiexponential model. Suppose that in a least squares estimation problem, the model fitted is described by

$$y_n(t) = a_1 \exp(-b_1 x_n) + \dots + a_L \exp(-b_L x_n)$$

where $t = (a^T b^T)^T$ with linear parameters $a = (a_1 \dots a_L)^T$ and nonlinear parameters $b = (b_1 \dots b_L)^T$. Then Eq. (23) shows that at the minimum of the least squares criterion, the derivatives with respect to the linear parameters a must satisfy

$$\sum_n [w_n - a_1 \exp(-b_1 x_n) + \dots + a_L \exp(-b_L x_n)] \exp(-b_\ell x_n) = 0$$

with $\ell = 1, \dots, L$. This may be considered a set of L linear equations in L unknowns a_ℓ . The solution for these unknowns is a function of the unknown nonlinear parameters b_ℓ and is denoted as $a_\ell(b)$. Substitution of the $a_\ell(b)$ for the a_ℓ in the least squares criterion yields

$$\sum_n [w_n - a_1(b) \exp(-b_1 x_n) + \dots + a_L(b) \exp(-b_L x_n)]^2$$

Thus, the least squares criterion has become a function of the nonlinear parameters b only. Minimization of it with respect to b yields the solution $\hat{b}$ for β and the solution $\hat{a} = a(\hat{b})$ for α .

Nonlinear least squares problems of the kind described in Example 11 are called separable nonlinear least squares problems since the linear and the nonlinear parameters are estimated separately. Notice that in Example 11, the number of parameters involved in the iterative numerical minimization is reduced by a factor of two. This also means that the number of initial values for the procedure is reduced correspondingly.

HANDLING MEASUREMENT ERRORS IN NONSTANDARD PROBLEMS

Complex Parameter Estimation

Many practical measurement problems concern complex valued parameters or mixtures of real and complex valued parameters. In particular, these problems are found in measurement in the frequency domain. Such complex parameter estimation problems can always be transformed into real parameter estimation problems by splitting a complex parameter into its real and imaginary part and estimating these real quantities separately. This, however, leads to unnecessarily complicated expressions for the estimator and, as a result, to complicated

numerical procedures. This is avoided by leaving quantities complex if they are complex by nature.

The most important tool in the formulation of complex parameter measurement from error corrupted observations is the following. Suppose that in a measurement problem there are $K + 2L$ parameters

$$\theta = (\eta_1 \dots \eta_K \alpha_1 \beta_1 \dots \alpha_L \beta_L)^T$$

of which the η_k are intrinsically real, and the α_ℓ and β_ℓ are the real and imaginary parts of the complex parameters $\gamma_\ell = \alpha_\ell + j\beta_\ell$ with $j = \sqrt{-1}$. Then γ_ℓ and its complex conjugate γ_ℓ^* on the one hand and α_ℓ and β_ℓ on the other are connected by the linear transformation

$$\begin{bmatrix} \gamma_\ell \\ \gamma_\ell^* \end{bmatrix} = J \begin{bmatrix} \alpha_\ell \\ \beta_\ell \end{bmatrix}$$

where

$$J = \begin{bmatrix} 1 & j \\ 1 & -j \end{bmatrix}$$

Therefore, the mixed real complex parameter vector

$$\zeta = (\eta_1 \dots \eta_K \gamma_1 \gamma_1^* \gamma_L \gamma_L^*)^T$$

and θ are connected by

$$\zeta = B_{K+2L} \theta \quad (24)$$

where B_{K+2L} is the $(K + 2L) \times (K + 2L)$ block diagonal matrix

$$B_{K+2L} = \text{diag}(I_K \quad A_{2L})$$

with I_K the identity matrix of order K and A_{2L} the $2L \times 2L$ block diagonal matrix

$$A_{2L} = \text{diag}(J \dots J)$$

The theory, methods, and techniques presented up to now concerned the estimation of real parameters from error corrupted observations. Using the linear transformation described by Eq. (24), transformation of the pertinent expressions into those for estimating a mixed real complex parameter vector is relatively easy. All that is required is observing the mathematical rules governing linear transformation of coordinates in general. For what follows, it is important to notice that Eq. (24) implies that α_ℓ and β_ℓ are transformed into both γ_ℓ and γ_ℓ^* . Also, the definition of the covariance matrix of a vector of complex stochastic variables is needed. Let z be a vector of stochastic variables. Then, the covariance matrix of z is defined as

$$E[(z - E[z])(z - E[z])^H]$$

where the superscript H denotes complex conjugate transposition. The Fisher information matrix defined by Eq. (9) after the transformation of parameters described by Eq. (24) is given by

$$M = -E \left[\frac{\partial^2 \ln f}{\partial \zeta^* \partial \zeta^T} \right]$$

and the corresponding Cramér Rao lower bound on the variance of unbiased estimators of ζ is equal to M^{-1} . Again using Eq. (24), the Cramér Rao lower bound for a vector of real and complex functions $\phi(\zeta)$ of the mixed real complex parameter vector is found to be

$$\frac{\partial \phi}{\partial \zeta^T} M^{-1} \frac{\partial \phi^H}{\partial \zeta^*}$$

where for brevity, the argument of $\phi(\zeta)$ has been omitted. A further example is the weighted least squares estimator defined by Eq. (17). After transformation of θ into ζ and ℓ_Ω into $\hat{\zeta}_\Omega$, respectively, it becomes

$$\hat{\zeta}_\Omega = (R^H \Omega R)^{-1} R^H \Omega w$$

where the complex $N \times (K + 2L)$ matrix R is equal to XB^{-1}_{K+2L} . If Ω is equal to W^{-1} , this is the best linear unbiased estimator. Finally, suppose that the real complex $(P + 2Q) \times 1$ vector of observations u is composed of the elements of the real $(P + 2Q) \times 1$ vector of observations w as follows

$$u = B_{P+2Q} w$$

with $P + 2Q = N$. Then, u is a vector of real and complex observations described by

$$(w_1 \dots w_P w_{P+1} + jw_{P+2} w_{P+1} - jw_{P+2} \dots w_{P+2Q-1} + jw_{P+2Q} w_{P+2Q-1} - jw_{P+2Q})^T$$

and

$$\hat{\zeta}_\Psi = (S^H \Psi S)^{-1} S^H \Psi u$$

where S and Ψ are equal to $B_{P+2Q} R$ and $B^{-H}_{P+2Q} \Omega B^{-1}_{P+2Q}$, respectively. The covariance matrix of the mixed real complex observations is defined as $E[(u - E[u])(u - E[u])^H]$ and is, therefore, equal to $B_{P+2Q} W B^H_{P+2Q}$. Hence, the estimator $\hat{\zeta}_\Psi$ with $\Psi = (B_{P+2Q} W B^H_{P+2Q})^{-1}$ is the best linear unbiased estimator.

The iterative numerical optimization of likelihood functions and nonlinear least squares criteria of mixed real complex parameters may be carried out directly with respect to the vector of mixed real complex parameters. This is discussed in reference 9. In particular, use may be made of the complex gradient. Specifically, the complex gradient of the logarithm of the likelihood function $\ln f$ with respect to the complex parameter vector z is defined as $\partial \ln f / \partial z$. An important property of this complex gradient is that the real gradient $\partial \ln f / \partial t$ is equal to the null vector if and only if the complex gradient is equal to the null vector. Therefore, the complex gradient may be used to find maxima of the likelihood function and minima of the nonlinear least squares criterion in the same way as the real gradient.

Nonstandard Fourier Analysis

Estimation of Fourier coefficients from error disturbed observations made on periodic functions is an important problem in dynamic system identification in general and in specialized applications as crystal structure reconstruction. Suppose that the

problem is to estimate the Fourier coefficients γ_k , $k = 0, \pm 1, \dots, \pm K$ and, possibly, the period δ of the real periodic function

$$y_n(\zeta) = \sum_k \gamma_k \exp(-j2\pi k x_n / \delta) \quad (25)$$

from error corrupted observations $w = (w_1 \dots w_N)^T$ where the measurement points x_n are known, and the vector of unknown parameters ζ is either equal to $\gamma = (\gamma_0 \gamma_1 \gamma_{-1} \dots \gamma_K \gamma_{-K})^T$ or to $(\gamma^T \delta)^T$, where γ_0 and δ are real, while the remaining γ_k are complex and satisfy $\gamma_{-k} = \gamma_k^*$ since the $y_n(\zeta)$ are real. It will not be supposed that the measurement points are equidistant, nor if they are, that the period is a known integer multiple of the sampling interval, and an integer number of periods is observed. The purpose of this section is to formulate the estimation of the parameters ζ as a complex statistical parameter estimation problem and to describe the special conditions under which this problem simplifies to the standard Discrete Fourier Transform, the DFT.

Example 12. Estimation of Fourier coefficients from Poisson distributed observations. Suppose that observations $w_n \geq 0$, $n = 1, \dots, N$ are available with expectations described by Eq. (25) and that these observations have a Poisson distribution. Then, by Eq. (14), the likelihood function of the parameters is

$$\sum_n -y_n(z) + w_n \ln[y_n(z)] - \ln(w_n!) \quad (26)$$

with

$$y_n(z) = \sum_k c_k \exp(j2\pi k x_n / d)$$

where the elements of $z = (c^T d)^T$ correspond to those of ζ , and those of $c = (c_0 c_1 c_{-1} \dots c_K c_{-K})^T$ correspond to those of γ . Then, the complex gradient of Eq. (26) with respect to z is

$$-\sum_n \left(1 - \frac{w_n}{y_n(z)} \right) \frac{\partial y_n(z)}{\partial z} \quad (27)$$

Since the maximum of the likelihood function is, by definition, a stationary point, the $2K + 2$ elements of the maximum likelihood estimate $\hat{z}$ of ζ must satisfy the $2K + 2$ nonlinear equations in z obtained by equating Eq. (27) to the null vector. The numerical solution for z representing the absolute maximum of the likelihood function described by Eq. (26) is the maximum likelihood estimate of the Fourier coefficients.

It follows from Eq. (25) that the expectations $y_n(\zeta)$ of the observations w_n are described by

$$y_n(\zeta) = X\gamma$$

where the n -th row of X is defined as

$$(1 \exp(j2\pi x_n / \delta) \exp(-j2\pi x_n / \delta) \dots \exp(j2\pi K x_n / \delta) \exp(-j2\pi K x_n / \delta))$$

If the observations are normally distributed with covariance matrix W , then the maximum likelihood estimator of ζ has to minimize

$$[w - y(z)]^T W^{-1} [w - y(z)] \quad (28)$$

Hence, if only the Fourier coefficients are unknown, their maximum likelihood estimator is

$$\hat{c}_{W^{-1}} = (X^H W^{-1} X)^{-1} X^H W^{-1} w \quad (29)$$

For observations with a distribution different from normal, this estimator is no longer maximum likelihood but is still best linear unbiased. If, in addition, the period is unknown, the estimation problem is recognized as a separable nonlinear least squares problem. The model is linear in the $2K + 1$ Fourier coefficients and nonlinear in the period d . This means that, in addition to Eq. (29), one further equation must be satisfied. This is the equation resulting from equating the derivative of the least squares criterion with respect to d to zero. If, in this equation, Eq. (29) is substituted for the Fourier coefficients c , a scalar nonlinear equation is obtained in the period d only. Hence, all that needs to be done is real, scalar root finding to estimate the period d and substitute the estimate in the closed form of Eq. (29) for the Fourier coefficients. The estimates thus obtained are maximum likelihood if the observations are normal with covariance matrix W . They are weighted complex nonlinear least squares estimates with other error distributions.

If the covariance matrix W is unknown, the ordinary least squares estimator

$$\hat{c}_I = (X^H X)^{-1} X^H w \quad (30)$$

may be chosen, possibly combined with root finding for the period. This is a maximum likelihood estimator only if the w_n are independent and identically normally distributed about their expectations. For other distributions, it is a best linear unbiased estimator if only the Fourier coefficients are to be estimated, and the observations are uncorrelated with equal variance. In other cases, it is simply the ordinary least squares estimator.

A special case occurs if only the Fourier coefficients are to be estimated, the measurement points x_n are equidistant with interval Δ , the period is a known integer multiple of Δ , and an integer number of periods is observed. Under these conditions, the elements of $\hat{c}_I$ described by Eq. (30) may be shown to be equal to the DFT

$$\frac{1}{N} \sum_{n=1}^N w_n \exp[-j2\pi k(n-1)/M]$$

where $M\Delta$ is the period. Under the restrictive conditions mentioned, the DFT is, therefore, the maximum likelihood estimator if the observations are independent and identically normally distributed about their expectations. For other distributions, it is best linear unbiased if the observations are uncorrelated and have equal variance.

Measurement Errors and Resolution

Like precision and accuracy, resolution is a key notion in applied science and engineering. It is used in fields as diverse as radar, sonar, optics, electron optics, seismology and various

forms of spectroscopy. An extensive review of resolution is presented in reference 10.

The most important form of resolution is two-component resolution.

Example 13. Rayleigh two-component resolution. As discussed in reference 10, Rayleigh considers observations described by

$$\alpha \{\text{sinc}^2[2\pi(x - \beta_1)] + \text{sinc}^2[2\pi(x - \beta_2)]\}$$

with $\text{sinc}(x) = \sin(x)/x$. This is a pair of sinc-square components of equal height and located at β_1 and β_2 , respectively. As the difference in location decreases, the components increasingly overlap and become increasingly difficult to distinguish visually. According to Rayleigh, the components are resolvable if the absolute difference of β_1 and β_2 exceeds 0.5. At this distance, the maximum of the one component coincides with the first zero of the other, and the component sum has two maxima and a relative minimum in between. Then, the ratio of the value at the relative minimum to that at the maxima may be shown to be 0.81. Later, this ratio has been generalized to other component functions, and the distance corresponding to this ratio has been called generalized Rayleigh resolution limit.

From this example, it is clear that this classical resolution limit and comparable ones proposed later are, in fact, measures of component width. Since in definitions such as Rayleigh's, the component functions are known, and the observations are exact, today, the model could be exactly fitted numerically to the observations with respect to the locations, the result would be exact, and there would in fact be no obvious limit to resolution. The reason why in practice unlimited resolution cannot be achieved is that observations exactly describable by two component functions do not occur. Therefore, it is not the distance of the components, but it is the errors in the observations, systematic and nonsystematic, that ultimately limit resolution. During the last decades, a number of measurement error based resolution limits have been proposed in the literature reviewed in Ref. 10. One of the most recent ones will now be described.

Suppose that a number of two-component observations $w = (w_1 \dots w_N)^T$ has been made, and that the two-component model

$$a[h(x; b_1) + h(x; b_2)] \quad (31)$$

is fitted to these observations with respect to a , b_1 , and b_2 . Then, depending on the set of observations available, two essentially different types of solutions for a , b_1 , and b_2 may occur. In the first type, the solutions for b_1 and b_2 are distinct. This implies that the two components in Eq. (31) are resolved from the observations. In the second type of solution, the solutions for b_1 and b_2 exactly coincide. Then, the model corresponding to this solution is $2a h(x; b)$ with $b_1 = b_2 = b$. Thus, it is concluded that a one-component model is found as solution. This one-component solution is, of course, not found from exact two-component observations of the same functional family as the model fitted. However, it may result from error corrupted, two-component observations if the components seriously overlap.

At first sight, exactly coinciding solutions may look highly improbable. However, their coincidence is not caused by mere chance but by a structural change of the criterion of goodness of fit under the influence of the set of observations. In the

N -dimensional Euclidean space of the observations, where the n -th coordinate axis corresponds to the n -th observation w_n , a set of observations is represented by a single point. If two-component models are fitted, this space may be divided into two parts. For observations in the one part, the criterion has an absolute minimum with $b_1 \neq b_2$. For observations in the other part, only a minimum can be shown to exist with $b_1 = b_2$. The boundary of both parts separates the sets of observations from which the components can be resolved from those from which they cannot. Therefore, it is this boundary that constitutes the limit to resolution in terms of the observations. Of course, hypothetical, errorless two-component observations to which a two-component model of the same family is fitted are on the side of the boundary corresponding to resolution. However, nonsystematic and systematic measurement errors may move this point to the other side of the boundary, where resolution is impossible since the solutions coincide. Systematic measurement errors influence the location of the point around which sets of observations are distributed. This point represents the expectations of the observations. The systematic errors may move this point close to the boundary. The kind of distribution of the nonsystematic errors defines how the sets of observations are distributed around this point. Therefore, the probability of resolution is determined by both types of errors combined.

AUTOMATIC TEST EQUIPMENT

Automatic test equipment (ATE) embraces a very broad array of test equipment ranging from hand-held meters to multiple racks of sophisticated instrumentation and *unit under test* (UUT) handling equipment all controlled by test programs. Automatic test equipment is applicable to the full spectrum from invisible light to direct current (dc). It involves an approach to testing rather than any particular configuration. Thus this

treatise addresses the principles and philosophies of automatic testing rather than specific designs of ATE. Various ATEs have incorporated just about every imaginable variety of instrument in existence. Design parameters for instruments used in ATE vary little from those of stand-alone instruments other than in their method of control. They follow industry developments, becoming smaller, more complex, and requiring less power as the years pass. Thus, examining the attributes of such instruments would be far beyond the scope of this chapter. Specifics of instrument design are covered in many other sources, including other chapters of this encyclopedia.

EARLY HISTORY OF AUTOMATIC TEST EQUIPMENT

The decade of the 1960s spawned a new class of test equipment that had its roots in the prototypes of the late 1950s. Known as ATE, these testers used the programmable feature of digital computers to store “intelligence” pertaining to a testing procedure or process. This stored program, coupled to a variety of programmable instruments, provided a capability to perform a wide variety of complex tests on a device or UUT with a minimum of operator knowledge or intervention. Automatic test equipment was first developed and introduced to meet field maintenance needs of the military.

By the mid-1960s, military electronics equipment and systems had increased in complexity to a point where well-trained technicians were required to maintain them. In the Navy, for example, the Class A electronics school course was 42 weeks long. Additional schooling was required to qualify a technician in specialized equipment. By the time a technician was adequately trained and gained a year or two of field experience, the enlistment was over. Most chose to accept a discharge rather than reenlist, because civilian work was less demanding and paid better. Thus the military faced a real problem in meeting the maintenance needs of ever increasingly complex electronics equipment and weapons.

Automatic test equipment offered a solution to the military maintenance problem. Accordingly, the army pioneered the development of ATE by funding prototype designs of ATE. One of the first testers was designed to test Atlas missiles. Other testers followed for communications equipment and advanced missile system components and subassemblies. By the late 1960s military applications of ATE abounded. The thrust then was to build very capable and therefore large, complex ATE with a very wide variety of testing devices (often referred to as building blocks) capable of testing almost anything in the current electronics inventory and even provide for testing systems yet to be developed. This multipurpose test equipment became systems with up to a dozen 5 ft racks of electronics and costing several million dollars per copy. Still they were called simply, ATE.

The promises of military ATE technology were fantastic. Suppliers claimed that an unskilled person with only a couple of weeks of training could now do the work of a skilled technician with several years of training and experience. This, of course, greatly reduced the cost of maintenance over manual testing procedures.

What vendors failed to mention was the enormous cost of developing a set of test programs and interface devices required to test that wide variety of UUTs. A test program had to incorporate a complete qualification testing process (referred to

as the *go chain*) as well as a complex network of fault isolation tests to diagnose the UUT when any go-chain test failed. This is analogous to anticipating all probability of failures during the lifecycle of a product and incorporating corrective actions even though in reality many of the failure modes might never be experienced. It is like buying a very expensive insurance policy and paying for it all at once rather than by modest premiums. It soon became evident that the claim of reduced cost of testing, at least during the early life of a product, was a myth; ATE was not nearly as cheap as believed. Yet, while not being as simple to use as claimed, it did greatly expand the capability of a trained technician to perform tests much more complicated than typical skills and time permitted. Thus ATE, in spite of its cost and impact on logistics requirements, became a necessary evil for maintaining complex military systems—ATE remains the backbone of modern weapon systems support.

In the 1970s ATE found a niche in the commercial manufacturing world. Here the challenge was not so much to test a wide diversity of complex assemblies, but rather to test large quantities of electronic components such as transistors and memory devices very rapidly and cheaply by minimizing costs and increasing manufacturing yield. As components increased in complexity ATE became an essential part of the manufacturing process.

For many years maintenance testing remained in the military domain, while manufacturing testing dominated the commercial world. Maintenance testing approaches the problem *top down*, starting at the system level and progressing to major assemblies, subassemblies, modules, and finally to the component level. Manufacturing testing generally works from the *bottom up*, beginning with basic materials and progressing to the finished product. Because of these basic differences and very different testing philosophies, there has been little cross-pollination between maintenance and manufacturing testing. Yet there is much to be gained from the common experiences of these seemingly independent areas of interest, because, broadly speaking, they do share a single technology. The basic principles apply to both maintenance testing and manufacturing testing. Differences and similarities are pointed out as applicable.

MAINTENANCE VERSUS MANUFACTURING TESTING

The basic principles of ATE and functional elements as described apply generally to both maintenance and manufacturing testing. The greatest differences lie in the testing philosophies and the design of the ATE hardware. Maintenance testing assumes that the UUT has been properly manufactured, and it once operated satisfactorily so the objective is to return the product to its original operating condition. Manufacturing testing is designed to assure that the product is properly assembled using tested components and that it is ready for packaging and sale. The failure modes of these differing processes are very different. The organization of the ATE hardware is also very different. Maintenance ATEs are durably constructed and fairly simple to operate in a field environment. Manufacturing ATEs are designed to be fast, flexible, reconfigurable, fully automatic, and suitable for factory environments. The most salient differences between maintenance and manufacturing ATE are identified in Table 1.

BASIC PRINCIPLES OF AUTOMATIC TEST EQUIPMENT

Fundamentally any combination of instrumentation controllable by a programmed sequence of events or algorithm can be considered to be an ATE. This sequence is commonly referred to as a test program. Once the system has been properly energized and initially set up, control of the instruments and the testing process is vested in the test program. In the early days of ATE, the control logic that executed the programmed instructions was of a design unique to the special needs of a given ATE. Soon, however, digital computers were generally utilized as the control system. They offer both improved flexibility and reduced cost over specially designed controllers. Today computers find multiple usage in ATEs, not only as the central control unit but also in many “building blocks” or instruments embodied in a system.

In its basic form, an ATE consists functionally of five subsystems: control, stimulus, measurement, switching, and system software. An ATE also contains various peripheral devices to facilitate user communication with the system. They include but are not limited to maintenance panels, input keyboard, printers, and output panel for connecting to the UUT interface device (ID). A simplified block diagram is shown in Fig. 1.

Control is generally provided by one or more general purpose digital computer(s) with associated memory. Switching consists of a network of electrically actuated paths interconnecting all of the internal elements of the ATE and the interface to the outside world. It is through the switching subsystem that the control subsystem *instructs* and actuates each ATE function as to when and how to execute the programmed instructions. It also provides paths for the ATE and its associated input/output devices, such as control panels and bulk memory storage devices. The stimulus subsystems comprises all of the power and signal sources required to energize the instruments internal to the ATE and the device or unit being tested. The measurement subsystem comprises all of the instrumentation required to measure both internal signal sources and responses from the UUT. The interface subsystem consists of all control panels, operator interface devices and linkages to the outside world, to which the UUT is connected directly or through an ID.

COMPARISON OF MANUAL AND AUTOMATIC TESTING

Manual and automatic testing have much in common. In both instances, the objective is to evaluate the item to be tested to verify proper performance or to detect and isolate a fault. Both approaches require several elements:

1. A way to energize and stimulate the UUT
2. Signal routing devices such as wire, switches, or relays
3. One or more devices or meters to condition signals and measure the signals involved
4. Controls and displays to allow interaction between the test technician and the hardware
5. A procedure, written or intuitive, that the technician follows in the testing process
6. The item or unit being tested

In the manual testing process these elements tend to be discrete instruments and components tied together by

Table 1. Comparison of Manufacturing and Maintenance Testing

	Manufacturing Test	Maintenance Test
First applications	Late 1960s	Late 1950s
Product perspectives	Speed	Integrity
	Cost to test	Life cycle cost
	Cost to produce	Cost of ownership
	Marketability	Reliability
Product mix	Large quantities	Small quantities
	Small variety	Large variety
	Inexpensive	Very expensive
Operating environment	Factory	Field
Test philosophy	Test to sell	Test to repair
	Discard	Salvage and repair
	Stand alone	Hierarchical
	Structural	Functional
Test logic	Bottom up	Top down
	Component to unit	Unit to component
Failure modes	Multiple	Single
	Out of tolerance	Catastrophic
Test techniques	Boundary scan	Logic tree
	Iddq	Guided probe
	Pseudorandom inputs	Truth table
ATE hardware	Standard commercial	Custom
Test languages	C, C++, custom	ATLAS, BASIC
Compilers	Incremental	Full pass
Test specification	Performance parameters	Test requirements
	original	traceable
Operators	Engineers	Technicians
Documentation	Listings	Flow charts
		User instructions
Validation	Compare golden unit	Insert faults
UUT handlers	Automated	Manual
Common needs:	Verification, validation	
Common tools:	Test design tools, compilers, simulators, automatic test generators, software support stations	

cables or wires. In an ATE most of these elements are embodied in the tester. If a good match exists between testing requirements and tester capability (referred to as assets), the only external elements are the interfacing connectors or cables connecting the tester to the UUT. The most signifi-

cant difference is that with the ATE the procedure used in testing is neither dependent on intrinsic knowledge or sequence of actions by a technician nor on a written procedure. It is embodied in the ATE memory and is called a test program.

**Figure 1.** Simplified block diagram of an ATE.

CONTROL SUBSYSTEM

The control subsystem is a functional entity rather than a single physical unit. In the early days of ATE it consisted of the system input and output devices such as a perforated tape or punched card reader, an operator control and display panel, a printer, and a uniquely designed logic network for interpreting and executing instructions fed into the system through the input device. Some of the earliest testers did not contain an internal memory but simply executed instructions directly from the input device. Later, specially designed computers with bulk and random access memories were developed for controlling the ATE. By the late 1960s commercial, general-purpose computers became popular because they offered greater versatility and reduced design and manufacturing costs. Some military ATEs used rather sophisticated, medium-scale computers, whereas those used in commercial manufacturing applications tended to use basic, 8-bit computers.

Once loaded with necessary software and a test program the role of the control subsystem is to execute all programs, both system level and application (test) programs. It works very much like any general-purpose computer, but instead of simply doing clerical work it actuates the various paths and instruments of the system as it interprets programmed instructions.

STIMULUS SUBSYSTEM

The most elaborate and costly subsystem of an ATE is the stimulus subsystem. It consists of all the power supplies, signal generators, and signal conditioners required to energize the UUT during dynamic testing, that is, operating the UUT in as close to its normal operational modes as practicable. In elaborate, general-purpose ATEs the stimulus subsystem can occupy several racks of signal generators, depending on the range of and complexity of the family of UUTs it is intended to test. Special-purpose testers require only a few signal sources, because the application is limited to a small variety of UUTs.

In early maintenance testers, the signal generators consisted of building bricks or chasses of standard test equipment with programmable controls. In recent years many of the signal sources have been reduced in size to plug in cards. These signal sources (building bricks) are often coupled together to generate complex signals from basic circuits. For example, instead of using three signal generators to produce square, triangular, and sawtooth waves, a single signal synthesizer is utilized, thus saving space and cost. Some building bricks, such as a frequency multiplier, can serve for either signal generation or as a measurement resource. Hence, the actual role of building bricks can vary depending on how they are programmed and for what purpose.

MEASUREMENT SUBSYSTEM

The measurement subsystem provides the capability to measure the responses from a UUT during the testing process. Collectively the elements of the measurement subsystems serve as a programmable multimeter. The measured responses from the UUT are compared to the programmed upper and lower limit stored in the test program. The control subsystem then

directs the testing sequence according to the results of the measurement.

SWITCHING SUBSYSTEM

The switching subsystem consists of all the programmable paths in the ATE required to connect the tester to and from the UUT through the interface panel, select the proper stimuli, choose the measurement instrumentation, and switch all of the tester resources as required for each test in sequence. Some testers incorporate a network of relays for internal signal routing, some use solid-state switching networks, and some have patch panels with wires connected as appropriate for the given UUT. Some testers use combinations of all of these switching mechanisms. Some utilize a *universal* routing system for maximum flexibility by allowing any tester resource to be connected to any other and to any pin in the ATE/UUT interface panel.

Some type of connecting mechanism is required to connect the ATE to the UUT. It can be as simple as a cable or as complex as a network of components within an enclosure. The general term for the interface hardware is the ID. In maintenance applications the ID typically consists of an assembly that mounts onto a patch panel. In manufacturing applications the ID can actually be a complex electromechanical unit for automatically feeding UUTs such as integrated circuit (IC) chips into test receptacles and sorting the tested chips into bins based on test results.

SYSTEM SOFTWARE SUBSYSTEM

As with general-purpose computers, an ATE requires several software subsystems or modules to effect its operation. The operating system provides all of the facilities required for operator interface, communicating with input-output devices, allocation of the system resources, and execution of various mathematical subroutines commonly used during the testing process.

No ATE is complete without its software. The software consists of a hierarchy of programs (or software models), most of which are intrinsic to the ATE design and not modifiable by the user. Among the software programs are the operating system, the self-test system, and the user libraries and test program. The operating system controls all of the basic operations such as loading the test program, calling and executing subroutines, executing the testing sequence, and driving the peripheral equipment, such as operator displays and printers.

System software is built up in hierarchical layers, much like the cross-section of an onion, as illustrated in Fig. 2. The core of the system consists of the basic machine instructions of the computer that is the nerve center of the control subsystem. The next innermost layer is the operating system followed by the utilities that facilitate *booting* up the system and input-output operations. Next is the on-line interpreter that converts input code to executable code during program execution. Next is the set of self-test programs that consist of a hierarchy of programs as described later. Next is a library of user subroutines and/or macros that can be initiated by the test program during run time to perform various, standard testing and/or to test set-up functions such as power on sequence of combining several stimuli outputs to generate a complex signal or waveform. Finally there is the specific test program for the UUT to be tested.

Figure 2. System software hierarchy.

MACHINE INSTRUCTIONS

Computers are designed to execute a set of basic instructions such as add, subtract, store, and get, that provide the capability to sequentially perform arithmetic functions and data manipulations. These functions are performed by logic circuitry that interprets *words* composed of different combinations of ones and zeros. It is only through the addition of various software programs that ascribe specific meanings to these words that the user is able to communicate with the computer in an English-like language.

OPERATING SYSTEM AND RUN TIME EXECUTIVE

The operating system is a program that is fundamental to controlling the activity of the computer. It is a fixed part of the ATE design that the user cannot modify. As in most computer systems the operating system is the *traffic controller* for the various activities needed to allocate the system resources such as the arithmetic unit, executable and bulk memory, and input and output devices. In an ATE there often is also a *run-time* executive program that can be considered part of the operating system. It interprets programmed test statements and sends appropriate signals to the ATE resources.

TRANSLATORS

Translators simply interpret the source language statements, check them for proper format, and generate equivalent object language statements without attempting to evaluate the validity of the statements to perform the appropriate action in the ATE. Usually translators are used only to make changes to a test program during program validation rather than to generate the original object program. Hence they are often resident on the ATE as a auxiliary tool called into service through the maintenance panel when needed. Some ATEs utilize an on-line

translator that converts the object program to executable code during test time. Its use is automatic and invisible to the user. It is one of the functions performed by the run time executive program.

COMPILERS

Interpretation of English-like (source language) test statements are accomplished by either compilers or translators. Compilers are not generally resident in the ATE. Rather they are hosted on a powerful, off-line data processing system. Hence no compiler is shown to be part of the ATE system software in Fig. 2. Compilers do much more than translate source language to ATE language. They generally screen test procedures to assure that the target ATE resources are available to perform the functions called out, that none of the tests programmed violate safe rules for using the ATE, and sometimes even automatically allocates ATE resources such as signal sources and generates the linkages to apply the signal to a specific set of pins on the ATE external connection panel.

SELF-TEST

One of the features of an ATE is the ability to test itself. To accomplish self-testing, however, certain features must be incorporated in the stimulus and measurement building bricks, and the diagnostic programs must be designed and incorporated in the ATE. The stimulus signal sources must have self-test outputs that can be internally routed to the ATE measurement subsystem. These outputs can be used to evaluate stimulus assets during self-test or used to measure current signal settings prior to being applied to the UUT. Likewise, the measurement subsystem must have entry points for the selected stimulus signals to be routed to the proper measurement circuitry. These features are intrinsic to the ATE system hardware design. They cannot be added on later or implemented effectively with software only unless a network of programmable switches are provided to route signals internally. That is a poor alternative because of the signal losses or contamination that is introduced by long signal paths and switching devices.

When the required hardware features are provided to internally link the stimulus and measurement subsystems, a set of self-test programs can be incorporated in the ATE. Self-test capabilities range from a simple set of system *health checks* to a multilevel hierarchy of self-test programs, some of which are automatically executed during UUT test time or as more detailed tests selected at the user's option. A comprehensive set of self-tests are described in conjunction with the illustration of Fig. 3. Not all ATEs will provide such a complete set of test programs but they are desirable features to look for in selecting an ATE. Although these features add to the design cost of an ATE, that cost is amortized across all of the ATEs of a given design and not borne by a single customer.

SELF-TEST HIERARCHY

Just as system software is built up from a hierarchy of interdependent software modules, self-testing is also a hierarchical set of software modules. Figure 3 shows an expansion of the self-test function indicated in Fig. 2. The software modules shown

Figure 3. Self-test software hierarchy.

in Fig. 3 are typical but not always organized in the fashion shown.

TURN-ON TESTS

Automatic test equipment is designed to provide maximum versatility to the user. This versatility can lead to misuse and possible damage to the hardware or even harm to the operator. Accordingly, a well-designed ATE incorporates safeguards that preclude damage to the hardware or danger to the user. These are sometimes called *safe to turn on* tests. For example, they check to see that the hook up between the ATE and UUT will not draw excessive current or that high voltages are not connected to low-voltage terminals or where they are exposed to operator controls.

AUTOCHECK

After a safe turn on, the system automatically performs a set of basic tests of the ATE subsystems to assure that the system is *healthy* enough to be used. These tests, called *autocheck* continually monitor the health of the ATE during normal testing of a UUT. They perform routine measurements of stimuli and check for proper operation of measurement circuits. If any test fails, testing of the UUT is halted and the operator is advised that there is a problem. Generally the fault is not isolated by autocheck, but it does instruct the operator as to which set of diagnostic tests should be performed.

SYSTEM DIAGNOSTIC AND CALIBRATION TESTS

Some ATEs include secondary standards, such as standard voltage cells. These, together with the measurement subsystem, can be used to calibrate many of the system resources. Tests can be incorporated in the basic system design to con-

tinuously or periodically check the calibration of the most sensitive circuits of the ATE. These tests would automatically be executed without the need for the UUT test program being impacted unless a capability required falls below acceptable tolerance. Hence calibration tests are at the very core of the self-test hierarchy.

These consist of a library of tests generally resident in the ATE but initiated by the operator in the event of an autocheck indication of failure. They check out the system in more detail to automatically adjust calibration of the ATE resources or, when not corrected by calibration, to indicate which subsystem has failed. The operator or maintenance person can then initiate testing with the indicated subsystem diagnostic tests from the subsystem test library.

SUBSYSTEM TEST LIBRARY

This is a library of test routines grouped according to the ATE subsystems. Because the system diagnostic tests indicate which subsystem tests should be performed a logical linkage exists. It may be necessary to load in the appropriate subsystem diagnostic test program or it could be resident in the ATE so that it is selected from a maintenance panel. Normally the operator must call in an authorized maintenance person, because the maintenance panel can only be activated by a key. Once loaded the subsystem test program identifies the faulty assembly (or ATE building brick) requiring repair. Ideally the faulty assembly can be replaced with a spare, and the ATE can be returned to service. The diagnostic test must be repeated to assure that the maintenance action solved the problem. The faulty assembly can then be tested as a UUT using building-brick tests.

BUILDING-BRICK TEST LIBRARY

The building-brick test library is a set of test programs comprised of individual test programs for each ATE building brick. They are hooked up to the ATE through the standard interface panel and the appropriate ID just as any UUT would be tested.

USER LIBRARIES

As experience is gained through significant use of an ATE, commonly required tests of specific elements of the system are developed into standard test sequences. They can be implemented as subroutines or macros. The purposes vary but can include self-tests for specific building blocks known to be critical to a given test procedure or simply sets of instructions often required to perform complex measurements such as for gain measurement. This library is generally developed by the test design team and developed over a period of time as new ways are found to reduce test design time and/or increase standardization. Such a library is limited only by the ingenuity of the users.

THE TEST PROGRAM

At the top of the software hierarchy is the test program. It is the real workhorse of the ATE. All other software in the lower rings of the system are there to facilitate testing. The effectiveness of an ATE is dependent on a good test program design.

TEST PROGRAM SET DESIGN AND PRODUCTION

A test program set (TPS) consists of a test program, an ID, and a test program instruction. Producing a TPS for other than a trivial UUT is a complex, time-consuming, tedious process. It often involves a team effort with a variety of skills and a whole host of specialized hardware and software tools as well as the target ATE. However, it is divided into five fundamental processes performed more or less in sequence, but with multiple feedback loops when things don't go right the first time—and they rarely do. The five processes are test design, program production, ID design and fabrication, validation, and demonstration and acceptance.

TEST DESIGN

Test design is the most challenging part of the test program development process, requiring a skilled, technically competent individual with both design and maintenance experience. It requires years of training and experience to become adept in the science and art of test design. Neither this document nor any other can compensate for a lack of testing experience. However, an overview is offered here with some valuable tips and recommendations based on many years of TPS development experience applicable to maintenance testing.

Test design is the process of developing the testing requirements of the UUT and the logical sequence or flow of the intended process of testing. For maintenance applications the testing information required is derived from many sources. The performance tests, referred to as the go-chain tests, are usually derived from the factory acceptance test (FAT) procedure. It should provide basic information on the acceptable performance requirements for a properly operating UUT. However, the FAT is most likely performed with test equipment other than the target ATE and the test process is designed to quickly check if the UUT has been properly assembled and tries to detect typical manufacturing errors such as solder splashes, open connections, or improperly mounted components. So although the go-chain tests might be usable in maintenance testing, the fault detection and isolation tests are not. And the go-chain tests most likely will have to be modified to take into account signal deterioration due to signal routing in the ATE as well as making the test limits less demanding to account for acceptable performance degradation or UUTs in service.

Sometimes a test requirements document (TRD) is provided by the UUT manufacturer. It identifies input and output signal requirements for normal testing of the UUT as well as some fault mode information. It may also recommend the proper sequence of testing. Test requirements documents are not cheap and often are hastily produced and contain numerous errors and voids. Making the producer of a TRD accountable for its completeness and accuracy is not easy. Ultimately the burden for proper test design rests on the test design engineer, regardless of how good the data package may be.

Software tools are sometimes available to assist in designing some tests. Such a tool is often called an automatic test program generator (ATPG). It consists of a powerful, special simulation program operable on a general-purpose computer. The program automatically generates test patterns based on a defined digital logic design. These patterns must then be integrated into the remainder of the test program. Some ATPGs

can handle limited hybrid circuit simulation, but to date none provide a comprehensive analog circuit simulation capability.

The test designer need not know exactly how the ATPG works, but must become adept at interacting with it because ATPGs are not really as automatic as they profess to be. Specialized training is required to become adept at using an ATPG, and the availability of expert consultants may also be required. Even with the aid of an ATPG, much of the test-design process depends on the ingenuity of the test designer.

The objective of the test-design process is to develop a detailed, unambiguous, step-by-step procedure that becomes the controlling program used by the ATE to test a UUT. It is up to the test designer to "think as a machine thinks," while generating tests consisting of a series of interrelated tests pertinent to the UUT involved. Here, an individual test is defined as a set of instructions needed to set up the ATE instrumentation (sometimes referred to as ATE assets) as required to energize the UUT, route the ATE signals to the proper ATE output panel and interface device connectors, provide a signal response path from the UUT to the selected ATE measurement instrument, compare the response to stipulated upper and lower value limits, and direct the ATE to the next test to be performed based on the results of the current evaluation. The sequence of tests and all alternative branch paths between tests is referred to as the test-flow process. It is best recorded as a test-flow diagram showing all go-chain tests with appropriate branching to fault isolation tests. A typical test involves proper setting of all the parameters needed for a single measurement of a UUT response followed by a single decision in a three way branch in the program logic, based on a *high*, *low* or *go* test result. If the measured value is within the programmed limits the go branch is taken. If the measured value exceeds the upper limit, the high branch is followed. If less than the lower limit, the low branch is followed.

ESTABLISHING TEST LIMITS

One of the more difficult yet critical tasks of the test engineer is establishing upper and lower limits for each test in the program. The recommended approach is to begin the calculation with the *when-new* or manufacturer's specified limits for normal operation. These are the ideal limits which must be relaxed or made less demanding based on anticipated adverse impact due to expected environmental conditions of UUT usage, expected aging due to component deterioration while in use, and measurement inaccuracies of the ATE (including distortion and crosstalk). The final upper and lower limit values should be as broad as allowable for acceptable operation of the UUT in its normal environment but never beyond.

The sequence of tests begins with checks to assure that the UUT has been properly connected to the ATE via the proper ID. These tests are followed by several safe-to-turn-on tests that assure there is nothing in the setup that could damage the tester. The UUT tests begin with static tests to assure that there are no undesired open or short circuits in the UUT. Static tests are conducted without power being applied to the UUT. Having safely passed these tests power and signals are applied to the UUT to approximate normal operating conditions. Tests executed while the UUT is energized are called dynamic tests. They comprise the bulk of the testing process and require the greatest design skill.

Dynamic tests are generally grouped according to similar input signal requirements to minimize setup and signal settling times. It is also good practice to provide *break points* in the testing sequence. These are places in the testing process where it is safe to enter the process without having to begin with the first test. Break points assure that all ATE parameters are properly set. They are very handy during test design validation and also when attempting to repeat selected tests during a UUT retest.

Sometimes the test operator must interact with the testing procedure by performing manual actions. For example, the UUT may have operator controls or mode-setting switches. The test is not considered complete until each position of the switches or other UUT controls have been tested. The test designer must anticipate the need for manual intervention and program a stop or *pause* instruction and send a message to the operator regarding the action to be taken. When the manual action is completed, the operator initiates a *continue* action and the automatic testing sequence resumes.

When all parameters of a normally operating UUT have been programmed in a sequence of tests, the performance tests (referred to as go-chain tests) are considered complete. It is often necessary to redesign some of the tests based on actual results observed during the validation process as is discussed later. The entire go-chain should be designed before attempting to develop the fault isolation tests (referred to as the *no-go tests*). Results of each test are generally printed out together with a final judgment as if the UUT is okay or faulty.

Fault detection and isolation tests can be partially derived from deductive logic based on which go-chain tests fail. However, most no-go tests must be determined from anticipated field failures. Rarely is such information provided to the test designer, so developing it becomes one of the greatest challenges for the test design engineer. For this task there is no substitute for practical experience and, if available, help from the UUT designer.

When all anticipated failure modes (ways in which the UUT is anticipated to fail) have been accounted for in the test design the no-go chain is completed. Often the information concerning realistic field failures is not given in the source documentation on which the testing is to be based. The preferred solution is to hook up the UUT in a laboratory environment and induce failures in the UUT one at a time to determine the results of each anticipated failure. Without such bench testing the fault isolation tests are theoretical and are often found to be defective during validation when the UUT is attempted to be tested on the ATE. At the end of the fault isolation tests the ATE indicates any failed tests as well as notifying the operator what the most probable component in the UUT has failed. Once repaired, the UUT must again be tested to assure that it is now operating correctly. Usually only one fault is found at a time so it may take several passes in the ATE before the UUT is *ready for issue*.

TEST PROGRAM SET PRODUCTION

Test program production involves generating the object language test program (the language acceptable as an input to the ATE) that dictates the testing process, assembling the ID from existing hardware or building a prototype (called a brass board), and generating the TPS documentation. Generating the object language statements can involve two steps:

(1) Translating an English-language test procedure, such as a TRD, into test programming language (referred to as the source language). (2) Translating the source language statements into the object language. Many programming languages have been used for source code. The IEEE standard language ATLAS (automatic test language for all systems) has been used most for military applications. The airlines maintenance community generally uses a specialized version of the ATLAS language. Commercial manufacturing applications tend to utilize more general-purpose and flexible programming languages such as Fortran or C+ but they are not test-oriented languages so they require development of a specialized test statement dictionary developed by the user so they require a greater depth of programming skill. A good test programming language allows the test engineer to compose a program in engineering English statements, such as set supply A to 15 V, dc or connect supply A to pin 3 of J24. ATLAS provides such a capability but many versions or dialects of ATLAS have been used so that there are special instructions required for each dialect. The proper dialect for any given tester is generally defined in a test programming guide.

Once encoded in source language the source program must be converted to the object language peculiar to the ATE. Conversion is usually performed on a software generation station consisting of a general-purpose computer containing a compiler. A compiler is a program that not only translates source code to object code, but also performs a number of validity checks on the programming logic, allocates memory spaces, and performs numerous other *housekeeping* chores needed to handle test program execution during testing (referred to as run time).

Compiler design is a highly specialized technology relegated to skilled programmers and not the domain of the test engineer. However, the test engineer must become adept at using the compiler and resolving problems *flagged* in the compiler print-out or what is called the *object code*. The program is not considered completely compiled until all flagged statements have been corrected or resolved. It may take several passes through the compiler to get a clean object code listing that can be used during program debug and validation.

INTERFACE DEVICE DESIGN AND FABRICATION

The nomenclature of ID may be misleading because interfacing a UUT to an ATE is generally a complicated process. The term *interface device* was coined many years ago when a simple adaptive device such as a multipin connector or cable was all that was required to hook up a UUT to one of the early ATEs. Today a fairly large box is often required that contains a group of connectors, cabling, and some electrical components. Such an ID is typically used to interface a related group of circuit modules. In military terms the modules are generally called *shop replaceable assemblies* (SRAs). These consist of quite complex circuit boards or assemblies taken from larger UUTs called *weapon repairable assemblies* (WRAs) or *line replaceable units* (LRUs). Typically in aviation maintenance applications WRAs are 30 to 40 lb assemblies removable from an aircraft at the flight line, whereas SRAs are removed for testing in a maintenance shop. A WRA can contain 10 or more SRAs and a typical military aircraft can contain 80 or more WRAs.

Interface requirements linking UUT to the ATE are best determined and recorded concurrently with the test design

process. A standard ID wiring form is recommended with ATE panel connections at the left side and UUT connection points on the right. Adequate space should be provided for drawing wiring and component schematic symbols. Because an ID is often shared among several UUTs, it is important that there be no interference between diverse connections required by each UUT. Unique connections required by UUTs can usually be accommodated by programmable switches in the ATE or, if unavailable, relays may have to be incorporated in the ID design. If specialized signals are required that are not available from the ATE, signal conditioning circuitry may have to be incorporated in the ID. But every attempt should be made to avoid the use of active components in the ID, because they become likely candidates for failure.

Once the ID requirements are documented, they are submitted to a shop for manufacturing. A "brass board" preliminary design is recommended until the TPS has been validated, since changes are likely. After validation the ID should be manufactured as a deliverable item using good design and manufacturing practice.

The ID design is normally represented by a schematic drawing generated by the test designer at the same time as the test procedure is programmed in source language. It shows the connections between the ATE and the UUT with any intervening parts. Ideally only standard cables or patch panel connectors are required when all signals from and to the ATE are compatible with the ATE. Often, however, there are some components that must be included in the ID. They might include load resistors or special signal conditioning circuits. It is up to the test designer to specify the parts and the design of any nonstandard circuits. Assembly and testing of the ID is usually done by a technician.

In maintenance testing applications IDs are custom designed by the test design engineer to meet unique needs of a given UUT or set of UUTs. In manufacturing applications of ATE, interfacing the item to be tested to the tester is accomplished with a standard design *handler* that is part of the ATE system. Interfacing the tester to the items being tested typically involves a complex and expensive handler that automatically accepts each item to be tested from a *hopper* containing hundreds or thousands of items such as computer chips and feeds them in proper orientation to a standard test jig. There each is tested and fed to separate collecting chambers according to how it passed the tests. For testing circuit boards the interfacing is often accomplished by a *bed-of-nails* set of probes that make all contacts with the circuit board in a single operation. The tests are then performed and the next board is automatically loaded to the test position. Test results are automatically printed out and keyed to the pertinent board by serial number.

TEST PROGRAM INSTRUCTIONS

Test program set documentation is referred to as the test program instructions (TPI). Documentation requirements can vary widely depending on the needs and skill of the user. As a minimum it consists of source and object program listings, ID schematic, and instructions for the ATE operator. It may also include a flow diagram of the testing process and general operating procedures for the ATE operator.

During test design and ID design the test designer should also prepare notes on instructions that must be given to the

test operator for use while testing the UUT. Generally, this includes initial hook-up instructions for the ID, any precautions to be taken, and associated manual actions required of the operator to start the testing process. This information when properly edited becomes the TPI. Traditionally this is treated as a formal, hard-copy publication, deliverable as an element of the TPS. A better approach is to incorporate all instructions to the test operator within the test program. Initialization of the standard testing process can be built into the ATE in a resident *boot strap* program that is automatically executed when a start button is pressed on the ATE control panel. Information to be passed to the operator during testing, whether requiring operator intervention or simply informing the operator as to what is happening or relaying test results, should also be incorporated in the test program so that there is a constant communication and a symbiotic interaction between the operator and the ATE. With current technology and equipment there is no need to depend on hard-copy documentation for any part of the UUT testing process or even the trouble-shooting and repair of the ATE.

Once the test program listings, the ID with its schematic, and the draft copy of the TPI are available the test designer can begin TPS validation on the ATE.

VALIDATION

Validation is the process of testing a TPS on the target ATE to confirm that the testing process is valid and accomplishes the intended purpose. This process should be distinguished from the process called verification, which simply assures that the program is a faithful representation of what the test designer stipulated in source language statements during test design; not that the test design and ID are doing what is really required to test or fault-isolate the UUT. Verification can be performed by a good compiler but usually requires some *desk checking* of the compiler printout by the test designer to be sure that the program is ready to be tried on the ATE with the UUT hooked up and activated.

Once the compilation has been verified and the ID brass board is assembled and bench tested, the TPS is ready to be validated on the ATE. A known good (properly operable) UUT is required for the process of validating the go-chain. At least one additional known good UUT should be tested on the ATE to be sure that the testing process and operating limits of the program are generally valid and not unique to only one UUT of the type being tested. Go-chain validation should be completed before any attempt is made to validate the fault isolation (no-go) tests. Once the go-chain has been validated a sample number of anticipated field failures should be induced in the UUT, one at a time. Careful analysis of the UUT design is required to assure that induced faults will not damage the UUT. What failures are considered reasonable field type or operational failures and what percentage of anticipated failures should be induced during the validation process is a tough judgment call. It depends on the degree of confidence that the customer is willing to pay for. Formulas have been developed to assist in the process of computing the degree of confidence and the level of fault isolation that is desired. Some guidance along these lines is provided in future chapters.

It is important that the test designer has a clean compiler listing, tested ID and its schematic, and UUT documentation

prior to attempting to validate a TPS. Auxiliary external test equipment may also be needed to examine signals at interface points when the signals programmed or received from the UUT are in doubt. If a lot of validating is planned, it is a good idea to have an experienced trouble-shooter to assist in the validation process. Time on the ATE is very precious, so validation should proceed as rapidly as possible. That is not the time to design or redesign tests. One should note each problem and move on to the remaining tests unless precluded by the impact of previous failures. Problem solving and test redesign should be done off line. Validation can then be resumed at a later time when machine time can be scheduled. Any problems experienced with the ATE should be recorded in a validation logbook.

A TPS cannot be considered fully validated until a complete printout is obtained indicating all values measured with *go* results and printouts showing measured values for UUT failures with appropriate results and instructions printed for the test operator.

Demonstration and Acceptance. Once the TPS has been debugged and validated, some sort of demonstration is required to *sell off* the TPS to a customer. In the military sell off is a formal, well-documented, and explicit process. In a factory application it may be simply demonstrating to the production manager that the test program and ID operate as required. In a formal sell off, the documentation package describing the testing process is reviewed and accepted. Next the TPS operation on the ATE is demonstrated. The *go-chain* is executed to show that an operating UUT can be properly tested as operational. Then an agreed upon set of faults are inserted into a UUT, one at a time, to show that faults are identified by the testing process. Once an acceptable number of faults have been shown to be covered by the process the customer's representative signs the acceptance document.

Built-in Test (or Built-in Self Test)

In recent years, as components and systems have become much more complex, considerable attention has been given to designing devices, modules, and systems so that they are more readily testable. Since the cost of testing logic chips in the manufacturing process represents as much as 30% of the production cost, it has become cost effective to include built-in-test (BIT) features, which reduce manufacturing test time and the overall cost of producing the product. Typically approximately 10% of the *real estate* (surface area) of a chip is devoted to testing circuitry. A popular technique is called boundary scan. This methodology provides program-controlled access to the internal circuits of a chip to allow sampling internal circuits without the need for an external probe.

In maintenance applications, the BIT features introduced in the manufacturing process is utilized to isolate faults in the product's components. In large systems such as aircraft, system-level BIT is usually incorporated in the design to assist in maintenance testing. BIT becomes a subsystem of the design and provides in-flight health monitoring as well as indications of particular failures. Identification of a fault allows the pilot to select alternate modes of operation during flight. Once landed the BIT subsystem can be queried to determine which subassemblies need to be replaced to restore the aircraft to full operation. In the maintenance shop the information gained from the BIT circuitry can be used to help isolate faulty

components and thus facilitate the repair of the failed units removed from the aircraft. Automobiles are also being equipped with some BIT features.

Simulation as a Test Tool

Simulation provides a means for modeling a circuit, network of circuits, or even an entire system on a computer. Simulation finds greatest utility in the design process but can also help in test design. For many years software programs have been used to simulate digital circuits and networks and automatically generate test patterns needed for testing. More recently some simulators have incorporated test generation features for hybrid networks (a mix of analog and digital circuitry). Simulation of complex analog networks has not been very successful due to the complexity of developing effective models. Simulators used in circuit design generally do not provide for simulating fault modes as required for maintenance testing, so they offer only limited utility for test design. Future design simulators very likely will begin to address the needs of the test designer as well as the product designer.

Golden Card as a Testing Standard

Some manufacturing applications have utilized a circuit card or subassembly known to be operating properly as a standard against which newly manufactured cards of the same design can be tested by comparing input and output signals. The standard card is referred to as the *golden card*. This approach works well in some applications and is easier to use than a software simulator. The danger lies in the possibility that the golden card could fail and result in erroneous testing of the new cards. A more effective technique is to develop a software model of the golden card to use as a standard since once software is properly designed and tested it does not fail.

Guided Probe

Some commercial ATE includes a feature called *guided probe*. It is a system software module that helps in trouble-shooting a circuit card or assembly. In the probe mode of operation the ATE directs the operator where to put a signal probe in each of a series of points while the tester evaluates the signal from each point probed. Thus by use of a trouble-shooting algorithm the ATE leads the person to identify the faulty component. This technique can be more effective than relying only on access to the circuitry from input and output connectors, as is the case with many testers.

BIBLIOGRAPHY

Although ATE is utilized extensively in both manufacturing and maintenance applications, surprisingly few textbooks have been published on the subject. A search through the Library of Congress index of published books reveals that by 1997 only four have been published that are devoted to ATE since the first was published in 1974 by IEEE Press. The three that could be classified as textbooks are entirely devoted to manufacturing applications of ATE with no mention of the multibillion dollar market for maintenance testing utilized principally by the military and the airline industry.

The principal sources of documentation are the periodic symposia, conferences, and workshops dedicated to various ATE

specialties. They provide both invited and volunteered papers which are subject to peer review. Copies of recent issues are generally sold directly by the technical societies sponsoring the events. Some conferences offer tutorial sessions that provide valuable prerequisite information covering basic principles or advanced techniques. These meetings, with their respective publications, are the best source of technical information, because they are directed at a wide variety of applications and tend to contain the latest developments in ATE technology. The International Test Conference is devoted almost exclusively to manufacturing test and AUTOTESTCON is almost exclusively devoted to maintenance testing.

There are many periodicals, generally published monthly, that provide a medium for publishing volunteered papers of variable quality. Industry studies are common but they stress marketing data rather than providing a source of technical information. Other publications, such as user guides, deal with the specifics of particular ATEs so they are of limited value for general education since all ATEs are different.

SENSORS AND TRANSDUCERS

ELECTRIC SENSING DEVICES

In a measuring chain or a measuring instrument, the sensor is the element that is directly affected by the measurand (1). Specifically, an electric sensing device converts the quantity to be measured into an electric output signal (generally a voltage) (2). Today electric measurement systems have replaced most nonelectric systems. Only in environments where ionizing radiation or explosive atmospheres are present, nonelectric (mechanical, hydraulic, pneumatic) or optical signals may be more suitable (3). The advantages of using electric sensing devices are numerous and are related above all to the current technology in electrical signal elaboration, recording, and transmission. There are, in fact, even sensors that incorporate integrated circuits for electric signal conditioning or modification in a single package and consequently provide outputs more suitable for the following elements of the measurement chain. Moreover, in the automatic control system where the sensor's outputs have to be elaborated by a numerical processor, it is very easy to convert an analog electric signal to a numerical form.

It is possible to design an electric sensor for measuring any nonelectric quantity. Because of the electronic structure of matter, by selecting appropriate materials, any variation in a nonelectric parameter yields a variation in the electric parameter (3).

Measurand quantities may be grouped on the basis of the form of energy in which the signal is received by the sensor: mechanical, thermal, electrical, magnetic, radiant (optics), or chemical. In Table 1 a limited number of significant examples belonging to each class are reported (4). Often more than one transformation step is required to generate an electric output signal. It is possible to (2) define *primary measurand* quantities directly sensed by electric sensor whereas *secondary measurands* include a combination of primary measurands (5). There are several physical effects that generate electric signals in response to nonelectric influences. It is very difficult to group the countless types of sensing devices. Table 2 gives an interesting summary of the most widely used physical principles of sensing with the electric output and the typical measured quantities (6).

Table 1. Examples of Measurand Grouped by Their Domain

Type of Sensor	Physical Quantities
Mechanical	Displacement, length, strain, velocity, acceleration, mass flow, force, torque, pressure
Thermal	Temperature, heat, heat flow, entropy, humidity
Electrical	Voltage, current, power, charge, resistance, inductance, capacitance, dielectric constant, electric field
Magnetic	Field intensity, flux density, magnetic moment, permeability
Radiant	Intensity, phase, wavelength, polarization, reflectance, transmittance, refractive index
Chemical	Composition, concentration, reaction rate, pH, oxidation

MATERIALS USED FOR SENSING DEVICES

Metals

Metals are characterized by high electric and thermal conductivity, high optic reflectivity, high deformability, plasticity, mechanical tenacity, and high electronic extraction potential. Alloys or intermetallic compounds conserve these qualities to a high degree. Consequently, many sensors operate on the basis of the variation of physical proprieties of pure metals or alloys following variations of external quantities. In general, from the standpoint of sensor design, there are two classes of metals: nonferrous and ferrous. Ferrous metals, like steel, are often used in combination with a magnetic sensor to measure motion, distance, magnetic field strength, etc. Nonferrous metals offer a wide variety of mechanical and electric proprieties but are permeable to magnetic fields and used whenever these fields are not involved. The major use of nonferrous metals is to produce thermoresistances and thermocouples (5). Metals also exhibit piezoresistant effects, but because they are more sensitive to temperature, the production of strain gauges by using metal alloys rather than pure metals is preferred.

When selecting a metal for a sensor design, one must consider its physical proprieties, and also the relative ease of mechanical processing. For example, copper has excellent thermal and electric proprieties, yet is difficult to work with. So in many cases aluminum is considered a compromise alternative (5).

Ceramics

Ceramic oxide materials play an important, steadily increasing role in almost all fields of electronics. In sensor technologies, ceramics are very useful because of their structural strength, thermal stability, light weight, resistance to many chemicals, ability to bond with other materials, and excellent electric properties (5). There are, moreover, abundant opportunities for optimizing performance and tailoring to specific demands by modifying their chemical composition and/or varying their microstructure by changing parameters in manufacturing. There are ceramic materials with piezoelectric, pyroelectric, and ferroelectric proprieties (4).

Glass

Glass is characterized by transparency, hardness, and resistance to most chemicals. The main type of glass used in sensor technologies is lead alkali, which is a good electric insulator and is used for manufacturing optical windows, prisms, and nuclear radiation shields. Furthermore, optical fibers can be realized from glass (5). Optical fiber sensors can be separated into extrinsic and intrinsic types. In extrinsic fiber-optic sensors, sensing process takes place externally to the fiber, and the fiber itself plays a passive role as a light conduit (characterized by a very low attenuation factor). In intrinsic transducers, however, the measurand interacts locally with the light in the fiber by changing a parameter of the fiber, such as the refractive index, and the fiber in turn modulates the light beam propagating through its core (4,7).

Table 2. Physical Principles of Electric Sensing Devices

Physical Principle	Typical Application	Measurand	Output
Resistive The variation of the sensing element electric resistance depends on the measurand.	Thermistor or resistance thermometer	Temperature	Resistance
	Potentiometer	Displacement, force, pressure	Resistance
	Hot-wire anemometer	Flow	Resistance
	Resistive hygrometer	Humidity	Resistance
	Chemioresistor	Presence of gas	Resistance
Capacitive The sensing element capacitance depends on the measurand.	Parallel-plate capacitor sensor	Displacement, force, liquid level, pressure	Capacitance
	Rotary-plate capacitor sensor	Displacement, force, angular position, torque	Capacitance
	Differential capacitor	Small displacement	Capacitance
	Capacitance manometer	Very low pressure	Capacitance
	Humidity sensor	Moisture	Capacitance
	Capacitive diaphragm	Pressure	Capacitance
Inductive The sensing element inductance depends on the measurand.	Linear variable differential transformer	Displacement, torque	Inductance
	Self inductance sensor	Displacement, torque, liquid level	Inductance
	Eddy current sensor	Position, conductivity, thickness, cracks in materials	Inductance
Reluctive The variation in the reluctance path between two or more coils depends on the measurand.	Linear variable differential transformer	Linear displacement	Voltage
	Rotary variable differential transformer	Angular rotation	Voltage
	Microsyn	Angular displacement	Voltage
	Resolver	Position	Voltage
	Syncro	Position, torque	Voltage
	Reluctive diaphragm	Pressure	Reluctance
Piezoresistive effect Resistance of the sensing element depends on the strain.	Strain gauge	Stress, strain, fluid pressure, displacement, force	Resistance
Electromagnetic In any circuit capturing a magnetic flux, whenever the flux changes an electromotive force is induced (Faraday law).	Linear velocity sensor	Linear velocity	Voltage
	Flowmeter	Flow	Voltage
	Tachometer generator	Angular speed	Voltage
	Torque sensor	Torque	Voltage
Superconducting Josephson effect When a superconductor is placed inside a magnetic field, the field is completely expelled from the interior of the superconductor.	RF SQUID	Magnetic field	Voltage
	DC SQUID	Magnetic field	Voltage
Hall effect If the sensing element, carrying current, is put in a magnetic field, a difference in electric potential among its sides is generated.	Gaussmeter	Magnetic field, displacement	Voltage
	Wattmeter	Power	Voltage
Magnetoresistive effect Resistance of the sensing element depends on the strain.	Magnetoresistor	Magnetic field, linear and angular displacement, proximity, position	Resistance
Piezoelectric effect Subjecting the sensing element to stress there is a generation of electric charge.	Vibration cables	Vibration	Voltage or charge
	Active and passive force sensor	Force	Voltage or charge
	Piezoelectric microphone	Ultrasonic waves	Voltage or charge
	Piezoelectric temperature sensor	Temperature	Voltage or charge
Pyroelectric effect The sensing element generates an electric charge in response to heat flow.	Heat flowmeter	Change in the temperature	Voltage
	Pyroelectric sensor		
Thermoelectric effect When there is a difference in temperature between two junctions of different metals, a difference of electric potential is generated.	Thermocouples, thermopiles, infrared pyrometer	Difference of temperature	Voltage
Ionization effect The sensing element when exposed to the measurand becomes ionized.	Electrolytic sensor	Electrical conductivity, pH	Current
	Vacuum gauges	Pressure	Current
	Chemical ionizer	Atomic radiation	Current
Photoresistive The electric resistance of the sensing element is caused by the incidence of optical radiation.	Photoresistor, photodiode, phototransistor, photofet	Light, position, motion, sound flow, force	Resistance
Photovoltaic effect When the sensing element is subject to a radiation it generates an electric potential	Flame photometer	Light intensity	Voltage
	Light detector	Light, position, motion, sound flow, force	
	Pyrometers	Temperature	
Acoustooptic effect The interaction of an optical wave with an acoustic wave produces a new optical wave	Acoustic optic deflection, Bragg cell	Physical vibration	Phase modulated voltage
Doppler effect The apparent frequency of a wave train changes depending on the relative motion between the source of the train and the observer.	Remote sensor of linear velocity, Doppler radar, laser Doppler velocimeter	Relative velocity	Frequency
Thermal radiation An object emits thermal radiation, whose intensity is related to its temperature	Pyrometer	Temperature	Voltage

Plastics

The most widely used polymers in sensor-related applications are thermoplastic polymers, such as polyester, phenolic, alkyd, allyl, and epoxy (5). These are characterized by high flexibility and stability to mechanical stress and can be formed into any desirable shape. Because plastics are excellent electrical isolators, different methods are used to provide them with electrical conductive properties required for shielding: lamination with metal foil, painting with conductive paint, metallization, mixing plastics with conductive additives, and building composite plastic parts incorporating metal mesh. For example, piezoelectric plastics are realized by poling them either in high voltage or by corona discharge and depositing metal electrodes on both sides of the plastic film.

Furthermore, polymers are used together with glass or alone to produce optical fiber. The plastic fibers (plastic-plastic or plastic-glass) are more commonly used than glass because it is possible to realize fibers with any refractive index.

Semiconductors

There are relatively few types of intrinsic semiconductors. Those made of germanium and gallium arsenide are the most widely used (8). Adding impurities to these materials, forms extrinsic semiconductors, also called doped semiconductors, which are characterized by an increased number of carriers (9). In sensor designs the semiconducting materials (intrinsic and extrinsic) are used both as active materials and as passive materials. In some cases, the sensing element is constituted by the semiconductor itself (active material). The semiconducting materials and, in particular, silicon actually exhibit a great number of physical effects which are quite useful for sensor application, for example, photovoltaic, photoelectric, photoconductive, piezoresistive, magnetoresistant, and ion sensitive. On the other hand, when a semiconducting material does not display the proper effect, it is possible to deposit layers of materials, that have the desired sensitivity on top of the silicon substrate, which provide either a mechanical structure or electrical connection to a sensing device. Silicon, in fact, exhibits very useful mechanical proprieties and is a relatively inert element. Most acids, except hydrofluoric acid, do not affect it, but it is affected by halogens and dilute alkali. The large use of semiconducting materials is also due to the fact that these materials are inexpensive and now are produced and processed in controlled conditions to unparalleled standards of purity and perfection.

SENSOR CHARACTERISTICS

Because sensors provide an interface between the measurement system and the outside world, the choice of a sensor involves evaluating its input-output relationship and also all links with external systems (6). In Fig. 1 the physical systems directly connected to the sensing device are reported, and the information path and interaction between the sensor and the other systems are indicated. Naturally, upstream there is the system to be measured and down stream is the user system. By user system we mean the system to which the sensor provides information. It may of course perform other elaborations on the sensor output. In the environment system all interfering sources are summarized, and an auxiliary

Figure 1. A sensing device and its interactions with the outside world.

system is required to operate the sensor (e.g., for the power supply) (6).

In the following, the most important characteristics of sensors are reported, organized on the basis of the systems to which they are related. The analysis and comparison of these characteristics among different sensors can help the user to choose the most suitable sensor for each particular application. Naturally, depending on the application requirements, some characteristics may be more important than others.

Measured System

Input Range, Overload, Overrange. The sensor's nominal range indicates the lower limit and the upper limit values of the measurand between which the sensor is designed to operate. The span refers to the modulus of the difference between the two limits of the nominal range. In some fields, this is called input full scale (FS). (1,2). Often the overload values or the overrange value are also provided. The overload values are the extremes of the safety field of the measurand, whereas the overrange value is the maximum value safety field of the measurand, implying that the minimum coincides with the lower limit of the measured field.

Loading Effects. The introduction of any measuring device into a measured system always results in modifying the characteristics of the measurand, thereby changing its value from its undisturbed state, and thus making a perfect measure theoretically impossible (10). For example, introducing a temperature sensor into a vessel of liquid may change its temperature (7). Consequently, the sensor manufacturer has to indicate the sensor loading effects. In particular, the sensor input impedance indicates the electric loading. In general, to limit the electric loading effects, the input impedance of the sensor must be high compared to the output impedance of the system to which the sensor is connected (10).

Mechanical Coupling. From this viewpoint, sensors can be divided into two very broad categories: contacting sensors and noncontacting sensors (2). These categories indicate whether or not the sensor must be in direct contact with the measurand. Inability to connect suitably may depend on physical requirements (the fingers cannot reach the point of interest or it is impossible to see inside the container holding the measurand) or on safety considerations (the measurand or its environment may be hazardous) (7).

Sensing System

Sensor performance characteristics are generally categorized as static and dynamic. The first describe performance at room conditions with very slow changes in the measurand and without any shock, vibration, or acceleration. The latter are related to the response of the sensor to variations of the measurand with time (11). In most measurement systems the quantity to be measured changes so slowly that it is only necessary to know the static characteristics of sensors. But the same sensor in the same operating conditions can be defined in a static or a dynamic regime according to the accuracy required (3).

Finally it is necessary to emphasize that we regard the sensor as a black box and that we are only concerned with the relationship existing between input and output quantities, even if more than one conversion step is involved from the input to the output.

Static Characteristic

Accuracy, Uncertainty, Bias, Repeatability, Reproducibility. Accuracy indicates the closeness of agreement between the result of a measurement and the value of the measurand (1).

Uncertainty characterizes the dispersion of values that could reasonably be attributed to the measurand. Thus, it expresses the fact that, for a given measurand and a given response to it, there is not one value but an infinite number of values dispersed around the result that are consistent. Even if the uncertainties are small, there is no guarantee that accuracy is high. Thus the uncertainty does not necessarily indicate the likelihood that the sensor response is close to the value of the measurand (12).

The bias of a sensor is the constant error that exists for the full range of its measurements (6).

Repeatability indicates the closeness of the agreement between the results of successive measurements of the same measurand carried out under the same conditions of measurement. These conditions are called repeatability conditions and include the same measurement procedure; the same observer; the same location; and repetition over a short period of time. Repeatability may be expressed quantitatively in terms of the dispersion characteristics of the results (1).

Reproducibility is the sensor's ability to indicate identical values of the measurand each time a measurement is made, assuming that all environmental conditions are the same for each measurement. It is defined as the closeness of agreement between the results of measurements of the same measurand carried out under changed conditions of measurement. Changes in conditions may include the principle of measurement; the method of measurement; the observer; and the same location, time, and condition of use. Reproducibility may be expressed quantitatively in terms of the dispersion characteristics of the results, and it is necessary to specify the conditions changed (1).

Response Characteristic, Static Calibration. The response characteristic for a sensing device is the relationship between the input quantity (also called stimulus) and the corresponding output value (also called response) for defined conditions. This relationship may be expressed in the form of a mathematical equation, a numerical table, or a graph. An ideal or theoretical response characteristic exists for every sensor, and if the sensor follows this ideal behavior, its output always represents the value of the stimulus. But because of variations of

materials, design errors, manufacturing tolerances, workmanship and other limitations, the real response characteristic rarely coincides with the ideal. Consequently, it is necessary to establish a relationship between the sensor response and the value, with its uncertainty, to be assigned to the measurand. A calibration process helps determine this relationship. This is a test during which known values of the measurand, also called calibration points, are applied to the sensor, and the corresponding output values are recorded. The input is changed very slowly over the entire range, first increasing and then decreasing the measurand and keeping all other influential quantities constant. A single performance of this test is called a calibration cycle. A complete calibration process usually comprises two or more calibration cycles. The choice of the number and location of the calibration points and of the number of calibration cycles is very important because they may affect the achievable accuracy for a given total number of measurements. The sensor responses are suitably fitted against the input values to form the calibration curve (or calibration diagram). On the basis of all of the gathered calibration points an uncertainty band, which can vary along with any variation of the measurand, can also be added to the calibration curve. The value of measurand (y_0) corresponding to a sensor response (x_0) is obtained as the ordinate of the point of intersection between the calibration curve and the straight line parallel to the ordinate axis passing through x_0 . The uncertainty given to the input (Δy_0) is determined by the width of the segment obtained by the intersection of the same line with the uncertainty band (see Fig. 2) (1–4,9,11).

In the calibration process the value of the measurand can be determined by using two different methods: direct comparison and indirect comparison (see Fig. 3). In the first case, a standard generator furnishes a known stimulus to the sensor being calibrated. The values of these stimuli should be at least ten times more accurate than the sensor. In the indirect comparison, the calibration test consists of comparing the calibrating sensor outputs to the outputs of a standard sensor. In this case an approximate level of stimulus source is required, but the time stability and the spatial uniformity of the source must be guaranteed (7).

Sensitivity, Offset, Resolution, Dead Band, Threshold, Saturation

Sensor sensitivity refers to the sensor's ability to generate an output response to a given change in the measurand (1). It is expressed as the change in the response divided by the corresponding change in the stimulus ($\Delta y/\Delta x$). If the response

Figure 2. An example of a calibration diagram.

Figure 3. Techniques for calibration: (a) direct comparison; (b) indirect comparison.

characteristic of the sensor is not a straight line, the sensitivity varies with the value of the stimulus (1,2,10).

Offset is the deviation of the output signal from zero when the input is zero (6).

Resolution is defined as the smallest difference between sensor readings that can be clearly distinguished. In other words it is the minimal change of the input necessary to produce a detectable change at the output. When the output signal is digital, the resolution represents the smallest change in analog input that generates a change of one bit. The resolution is sometimes expressed as a fraction of the maximum input value (1,3,6).

The dead band describes the insensitivity of a sensor in a specific range of the input signal. It is defined as the maximum interval through which a stimulus changes in both directions without producing a change in response. It may depend on the rate of the change. The dead band is sometimes deliberately widened to prevent any change in response for small changes in the stimulus (1,9).

The sensor threshold is the largest change in a null-stimulus that produces no detectable change in the response of the sensor. The threshold may depend, for example, on noise, friction, and also on the value of the stimulus (1).

Almost any sensor has its operating limits. Further increase of the stimulus does not produce an increase (or decrease) of the output, and the sensor goes into a saturation zone.

Linearity. Sometimes, rather than expressing the calibration curve as a numerical table or a graph, its linear approximation is furnished. There are different methods for constructing the line (2,3,11) (see Fig. 4):

Least-Square Linearity. The straight line is defined by the least square criterion. Consequently the sum of the squares of the residuals is minimized. This is the method that usually gives the lowest value of nonlinearity error.

Zero-Based Linearity. The straight line is also defined by the least square but with the additional restriction that it passes through zero.

Theoretical-Slope Linearity. The straight line is referenced to the theoretical line defined in the sensor design phase.

Terminal-Based Linearity. The straight line is defined as the line that passes through the output corresponding to the lower input and the theoretical output when the higher input is applied.

Figure 4. Different strain lines: 1. least-square; 2. theoretical slope; 3. terminal-based; 4. end points.

End-Point Linearity. The straight line is defined by the real output when the upper and lower input range are applied.

The nonlinearity error is defined as the maximum deviation of any calibration point from the corresponding point on a specified straight line. Normally it is defined as a percentage of the output range.

Another term sometimes used is conformance (or conformity), which indicates the closeness of a calibration curve to a specific curve (normally the theoretical curve) for a nonlinear sensor (4,5).

Hysteresis. Hysteresis is the difference between two output values that correspond to the same stimulus depending on the direction (increasing or decreasing) and whether that value is reached. There is a chance that the output corresponding to a given input depends on whether the previous input was higher or lower than the present one. That is similar to the magnetization of ferromagnetic materials (3). Typical causes for hysteresis are friction and structural change in the material of the sensing element. Hysteretic error is defined as the difference between the measured values obtained when the measured quantity is increasing and when decreasing to that value. Hysteresis is usually quantified in terms of the maximum hysteretic error as a percentage of the full-scale output (6,9).

Stability, Creep, Drift, Zero-Shift, Sensitivity Shift. Stability indicates the sensor's ability to maintain constant metrological characteristics in time (1). Short-term stability is manifested as changes in the sensor performance within minutes, hours, or even days. The long-term stability may be related to aging of the sensor materials, which causes an irreversible change in its material properties. Aging depends greatly on environmental storage and operating conditions and how well the sensor components are isolated from the environment. Stability may be quantified in several ways, for example, in terms of the time over which a metrological characteristic changes by a stated amount or in terms of the change in a characteristic over a stated time (5).

A sensing device shows drift if there is a gradual change in output over a period of time which is unrelated to any change in input (6).

Zero-shift is a change in the zero measurand over a specific time interval at room conditions. The zero-measurand output is the output of the sensor under room conditions with nominal excitation and zero measurand applied (1).

Figure 5. Different damping characteristics.

Sensitivity shift is a change in the sensor's sensitivity over a specific period at room conditions (1).

Dynamic Characteristics. When an input stimulus varies suddenly, the sensor response does not follow this variation with perfect fidelity. The sensor does not respond instantly to the stimulus change. The sensor's dynamic characteristics can be stated in term of speed of response, velocity limit, slew rate, and recovery time (2,5,11). Speed of response indicates how fast the sensor reacts to changes in the output variable. Slew rate is the maximum rate of change with time of the input for which the output can keep up with the change. Recovery time is the time interval necessary after a specified event for the sensor to resume functioning as specified.

For linear sensors other parameters are used to describe the sensor behavior in dynamic conditions. They refer to the time and frequency domains.

Time Domain. The most commonly used dynamic characteristics in the time domain are the step response and the natural response. In response to a step in a measurand, the sensor may have different damping characteristics (see Fig. 5):

- An underdamped sensor oscillates around its final value (y_∞) before coming to rest at that value.
- An overdamped system comes to a final value without overshoot.
- A critically damped system is at the point of change between underdamped and overdamped conditions.

The ratio of the actual damping to the degree of damping required for critical damping is the damping factor. A damping ratio of 1.0 indicates critical damping. Damping ratios larger than 1.0 signify overdamping. Finally, underdamping is indicated by a damping ratio of less than 1.0 (11).

The parameters of an overdamped or critically damped sensor are defined as follows:

Dead time is the time interval between the instant of step application (t_0) and the instant (t_1) in which the response exceeds a threshold value (y_1), usually defined as a percentage of (y_∞).

Response time describes the time that has to elapse before the sensor fully responds to the change. It is defined as the length of time required for the output to rise to a specified percentage of (y_∞) (the percentage is typically 95% or 98%).

A special term has been assigned to 63.2% response time: the time constant (τ).

Having fixed two percentages of the final output value, the rise time is the interval necessary for the output to rise from the smaller percentage to the larger. Unless otherwise specified, the percentages should be assumed to be 10% and 90% of the final value, respectively.

For underdamped systems other parameters are also used:

The overshoot is the difference between the maximum output value ($y_{\max}$) and y_∞ .

After having fixed a value band at around y_∞ (normally it is equal to 5% of y_∞), the settling time is the time interval between t_0 and the instant in which the output remains limited to the previously mentioned band;

The ringing frequency is the damping oscillation frequency.

With reference to natural response, which is the evolution of the sensor output starting from a not null initial value and without measurand, two parameters are defined, the natural frequency and the natural undamped frequency. The natural frequency is the fundamental sinusoidal component of the natural response (14).

Frequency Domain. In the frequency domain a very important dynamic characteristic is the frequency response. It is the change of the amplitude and phase of the output as a function of the frequency of a unit amplitude sinusoidal input. These two curves are, respectively, the module and the phase of the so-called Fourier transfer function [$G(\omega)$] (4). The frequency response is displayed graphically (see Fig. 6) as the plot as a function of the frequency of the sensor amplitude output (amplitude diagram), normally using a logarithmic scale, and of the phase displacement between the input sinusoid and the output sinusoid (phase diagram). Many synthetic parameters describe the frequency response of a system. The bandwidth, also called frequency range, indicates the range

Figure 6. An example of the (a) amplitude and (b) phase frequency response of a sensor.

Figure 7. A static compensation technique.

of frequencies over which the sensor can be used. It is defined as the range of frequencies for which the transfer function is within a fixed band (normally 3 dB, 70.7%) of its peak value and is defined by the lower and upper cutoff frequencies. The resonant frequency is the frequency corresponding to which the module of the frequency response has a maximum value (6).

Static and Dynamic Compensation Technique. Generally, the sensor calibration curve is nonlinear, but it may be corrected by a suitable static compensation technique. One of the most common methods consists of introducing a compensating nonlinear element in cascade connection to the sensing device. This method is illustrated in Fig. 7, which also shows the response characteristic of the single blocks and the whole compensated system (13). As a consequence the relationships between response y and stimulus x can be expressed as: $y = ax + b$. Sometimes, to obtain a proportional relationship $y = kx$, another compensation stage is added, which allows compensating the sensor's sensitivity (a) and the shift from zero (b).

When the sensing fails to meet the dynamic specifications, that is, the dead time is too long or equally the frequency range is too small, it is necessary compensate for it (15). Having identified the dominant element in the system, the most obvious method of improving the dynamic response is that of the inherent design, that is, the design parameters are varied to improve the dynamic response of such an element. Two other methods are normally used: open-loop and closed-loop dynamic compensation. In the open-loop technique a linear element, with a transfer function in the Laplace domain $H_c(s)$, is introduced into the sensor system, such that the overall Laplace transfer function $H(s) = G(s)H_c(s)$ fulfils the required condition [Fig. 8(a)]. In the closed-loop, the compensation is obtained by using a high negative feedback [Fig. 8(b)]. The output of the sensing device is amplified by a high-gain amplifier [$H_g(s)$]. The amplifier output is fed back to an element [$H_c(s)$] which provides a balancing force to oppose the input force. In this case the compensated transfer function is given by

$$H(s) = \frac{G(s)}{1 + H_c(s) \cdot G(s)}$$

If the amplifier gain is rendered large such that the condition $G(s)H_c(s)H_g(s) \gg 1$ is satisfied, then $H(s) \sim 1/H_c(s)$. This means that, providing the previous condition is respected, changes in

Figure 8. Sensor dynamic compensation, using (a) an open-loop technique; (b) a closed-loop with high negative feedback.

$G(s)$ due to nonlinear effects have a negligible effect on the compensated output (13) (Fig. 9).

Today, compensation is often realized by numerical microprocessors. In static compensation, using a look-up table based on the results of the calibration or using an interpolation technique, the microprocessor gives the corresponding input value for each measured value. Consequently, there is more interest in repeatability than in linearity. As for dynamic compensation,

Figure 9. Compensation for interfering inputs (x') using (a) opposing environmental inputs or (b) a differential system for a linear sensor.

the transfer function of the sensor is stored in the processor memory, and using a deconvolution technique and the previous output values, the processor gives the corresponding input value for each output value. The sensor transfer function is obtained by an identification procedure realized in a preliminary dynamic calibration. Naturally, it is necessary that the dynamic behavior of the sensor not vary in time (10).

Reliability Characteristics. Reliability characteristics are those characteristics relating to the useful life of a sensor. These characteristics can be specified in different ways depending on the sensor type and, for a sensor, depending on what aspect has to be highlighted. In particular, the following parameters can be of interest:

Operating Life. It is the minimum length of time over which the sensor will operate, either continuously or over a number of on-off cycles, whose duration is specified, without changing its performance beyond specified tolerances.

Cycling Life. It is the minimum number of measurand full-range excursions (or specified partial range excursions) over which a sensor will operate without changing its performance beyond specified tolerances.

In some cases it may also be necessary to specify or be concerned about a sensor's storage life, the length of time over which it can be exposed to specified storage conditions without changing its performance beyond specified tolerances.

The evaluation of the operating life, also of great interest in the field of industrial applications, is hardly ever performed, because specification for operating life tends to be in terms of years, typically between three and ten years. Sometimes, field experience can be substituted for performing an operating life test, when it can be documented that at least one sensor of the same design, taken randomly from a production lot, has operated maintenance free and within specified tolerances but in its end-use application for a certain number of years. In order to reduce the testing time and consequently the cost, suitable accelerated life tests (tests performed under environmental conditions more severe than normal) can be set up for some kind of sensors. Of course, the results of these kind of tests have to be considered as indicative and have to be verified by a life test under nominal environmental conditions.

Cycling life tests are usually performed as part of a qualification test when a sensor specification call for full-range or partial range cycling life. Equipment has been designed for rapid and automatic cycling of many categories of sensors.

User System

Output Signal. There are three major categories of data signal forms: analog, carrier, and digital or pulse. In the analog sensor the output signal level is directly correlated to the value of the measurand. In the so-called carrier form the measured value modulates the characteristics of a carrier sinusoid. The amplitude (amplitude modulation AM), the frequency (frequency modulation FM) or the phase relationship with a reference signal (phase modulation PM) of the sensor output signal depends on the measurand. The most widely used modulation is frequency modulation, because the analog signal frequency has great advantages for signal transmission, for example, fail-safeness and easy galvanic separation. Furthermore it is

very easy to obtain a digital output from FM (2). A digital signal consists of a series of pulses containing the encoded information corresponding to the input data. The information may be encoded into the amplitude, width, position or frequency of the pulses. Only a few sensors with direct digital output are available (e.g., incremental or coded displacement and angle sensors) because it is mostly necessary to convert the output signals into digital form to interface them with digital system. Many sensing devices also incorporate an analog-to-digital converter.

Output Range. To indicate the output range, the most commonly used parameter is the full-scale output (FSO). This is the algebraic difference between the electric output signal measured, respectively, with the maximum and the minimum input in the input range. The output overload values are the sensor outputs that correspond to input overload values (9).

Output Noise. This is a random fluctuation of the output signal not correlated to any information. Noise at the sensor output is caused by internal and external sources, but when a sensor has to be characterized, only internal noise is considered. Noise is usually furnished in terms of rms value, and its considered bandwidth is also indicated. Sometimes the signal-to-noise ratio is indicated. This is the ratio of the signal level to the internally generated noise level usually expressed in decibels (4,14).

Output Impedance. The sensor output impedance is the impedance between the output terminals of the instrument (6). It may be connected in parallel or in series with the input impedance of the interface circuit. Output impedance generally should be represented in a complex form and may include active and reactive components. When the reactive part is negligible, it is called output resistance. It is important to know its value to better interface a sensor with the user system (5).

Output Power. This is the maximum value of the power that the sensor can supply to the user system without decreasing its own performance. Sometimes, if the sensor output is in voltage, the maximum deliverable current is indicated, whereas, for a current output signal, the maximum deliverable voltage or the maximum load impedance values are specified.

Grounding. Sometimes the sensing device is grounded to establish a common mode among different parts of the system with the requirement that no potential variation may occur along this common node with respect to any point inside the node (4). It is important to know the possible grounding circuit to avoid grounding some user system floating points unintentionally.

Auxiliary System

In considering the need for a power supply, sensors can be classified as modulating (passive) or self-generating (active). Modulating sensors require excitative power from an external source. To produce the output signal, the excitative signal is modified by the sensing element as a function of the measurand. In self-generating sensors, instead, output power comes from the input, that is they produce an electric output signal from their input quantity. For example, a thermocouple is a

self-generating thermal sensor. It produces an electromagnetic force from the difference in junction temperatures, whereas the resistance of a thermistor changes with temperature. To measure its value, it is necessary to pass a current through the thermistor. By using the power supply voltage, it is possible to control overall sensitivity. In fact, normally self-generating sensors produce very low output power, whereas modulating sensors produce much higher output energies. The presence of an auxiliary power source increases the danger of explosion in explosive atmospheres. (2,3,5,9).

Environment System

The static and dynamic performance characteristics of sensors are those which the sensor exhibits at room conditions and in the absence of any external conditions such as temperature, humidity, vibrations, that may affect the sensor's performance (11). The definition of influential quantity includes values associated with measurement standards, reference materials, and reference data, upon which the result of a measurement may depend, and phenomena, such as room temperature, barometric pressure, and humidity (11).

When a sensor is reasonably expected to operate under conditions, called operating environmental conditions, other than those under which it was calibrated, the environmental effects must be known, and the resulting deviations from static performance (environmental errors) must be determined by tests. Such environmental tests may have to be performed on each sensor used. Usually they are performed on a sampling basis (test one of every N sensors of each model and range) but sometimes only on a qualification basis (a test on a representative sensor). In linear sensors, the effect of a particular parameter can be studied in terms of its effect on static and dynamic sensor behavior, keeping the remainder of the parameters constant.

Other operating environmental effects on the behavior of a sensor during its normal operation which should be known and included in specifications include humidity or immersion in liquid; corrosive effects of high salt concentration in the ambient atmosphere; various effects of measured fluids on the sensing elements; the influence of ambient electromagnetic fields on sensor elements and integral circuitry; and the effects of radiation on various internal sensor elements.

Besides operating environmental conditions, there are other conditions to which a transducer may be exposed, but the sensor is not expected to operate within specified tolerances while exposed to them. However, the sensor is expected to perform within specified tolerances after exposure to such environmental conditions, called nonoperating environmental conditions (11).

In the following, the most common environmental effects are presented together with the parameter usually used to express them.

Temperature Effects. The operating range is the range of ambient temperatures, given by their lower and upper extremes within which the sensor is intended to operate and within which all specifications related to temperature effects apply. The maximum temperature is the highest (or lowest) temperature to which a sensor can be exposed without being damaged or subsequently showing performance degradation beyond specified tolerances. A more general and inclusive way of specifying thermal effects on performance characteristics is given by the

temperature error, which is the maximum change in output when the temperature is changed from room temperature to specified temperature extremes. Analogously, a temperature error band is defined as the error band applicable over the operating temperature range. For some sensors, temperature effects are stated only in terms of thermal zero shift and thermal sensitivity shift, which cause a parallel displacement and a slope change, respectively, of the calibration curve. Knowledge of these individual errors is useful when the prevailing temperature during a measurement procedure is known and appropriate corrections to final data are to be made (11).

It is necessary to emphasize that temperature also affects dynamic characteristics. Consequently, the specifications should include corresponding thermal effects.

Pressure Effects. In some sensors calibrated at room barometric pressure and used where the ambient pressure is very low (e.g., at high altitude on aircraft) or where the pressure is very high (far underground or deeply submerged underwater), significant variation of performance may arise. Ambient-pressure error is the maximum change in output at any measurand value within the sensor's range, when the ambient pressure is changed between specified values, usually between room pressure and a lower or higher ambient pressure. The pressure error can be stated in terms of an ambient-pressure error band. Sometimes the pressure error is referred to as altitude error, and ranges of pressures are stated in terms of altitude above sea level (11).

Acceleration Effects. Quasi-steady-state acceleration of internal elements of a sensor may act directly on a mechanical sensing element or its linkage and cause errors in its output. When a sensor is to be used in an application where it experiences acceleration, the possibility of acceleration errors must be considered and tolerances must be established for such error. The acceleration error is defined as the maximum difference between output readings taken without and with the application of specified constant acceleration along specified axes. The acceleration effects, in fact, are typically more evident when the acceleration is applied along one axis of the sensor than when it is applied along other axes. This error can also be reported in terms of acceleration error band (11).

Vibration Effects. Vibration acceleration affects a sensor in the same manner as steady-state acceleration. Stronger effects, however, are connected with the frequencies of vibration. Amplified vibration (resonances) of internal elements can occur at one or more frequencies, and different resonances may be observed for different measurand values, particularly when the sensor incorporates a mechanical sensing element. Vibration error is defined, then, as the maximum change in output when a vibration level of specified amplitudes and ranges of frequency is applied to the sensor. Consequently, it may be necessary to predict the measurand value most likely to be observed by the sensor while it is exposed to the most severe vibration environment, and then to specify and verify vibration errors at that value (11).

Mounting Effects. A sensor's performance may be changed during its installation, for example, when the mounting surface of the sensor is not evenly machined so that the case becomes deformed when all the mounting hardware is tightened

or when the torque applied to the coupling nut on a pressure fitting causes sensing element deformations. Mounting error is the error resulting from mechanical deformation of the sensor caused by mounting the sensor and making all electrical and measurand connections. Mounting error, obviously, is not included in specifications. However, it may be necessary to verify its absence (11).

Environmental Effects Reduction Technique. The most obvious method of reducing the effects of environmental parameters is that of isolation, which allows reducing undesirable electric, magnetic, electromagnetic, and mechanical coupling among various parts of the system and between the system and the outside (4).

The most successful techniques are the opposition method and the differential approach. The first is based on opposing environmental inputs. Suppose that an element is affected by an environmental parameter. Then a second element, subject to the same environmental input [see Fig. 9(a)], is introduced into the system so that the two effects cancel each other. An example of a differential system is shown in Fig. 9(b). As can be seen, two identical sensors are placed to sense the measurand and its opposite. Because both are affected by external quantities which are presented to both with the same sign, by calculating the difference between the two outputs, such effects can be eliminated. Naturally, environmental effects may be also compensated for by using the previously presented high-gain negative feedback and using a feedback system which is unsusceptible to environmental input (13).

Now the technique of computer estimation of measured value can also be used. A good model of the element in the system is required for this method. In fact, knowing the relationship between the sensor output, the environmental parameters, and the values of these parameters, the environmental effects can be numerically eliminated by the sensor output value.

MAGNETIC SENSORS

Magnetic sensors find many applications in everyday life and in industry. They provide convenient, noncontact, simple, rugged, and reliable operations compared to many other sensors. The technology to produce magnetic sensors involves many aspects of different disciplines such as physics, metallurgy, chemistry, and electronics.

Generally, magnetic sensors are based on sensing the properties of magnetic materials, which can be done in many ways. For example, magnetization, which is the magnetic moment per volume of materials, is used in many measurement systems by sensing force, induction, field methods, and superconductivity. However, the majority of industrial sensors make use of the relationship between magnetic and electric phenomenon. A typical application of the phenomenon is the computer memory requiring the reading of the contents of a disc without making any contact between the sensor and the device. In other applications, the position of objects sensitive to magnetic fields (e.g., the metals in the ground) can be sensed magnetically. Magnetic sensors find most sensitive applications in medicine to diagnose human illnesses, as in the case of superconducting quantum interference devices (SQUID) and nuclear resonance magnetic (NMR) imaging.

The magnetic elements in sensors are used in a wide range of forms: toroids, rods, films, substrates, and coatings. Some elements are essentially free standing, whereas others are an integral part of more complex devices. In order to obtain maximum material response in magnetic sensors, the relative orientation and coupling between input measurand and magnetic properties are very important, and they are optimized at the design stages.

Many different types of magnetic sensors are available. These sensors can broadly be classified as primary or secondary. In primary sensors, also known as the magnetometers, the parameter to be measured is the external magnetic field. The primary sensors are used in biological applications and geophysical and extraterrestrial measurements. In secondary sensors, the external parameter is made from other physical variables such as force and displacement. In this article, both the primary and secondary sensors will be discussed. These sensors include inductive, eddy current, transformative, magnetoresistive, Hall-effect, metal-oxide-semiconductor (MOS) magnetic field, and magneto-optical sensors; magnetotransistor and magnetodiode sensors, magnetometers; superconductors;

semiconductors; and magnetic thin films. They are offered by many manufacturers as listed in Table 1.

can be expressed as

$$e = -d\Phi/dt \text{ (V)} \quad (1)$$

INDUCTIVE SENSORS

Inductive sensors make use of the principles of magnetic circuits. They can be classified as passive sensors and self-generating sensors. The passive sensors require an external power source; hence, the action of the sensor is restricted to the modulation of the excitation signal in relation to an external stimuli. On the other hand, the self-generating types generate signals by utilizing the electrical generator principle based on Faraday's Law of Induction. That is, when there is a relative motion between a conductor and a magnetic field, a voltage is induced in the conductor. Or a varying magnetic field linking a stationary conductor produces voltage in the conductor, which

where Φ is the magnetic flux.

In instrumentation applications, the magnetic field may be varying in time with some frequency, and the conductor may be moving at the same time. In many cases, the relative motion between field and conductor is supplied by changes in the measurand, usually by means of a mechanical motion.

In order to explain the operation of the basic principles of inductive sensors, a simple magnetic circuit is shown in Fig. 1. The magnetic circuit consists of a core, made from a ferromagnetic material, and a coil of n number of turns wound on it. The coil acts as a source of magnetomotive force (mmf), which drives the flux Φ through the magnetic circuit. If we assume that the air gap is zero, the equation for the magnetic

Figure 1. A basic inductive sensor consists of a magnetic circuit made up from a ferromagnetic core with a coil wound on it. The coil acts as a source of mmf, which drives the flux through the magnetic circuit and the air gap. The presence of the air gap causes a large increase in circuit reluctance and a corresponding decrease in the flux. Hence, a small variation in the air gap causes a measurable change in inductance.

circuit may be expressed as

$$\text{mmf} = \text{Flux} \times \text{Reluctance} = \Phi \times \mathcal{R} \quad (\text{A-turns}) \quad (2)$$

such that the reluctance $\mathcal{R}$ limits the flux in a magnetic circuit just as resistance limits the current in an electric circuit. By writing the magnetomotive force in terms of current, the magnetic flux may be expressed as

$$\Phi = ni/\mathcal{R} \quad (\text{Wb}) \quad (3)$$

In Fig. 1, the flux linking a single turn is expressed by Eq. (3). But the total flux linking by the entire n number of the turns of the coil is

$$\Psi = n\Phi = n^2 i/\mathcal{R} \quad (\text{Wb}) \quad (4)$$

Equation (4) leads to self-inductance L of the coil, which is described as the total flux per unit current for that particular coil. That is,

$$L = \Psi/I = n^2/\mathcal{R} \quad (\text{H}) \quad (5)$$

This indicates that the self-inductance of an inductive element can be calculated by magnetic circuit properties. Expressing $\mathcal{R}$ in terms of dimensions as

$$\mathcal{R} = l/\mu\mu_0 A \quad (\text{A-turns/Wb}) \quad (6)$$

where l is the total length of the flux path (meters), μ is the relative permeability of the magnetic circuit material, μ_0 is the permeability of free space ($= 4\pi \times 10^{-7} \text{ H/m}$), and A is the cross-sectional area of the flux path.

If the air gap is allowed to vary, the arrangement illustrated in Fig. 1 becomes a basic inductive sensor. In this case, the ferromagnetic core is separated in two parts by the air gap. The total reluctance of the circuit now is the addition of the reluctance of the core and the reluctance of the air gap. The relative

permeability of air is close to unity, and the relative permeability of the ferromagnetic material can be on the order of a few thousand, indicating that the presence of the air gap causes a large increase in circuit reluctance and a corresponding decrease in the flux. Hence, a small variation in the air gap causes a measurable change in inductance. There are many different types of inductive sensors as will be discussed next.

Linear and Rotary Variable-Reluctance Sensors

The variable-reluctance transducers are based on change in the reluctance of a magnetic flux path. These types of devices find applications particularly in acceleration measurements. However, they can be constructed to be suitable for sensing displacements as well as velocities. They are constructed in many different forms, some of which will be described in this article.

Single-Coil Linear Variable-Reluctance Sensor. A typical single-coil variable-reluctance displacement sensor is illustrated in Fig. 2. The sensor consists of three elements: a ferromagnetic core in the shape of a semicircular ring, a variable air gap, and a ferromagnetic plate. The total reluctance of the magnetic circuit is the sum of the individual reluctances:

$$\mathcal{R}_T = \mathcal{R}_C + \mathcal{R}_G + \mathcal{R}_A \quad (7)$$

where $\mathcal{R}_C$, $\mathcal{R}_G$, and $\mathcal{R}_A$ are the reluctances of the core, air gap, and armature, respectively.

Each one of these reluctances can be determined by using the properties of materials involved as in Eq. (6). In this particular case, $\mathcal{R}_T$ can be approximated as

$$\mathcal{R}_T = \frac{R}{\mu_C \mu_0 r^2} + \frac{2d}{\mu_0 \pi r^2} + \frac{R}{\mu_A \mu_0 r t} \quad (8)$$

Figure 2. A typical single-coil variable-reluctance displacement sensor. The sensor consists of three elements: a ferromagnetic core in the shape of a semicircular ring, a variable air gap, and a ferromagnetic plate. The reluctance of the coil is dependent on the air gap. Air gap is the single variable, and the reluctance increases nonlinearly with the increasing gap.

In obtaining Eq. (8), the length of the flux path in the core is taken as πR , and the cross-sectional area is assumed to be uniform with a value of πr^2 . The total length of the flux path in air is $2d$, and it is assumed that there is no fringing or bending of the flux through the air gap, such that the cross-sectional area of the flux path in air will be close to that of the cross section of the core. The length of an average central flux path in the armature is $2R$. The calculation of an appropriate cross section of the armature is difficult, but it may be approximated to $2rt$, where t is the thickness of the armature.

In Eq. (8), all the parameters are fixed except the only one independent variable, the air gap. Hence, it can be simplified as

$$\mathcal{R}_T = \mathcal{R}_0 + kd \quad (9)$$

where $\mathcal{R}_0 = R/(\mu_0 r^2 [1/(\mu_C r) + 1/(\mu_A t)])$, and $k = 2/(\mu_0 \pi r^2)$.

By using Eqs. (5) and (9), the inductance can be written as

$$L = \frac{n^2}{\mathcal{R}_0 + kd} = \frac{L_0}{1 + \alpha d} \quad (10)$$

where L_0 represents the inductance at zero air gap and $\alpha = k/\mathcal{R}_0$.

The values of L_0 and α can be determined mathematically. They depend on the core geometry, permeability, and the like, as already explained. As it can be seen from Eq. (10), the relationship between L and α is nonlinear. Despite this nonlinearity, these types of single-coil sensors find applications in many areas, such as force measurements and telemetry. In force measurements, the resultant change in inductance can be made to be a measure of the magnitude of the applied force. The coil usually forms one of the components of an LC oscillator whose output frequency varies with the applied force. Hence, the coil modulates the frequency of the local oscillator.

Variable-Differential Reluctance Sensor. The problem of the nonlinearity may be overcome by modifying the single-coil system into variable-differential reluctance sensors (also known as push-pull sensors), as shown in Fig. 3. This sensor consists of an armature moving between two identical cores separated by a fixed distance of $2d$. Now, Eq. (10) can be written for both coils as

$$L_1 = \frac{L_{01}}{1 + \alpha(d - x)}, \quad L_2 = \frac{L_{02}}{1 + \alpha(d + x)} \quad (11)$$

Although the relationship between L_1 and L_2 is still nonlinear, the sensor can be incorporated into an ac bridge to give a linear output for small movements. The hysteresis error of these transducers is almost entirely limited to the mechanical components. These sensors respond to static and dynamic measurements. They have continuous resolution and high outputs, but they may give erratic performances in response to external magnetic fields. A typical sensor of this type has an input span of 1 cm, a coil inductance of 25 mH, and a coil resistance of 75 Ω . The resistance of the coil must be carefully considered when designing oscillator circuits. The maximum nonlinearity may be limited to 0.5%.

In typical commercially available variable-differential sensors, the iron core is located half way between the two E-shaped

Figure 3. A variable-differential reluctance sensor consists of an armature moving between two identical cores separated by a fixed distance. The armature moves in the air gap in response to the mechanical input. This movement alters the reluctance of coils 1 and 2 thus altering their inductive properties. This arrangement overcomes the problem of nonlinearity inherent in single-coil sensors.

frames. The flux generated by primary coils depends on the reluctance of the magnetic path, the main reluctance being the air gap. Any motion of the core increases the air gap on one side and decreases it on the other side. Consequently, the reluctance changes in accordance with the principles explained previously, thus inducing more voltage on one of the coils than the other. Motion in the other direction reverses the action with a 180° phase shift occurring at null. The output voltage can be modified depending on the requirements in signal processing by means of rectification, demodulation, or filtering. In these instruments, full-scale motion may be extremely small, on the order of few thousandths of a centimeter.

In general, variable-reluctance transducers have small ranges and are used in specialized applications such as pressure transducers. Magnetic forces imposed on the armature are quite large, and this limits the application severely.

Variable-Reluctance Tachogenerators. Another example of the variable-reluctance sensor is shown in Fig. 4. These sensors

Figure 4. A variable-reluctance tachogenerator is a sensor based on Faraday's Law of Electromagnetic Induction. It consists of a ferromagnetic toothed wheel attached to the rotating shaft and a coil wound onto a permanent magnet extended by a soft iron pole piece. The wheel rotates in close proximity to the pole piece, thus causing the flux linked by the coil to change. The change in flux causes an output in the coil similar to a square waveform whose frequency depends on the speed of the rotation of the wheel and the number of teeth.

are based on Faraday's Law of Electromagnetic Induction; therefore, they may also be referred as electromagnetic sensors. Basically, the induced electromagnetic force (emf) in the sensor depends on the linear or angular velocity of the motion.

The variable-reluctance tachogenerator consists of a ferromagnetic toothed wheel attached to the rotating shaft, and a coil wound onto a permanent magnet, extended by a soft iron pole piece. The wheel moves in close proximity to the pole piece, causing the flux linked by the coil to change, thus inducing an emf in the coil. The reluctance of the circuit depends on the width of the air gap between the rotating wheel and the pole piece. When the tooth is close to the pole piece, the reluctance is at a minimum, and it increases as the tooth moves away from the pole. If the wheel rotates with a velocity ω , the flux may mathematically be expressed as

$$\Psi(\theta) = \Psi_m + \Psi_f \cos m\theta \quad (12)$$

where Ψ_m is the mean flux, Ψ_f is the amplitude of the flux variation, and m is the number of teeth.

The induced emf is given by

$$E = -\frac{d\Psi(\theta)}{dt} = -\frac{d\Psi(\theta)}{d\theta} \times \frac{d\theta}{dt} \quad (13)$$

or

$$E = \Psi_f m \omega \sin n\omega t \quad (14)$$

Both the amplitude and the frequency of the generated voltage at the coil are proportional to the angular velocity of the wheel. In principle, the angular velocity ω can be found from either the amplitude or the frequency of the signal. In practice, the amplitude measured may be influenced by loading effects and electrical interference. In signal processing, the frequency is the preferred option because it can be converted into digital signals easily.

The variable-reluctance tachogenerators are most suitable for measuring angular velocities. They are also used for volume flow rate measurements and the total volume flow determination of fluids.

Microsyn. Another commonly used example of variable-reluctance transducer is the microsyn, as illustrated in Fig. 5. In this arrangement, the coils are connected in such a manner that at the null position of the rotary element, the voltages induced in coils 1 and 3 are balanced by voltages induced in coils 2 and 4. The motion of the rotor in the clockwise direction increases the reluctance of coils 1 and 3 while decreasing the reluctance of coils 2 and 4, thus giving a net output voltage e_o . The movement in the counterclockwise direction causes a similar effect in coils 2 and 4 with a 180° phase shift. A direction-sensitive output can be obtained by using phase-sensitive demodulators.

Microsyn transducers are extensively used in applications involving gyroscopes. By using microsyns, very small motions can be detected giving an output signal as low as 0.01° of changes in angles. The sensitivity of the device can be made as high as 5 V per degree of rotation. The nonlinearity may vary from 0.5% to 1.0% full scale. The main advantage of these transducers is that the rotor does not have windings and slip rings. The magnetic reaction torque is also negligible.

Figure 5. A microsyn is a variable-reluctance transducer that consists of a ferromagnetic rotor and a stator carrying four coils. The stator coils are connected such that at the null position, the voltages induced in coils 1 and 2 are balanced by voltages induced in coils 3 and 4. The motion of the rotor in one direction increases the reluctance of two opposite coils while decreasing the reluctance in others resulting in a net output voltage e_o . The movement in the opposite direction reverses this effect with a 180° phase shift.

Synchros

The term *synchro* is associated with a family of electromechanical devices. They are primarily used in angle measurements and are commonly applied in control engineering as parts of servomechanisms, machine tools, antennas, and the like.

The construction of synchros is similar to that of wound-rotor induction motors, as shown in Fig. 6. The rotation of the motor changes the mutual inductance between the rotor coil and the three stator coils. The three voltage signals from these coils define the angular position of the rotor. Synchros are used in

Figure 6. A synchro is similar to a wound-rotor induction motor. The rotation of the rotor changes the mutual inductance between the rotor coil and the three stator coils. The voltages from these coils define the angular position of the rotor. They are primarily used in angle measurements and are commonly applied in control engineering as parts of servomechanisms, machine tools, antennas, and the like.

connection with a variety of devices, such as control transformers, Scott T transformers, resolvers, phase-sensitive demodulators, and analog-to-digital (AD) converters.

In some cases, a control transformer is attached to the outputs of the stator coils such that the output of the control transformer produces a resultant mmf aligned in the same direction as that of the rotor of the synchro. In other words, the synchro rotor acts as a search coil in detecting the direction of the stator field of the control transformer. When the axis of this coil is aligned with the field, the maximum voltage is supplied to the transformer.

In other cases, ac signals from the synchros are first applied to a Scott T transformer, which produces ac voltages with amplitudes proportional to the sine and cosine of the synchro shaft angle. It is also possible to use phase-sensitive demodulations to convert the output signals to make them suitable for digital signal processing.

Linear Variable Inductor

There is very little distinction between variable-reluctance and variable-inductance transducers. Mathematically, the principles of linear variable transducers are very similar to the variable-reluctance type of transducers. The distinction is mainly in the sensing rather than principles of operations. A typical linear variable inductor consists of a movable iron core to provide the mechanical input and the two coils forming two legs of bridge network. A typical example of such a transducer is the variable coupling transducer.

The variable-coupling transducers consist of a former holding a center-tapped coil and a ferromagnetic plunger, as shown in Fig. 7. The plunger and the two coils have the same length l . As the plunger moves, the inductances of the coils change. The two inductances are usually placed to form two arms of a bridge circuit with two equal balancing resistors. The bridge is then excited with ac of 5 V to 25 V with a frequency of 50 Hz to 5 kHz. At the selected excitation frequency, the total transducer impedance at null conditions is set in the 100 Ω to 1000 Ω range. The resistors are set to have about the same value as transducer impedances. The load for the bridge output must be at least ten times the resistance R value. When the plunger is in the reference position, each coil will have equal inductances of value L . As the plunger moves by δl , changes in inductances $+\delta L$ and $-\delta L$ create a voltage output from the bridge. By constructing the bridge carefully, the output voltage may be made as a linear function displacement of the moving plunger within a rated range.

Figure 7. A typical linear variable inductor consists of a movable iron core inside a former holding a center-tapped coil. The core and both coils have the same length l . When the core is in the reference position, each coil will have equal inductances of value L . As the core moves by δl , changes in inductances $+\delta L$ and $-\delta L$ create voltage outputs from the coils.

In some transducers, in order to reduce power losses resulting from the heating of resistors, center-tapped transformers may be used as a part of the bridge network. In this case, the circuit becomes more inductive, and extra care must be taken to avoid the mutual coupling between the transformer and the transducer.

It is particularly easy to construct transducers of this type, by simply winding a center-tapped coil on a suitable former. The variable-inductance transducers are commercially available in strokes from about 2 mm to 500 cm. The sensitivity ranges between 1% full scale to 0.02% in long-stroke special constructions. These devices are also known as linear displacement transducers or LDTs, and they are available in various shapes and sizes.

Apart from linear variable inductors, rotary types are also available. Their cores are specially shaped for rotational applications. Their nonlinearity can vary between 0.5% and 1% full scale over a range of 90° rotation. Their sensitivity can be up to 100 mV per degree of rotation.

Induction Potentiometer

A version of rotary-type linear inductors is the induction potentiometer, as shown in Fig. 8. Two concentrated windings are wound on stator and rotor. The rotor winding is excited with an ac, thus inducing voltage in the stator windings. The amplitude of the output voltage is dependent on the mutual inductance between the two coils, where mutual inductance itself is dependent on the angle of rotation. For concentrated coil-type induction potentiometers, the variation of the amplitude is sinusoidal, but linearity is restricted in the region of the null position. A linear distribution over an angle of 180° may be obtained by carefully designed distributed coils.

Standard commercial induction pots operate in a 50 Hz to 400 Hz frequency range. They are small in size from 1 cm to

Figure 8. An induction potentiometer is a linear variable inductor with two concentrated windings wound on the stator and rotor. The rotor winding is excited with ac, inducing voltage in the stator windings. The amplitude of the output voltage is dependent on the relative positions of the coils determined by the angle of rotation. For concentrated coils, the variation of the amplitude is sinusoidal, but linearity is restricted in the region of the null position. Different types of induction potentiometers are available with distributed coils, which give linear voltages over an angle of 180° of rotation.

6 cm, and their sensitivity can be in the order of $1\text{ V}/1^\circ$ of rotation. Although the ranges of induction pots are limited to less than 60° of rotation, it is possible to measure displacements in angles from 0° to full rotation by suitable arrangements of a number of induction pots. As in the case of most inductive sensors, the output of the induction pots may need phase-sensitive demodulators and suitable filters. In many inductive pots, additional dummy coils are used to improve linearity and accuracy.

EDDY CURRENT SENSORS

Inductive transducers based on eddy currents are mainly probe types containing two coils, as shown in Fig. 9. One of the coils, known as the active coil, is influenced by the presence of the conducting target. The second coil, known as the balance coil, serves to complete the bridge circuit and provides temperature compensation. The magnetic flux from the active coil passes into the conductive target by means of a probe. When the probe is brought close to the target, the flux from the probe links with the target, producing eddy currents within the target.

The eddy current density is greatest at the target surface and become negligibly small about three skin depths below the surface. The skin depth depends on the type of material used and the excitation frequency. Even though thinner targets can be used, a minimum of three skin depths may often be necessary to minimize the temperature effects. As the target comes closer to the probe, the eddy currents become stronger, causing the impedance of the active coil to change and altering the balance of the bridge in relation to the target position. This unbalance voltage of the bridge may be demodulated, filtered, and linearized to produce a dc output proportional to target displacement. The bridge oscillation may be as high as 1 MHz. High frequencies allow the use of thin targets and provide a good system frequency response.

Probes are commercially available with full-scale ranges from 0.25 mm to 30 mm with a nonlinearity of 0.5% and a maximum resolution of 0.0001 mm. Targets are usually supplied

Figure 9. Eddy current transducers are inductive transducers using probes. The probes contain one active and one balance coil. The active coil responds to the presence of a conducting target, whereas the balance coil completes a bridge circuit and provides temperature compensation. When the probe is brought close to the target, the flux from the probe links with the target producing eddy currents within the target, which alter the inductance of the active coil. This change in inductance is detected by a bridge circuit.

by the clients, involving noncontact measurements of machine parts. For nonconductive targets, conductive materials of sufficient thickness must be attached onto the surface by means of commercially available adhesives. Because the target material, shape, and the like influence the output, it is necessary to calibrate the system statistically for a specific target. The recommended measuring range of a given probe begins at a standoff distance equal to about 20% of the stated range of the probe. In some cases, a standoff distance of 10% of the stated range for which the system is calibrated is recommended as standard. A distance greater than 10% of the measuring range can be used as long as the calibrated measuring range is reduced by the same amount.

Flat targets must be the same diameter as the probe or larger. If the target diameter is smaller than the probe diameter, the output drops considerably, thus becoming unreliable. Curved-surface targets may behave similar to flat surfaces if the diameter exceeds about three or four diameter of the probe. In this case, the target essentially becomes an infinite plane. This also allows some cross-axis movement without affecting the system output. Target diameter comparable to the sensor could result in detrimental affects from cross-axis movements.

For curved or irregularly shaped targets, the system needs to be calibrated using an exact target that may be seen in the operation. This tends to eliminate any errors caused by the curved surfaces during the applications. However, special multiprobe systems are available for orbital motions of rotating shafts. If the curved (shaft) target is about ten times greater than the sensor diameter, it acts as an infinite plane and does not need special calibrations. Special care must be exercised to deal with electrical runout resulting from factors such as inhomogeneities in hardness, particularly valid for ferrous targets. However, nonferrous targets are free from electrical runout concerns.

Figure 10. A linear variable-differential transformer is a passive inductive transducer consisting of a single primary winding positioned between two identical secondary windings wound on a tubular ferromagnetic former. As the core inside the former moves, the magnetic paths between primary and secondaries alter, thus giving secondary outputs proportional to the movement. The two secondaries are made as similar as possible by having equal sizes, shapes, and number of turns.

Figure 11. The voltages induced in the secondaries of a linear variable-differential transformer (a) may be processed in a number of ways. The output voltages of individual secondaries v_1 and v_2 at null position are illustrated in (b). In this case, the voltages of individual coils are equal and in phase with each other. Sometimes the outputs are connected opposing each other, and the output waveform v_o becomes a function of core position x and phase angle α as in (c). Note the phase shift of 180° as the core position changes above and below the null position.

TRANSFORMATIVE SENSORS

Transformative sensors make use of the principles of transformer action, that is magnetic flux created by one coil links with the other coil to induce voltages. There are many different types, such as linear variable transformers, rotary variable differential transformers, and flux-gate magnetometers.

Linear Variable-Differential Transformer

The linear variable-differential transformer (LVDT) is a passive inductive transducer that has found many applications. It consists of a single primary winding positioned between two

identical secondary windings wound on a tubular ferromagnetic former, as shown in Fig. 10. The primary winding is energized by a high-frequency 50 Hz to 20 kHz ac voltage. The two secondaries are made identical by having an equal number of turns. They are connected in series opposition so that the induced output voltages oppose each other.

In many applications, the outputs are connected in opposing form, as shown in Fig. 11(a). The output voltages of individual secondaries v_1 and v_2 at null position are illustrated in Fig. 11(b). However, in opposing connection, any displacement in the core position x from the null point causes amplitude of the voltage output v_o and the phase difference α to change. The output waveform v_o in relation to core position is shown in

Fig. 11(c). When the core is positioned in the middle, there is an equal coupling between primary and secondaries, thus giving a null point or reference point of the sensor. As long as the core remains near the center of the coil arrangement, output is very linear. The linear ranges of commercial differential transformers are clearly specified, and the devices are seldom used outside this linear range.

The ferromagnetic core or plunger moves freely inside the former; thus altering the mutual inductance between the primary and secondaries. With the core in the center, or at the reference position, the induced emfs in the secondaries are equal, and because they oppose each other, the output voltage is zero. When the core moves, say to the left, from the center, more magnetic flux links with the left-hand coil than with the right-hand coil. The voltage induced in the left-hand coil is therefore larger than the induced emf on the right-hand coil. The magnitude of the output voltage is then larger than at the null position and is equal to the difference between the two secondary voltages. The net output voltage is in phase with the voltage of the left-hand coil. The output of the device is then an indication of displacement of the core. Similarly, movement in the opposite direction to the right from the center reverses this effect, and the output voltage is now in phase with the emf of the right-hand coil.

For mathematical analysis of the operation of LVDTs Fig. 11(a) may be used. The voltages induced in the secondary coils are dependent on the mutual inductance between the primary and individual secondary coils. Assuming that there is no cross coupling between the secondaries, the induced voltages may be written as

$$v_1 = M_1 s i_p \quad \text{and} \quad v_2 = M_2 s i_p \quad (15)$$

where M_1 and M_2 are the mutual inductances between primary and secondary coils for a fixed core position, s is the Laplace operator, and i_p is the primary current.

In the case of opposing connection, no load output voltage v_o without any secondary current may be written as

$$v_o = v_1 - v_2 = (M_1 - M_2) s i_p \quad (16)$$

writing

$$v_s = i_p (R + s L_p) \quad (17)$$

Substituting i_p in Eq. (16) gives the transfer function of the transducer as

$$\frac{v_o}{v_s} = \frac{(M_1 - M_2)s}{R + s L_p} \quad (18)$$

However, If there is a current resulting from output signal processing, then describing equations may be modified as

$$v_o = R_m i_s \quad (19)$$

where $i_s = (M_1 - M_2) s i_p / (R_s + R_m + s L_s)$ and

$$v_s = i_p (R + s L_p) - (M_1 - M_2) s i_s \quad (20)$$

Eliminating i_p and i_s from Eqs. (19) and (20) results in a transfer

function

$$\frac{v_o}{v_s} = \frac{R_m (M_1 - M_2) s}{[(M_1 - M_2)^2 + L_s L_p] s^2 + [L_p (R + R_m) + R L_s] s + (R_s + R_m) + R} \quad (21)$$

This is a second-order system, which indicates that with the effect of the numerator the frequency of the system changes from $+90^\circ$ at low frequencies to -90° at high frequencies. In practical applications, the supply frequency is selected such that at null position of the core the phase angle of the system is 0° .

The amplitudes of the output voltages of secondary coils are dependent on the position of the core. These outputs may directly be processed from each individual secondary coils for slow movements of the core, if the direction of the movement of the core does not bear any importance. However, for fast movements of the core, the signals may be converted to dc, and the direction of the movement from the null position may be detected. There are many options to do this; however, a *phase-sensitive demodulator* and filter are commonly used as shown in Fig. 12(a). A typical output of the phase-sensitive demodulator is illustrated in Fig. 12(b), for core positions as in Fig. 12(c), in relation to output voltage v_o , displacement x , and phase angle α .

The phase-sensitive demodulators are extensively used in differential-type inductive sensors. They basically convert the ac outputs to dc values and also indicate the direction of movement of the core from the null position. A typical phase-sensitive demodulation circuit may be constructed, based on diodes shown in Fig. 13(a). This arrangement is useful for very slow displacements, usually less than 1 or 2 Hz. In Fig. 13(a), bridge 1 acts as a rectification circuit for secondary 1, and bridge 2 acts as a rectifier for secondary 2. The net output voltage is the difference between the outputs of two bridges as in Fig. 13(b). The position of the core can be worked out from the amplitude of the dc output and the direction of the movement of the core can be determined from the polarity of the dc voltage. For rapid movements of the core, the output of the diode bridges need to be filtered, and this passes only the frequencies of the movement of the core and filters all the other frequencies produced by the modulation process. For this purpose, a suitably designed simple *RC* filter may be sufficient.

In the marketplace, there are phase-sensitive demodulator chips available, such as AD598 offered by Analog Devices, Inc. These chips are highly versatile and flexible to suit particular application requirements. They offer many advantages over conventional phase-sensitive demodulation devices; for example, frequency of excitation may be adjusted to any value between 20 Hz and 20 kHz by connecting an external capacitor between two pins. The amplitude of the excitation voltage can be set up to 24 V. The internal filters may be set to required values by external capacitors. Connections to analog-to-digital converters are made easy by converting the bipolar output to a unipolar scale.

The frequency response of LVDTs is primarily limited by the inertia characteristics of the device. In general, the frequency of the applied voltage should be ten times the desired frequency response. Commercial LVDTs are available in a broad range of sizes, and they are widely used for displacement measurements in a variety of applications. The displacement sensors are available to cover ranges from ± 0.25 mm to ± 7.5 cm. They are sensitive enough to be used to respond to displacements

Figure 12. Phase-sensitive demodulator and filter (a) are commonly used to obtain displacement-proportional signals from LVDTs and other differential-type inductive sensors. They convert the ac outputs from the sensors into dc values and also indicate the direction of movement of the core from the null position. A typical output of the phase-sensitive demodulator is shown in (b). The relationship between output voltage v_o and phase angle α is also shown against core position x as sketched in (c).

well below 0.0005 mm. They can have operational temperature range from -265° to 600°C . They are also available in radiation-resistant designs for operation in nuclear reactors. For a typical sensor of range ± 25 mm, the recommended supply voltage is 4 V to 6 V, with a nominal frequency of 5 kHz and a maximum nonlinearity of 1% full scale. Several commercial models, which can produce a voltage output of 300 mV for 1 mm displacement of the core, are available.

One important advantage of the LVDTs is that there is no physical contact between the core and the coil form; hence there is no friction or wear. Nevertheless, there are radial and longitudinal magnetic forces on the core at all times. These magnetic forces may be regarded as magnetic springs that try to displace the core from its null position. This may be a critical factor in some applications.

One problem with LVDTs is that it may not be easy to make the two halves of the secondary identical; their inductance,

resistance, and capacitance may be different, causing a large unwanted quadrature output in the balance position. Precision coil-winding equipment may be required to reduce this problem to an acceptable value.

Another problem is associated with null position adjustments. The harmonics in the supply voltage and stray capacitances result in small null voltages. The null voltage may be reduced by proper grounding, which reduces the capacitive effects and the center-tapped voltage source arrangements. In center-tapped supplies, a potentiometer may be used to obtain a minimum null reading.

The LVDTs find a variety of applications, which include jet engines controls that are in close proximity to exhaust gases, and controls that measure roll positions in the thickness of materials in hot-slab steel mills. After some mechanical conversions, LVDTs may also make force and pressure measurements.

Figure 13. A typical phase-sensitive demodulation circuit based on diode bridges as in (a). The bridge 1 acts as a rectification circuit for secondary 1, and bridge 2 acts as a rectifier for secondary 2 where the net output voltage is the difference between the two bridges as in (b). The position of the core can be worked out from the amplitude of the dc output, and the direction of the movement of the core can be determined from the polarity of the voltage. For rapid movements of the core, the outputs of the diode bridges need to be filtered. For filters, a suitably designed simple RC filter may be sufficient.

Rotary Variable-Differential Transformer

A variation from the linear variable-differential transformer is the rotary core differential transformer, as shown in Fig. 14. Here the primary winding is wound on the center leg of an E core; the secondary windings are wound on the outer legs of the E core. The armature is rotated by an externally applied force about a pivot point above the center leg of the core. When the armature is displaced from its reference or balance position, the reluctance of the magnetic circuit through one secondary coil is decreased; simultaneously the reluctance through the other coil is increased. The induced emfs in the secondary windings, which are equal in the reference position of the armature, are now different in magnitude and phase as a result of the applied displacement. The induced emfs in the secondary coils are made to oppose each other, and the transformer operates in the same manner as LVDTs. The rotating variable transformers may be sensitive to vibrations. If a dc output is required, a demodulator network may be used, as in the case of LVDTs.

In most rotary linear-variable differential transformers, the rotor mass is very small, usually less than 5 g. The nonlinearity

Figure 14. A rotary core differential transformer has an armature rotated by an externally applied force about a pivot point above the center leg of the core. When the armature is displaced from its reference or balance position, the reluctance of the magnetic circuit through one secondary coil is decreased; simultaneously the reluctance through the other coil is increased. The induced emfs in the secondary windings are different in magnitude and phase as a result of the applied displacement.

in the output ranges between $\pm 1\%$ and $\pm 3\%$, depending on the angle of rotation. The motion in the radial direction produces a small output signal that can affect the overall sensitivity. But this transverse sensitivity is usually kept less than 1% of the longitudinal sensitivity.

MOS MAGNETIC FIELD SENSORS

The technology of integrated magnetic field sensors, also called semiconductor magnetic microsensors, is well developed. This technology uses either high-permeability (e.g., ferromagnetic) or low-permeability (e.g., paramagnetic) materials. The integrated circuit magnetic techniques support many sensors, such as magnetometers, optoelectronics, Hall-effect sensors, magnetic semiconductor sensors, and superconductive sensors.

At the present, silicon offers an advantage of inexpensive batch fabrication for magnetic sensors. Most of the integrated circuit magnetic sensors are manufactured by following the design rules of standard chip manufacturing. For example, MOS and complementary metal oxide semiconductor (CMOS) technologies are used to manufacture highly sensitive Hall-effect sensors, magnetotransistors, and other semiconductor sensors. Some of the magnetic semiconductor sensors are discussed in detail in the following sections.

MAGNETOMETERS

Magnetometers are devices that are produced to sense external magnetic fields mainly based on Faraday's Law of Induction. There are many different types of magnetometers including search coil magnetometers, SQUIDS, flux-gates, nuclear, and optical magnetometers. The two most commonly used types are the flux-gate and the search coil magnetometers.

Flux-Gate Magnetometers

Flux-gate magnetometers are made from two coils wound on a ferromagnetic material, as illustrated in Fig. 15. One of the coils is excited with a sinusoidal current, which drives the core into a saturation state. At this stage, the reluctance of the core to external magnetic field increases, thus repelling the external flux and so reducing the effect of the external field on the second coil. As the core becomes unsaturated, the effect of the external field increases. The increase and reduction of the effect of the

Figure 15. A flux-gate magnetometer consists of two coils wound on a ferromagnetic core. The driving coil is excited with a sinusoidal current, which drives the core into a saturation state. When saturated, the reluctance of the core to external magnetic field increases, thus repelling the external flux and hence reducing the effect of the external field on the second coil. The harmonics of the induced voltage in the sensing coil is an indication of the magnitude of the external magnetic field.

Figure 16. A search coil magnetometer uses Faraday's Law of Induction. The changing magnetic flux induces an emf in the coil. The sensitivity of the magnetometer depends on the properties of the core material, dimensions of the coil, number of turns, and rate of change of flux through the coil. They can sense weak fields as low as 100 pT within the frequency range of 1 Hz to 1 MHz.

external field on the second coil is sensed as the harmonics of the induced voltage. These harmonics are then directly related to the strength and variations in the external field. The sensitivity of these devices is dependent on the magnetic properties and the shape of the saturation curve of the core material. The measurement range can vary from 100 pT to 10 mT operating in the 0 kHz to 10 kHz frequency range.

Search Coil Magnetometers

Search coil magnetometers operate on the principle of Faraday's Law of Induction. A typical search coil magnetometer is shown in Fig. 16. The flux through the coil changes if the magnetic field varies in time or the coil is moved through the field. The sensitivity depends on the properties of the core material, dimensions of the coil, number of turns, and rate of change of flux through the coil.

Search coil magnetometers are manufactured from 4 cm in dimensions to 100 cm. They can sense weak fields as low as 100 pT within the frequency range of 1 Hz to 1 MHz. The upper limit is dependent on the relative magnitudes of resistance and inductance of the coil. During the signal processing, they can be used as part of a bridge or resonant circuits.

SQUID Magnetometers

Superconducting quantum interference device, SQUID, sensors are used in many diverse applications from medicine, geophysics, and nuclear magnetic resonance to nondestructive testing of solid materials. The SQUID offers high sensitivity for the detection of weak magnetic fields and field gradients. They are made from conventional superconductors such as niobium operating at liquid helium temperatures. They are manufactured by using integrated circuit technology, as illustrated in Fig. 17.

The principle of operation is the Josephson effect. If a magnetic flux links to a ring-shaped superconducting material, a current is induced in the ring. This current flows forever due to the lack of any resistance. The intensity of current is proportional to the intensity of the field. The current in the ring is measured by using the Josephson effect wherein a weak link in the superconducting ring causes the superconducting current to oscillate as a function of magnetic field intensity. These oscillations can be sensed by many techniques such as coupling to a radio-frequency circuit and other resonance techniques.

The SQUIDS are extremely sensitive devices, with sensitivities ranging from 10 fT to 10 nT. The SQUID sensors can be

Figure 17. A SQUID consists of a superconducting ring. When subjected to an external field, the current is induced in the ring, which flows forever. The current in the ring is measured by using the Josephson effect and by creating a weak link in the ring. This weak link makes the superconducting current oscillate as a function of the external magnetic field intensity.

arranged to measure magnetic fields in three dimensions in x , y , and z directions of Cartesian coordinates, as in the case of high-sensitivity gradiometers. One disadvantage of SQUIDs is that they need supercooling at very low temperatures. Much research is concentrated on materials exhibiting superconductivity properties at high temperatures. SQUIDs are used in gradiometers, voltmeters and amplifiers, displacement sensors, geophysics, gravity wave detection, and nondestructive testing, to name a few.

MAGNETORESISTIVE SENSORS

In magnetoresistive sensors, the magnetic field causes a change in resistance of some materials such as permalloys. In these materials, current passing through the material magnetizes the material in a particular magnetic orientation. An external field perpendicular to the current, as illustrated in Fig. 18, causes the magnetic orientation to be disturbed. The resistance is highest when the magnetization is parallel to the current and lowest when it is perpendicular to the current. Hence, depending on the intensity of the external magnetic field, the resistance of the permalloy changes in proportion.

Magnetoresistive sensors are manufactured as thin films and usually integrated to be part of an appropriate bridge

Figure 18. A magnetoresistive sensor's resistance changes in response to an external magnetic field. Magnetic domain orientation of the material is a function of external field and current flowing through it. The resistance is highest when the magnetization is parallel to the current and lowest when it is perpendicular to the current. These sensors are manufactured as thin films, and they have good linearity.

Figure 19. A magnetotransistor is an integrated silicon device that contains nnp or pnp junctions. The electron flow between emitter and collector is influenced by the external magnetic field in favor of one of the collectors. The two collector voltages are sensed and related to the applied magnetic field.

circuit. They have good linearity and low temperature coefficients. These devices have a sensitivity ranging from $1 \mu\text{T}$ to 50 mT . By improved electronics with suitable feedback circuits, the sensitivity can be as low as 100 pT . They can operate from dc to several gigahertz.

Magnetotransistor and Magnetodiode Sensors

Magnetotransistor and magnetodiode sensors are integrated silicon devices. They contain n -doped and p -doped regions forming pn , nnp , or pnp junctions. In the case of magnetotransistors, there are two collectors, as shown in Fig. 19. Depending on the direction, an external magnetic field deflects electron flow between emitter and collector in favor of one of the collectors. The two collector voltages are sensed and related to the applied magnetic field. These devices are more sensitive than Hall-effect sensors.

In the case of magnetodiodes, p and n regions are separated by an area of undoped silicon containing the sensor. An external magnetic field perpendicular to the flow of charges deflects the holes and electrons in the opposite directions, resulting effectively in a change in the resistance of the undoped silicon layer.

HALL-EFFECT SENSORS

In Hall-effect sensors, the voltage difference across a thin conductor carrying current depends on the intensity of the magnetic field applied perpendicular to the direction of current flow, as shown in Fig. 20. An electron moving through a magnetic field experiences Lorentz force perpendicular to the direction of motion and to the direction of the field. The response of electrons to Lorentz force creates a voltage known as the Hall voltage. If a current I flows through the sensor, the Hall voltage can mathematically be found by

$$V = R_H IB/t \quad (22)$$

where R_H is the Hall coefficient (cubic meters per degree Celsius), B is the flux density (tesla), and t is the thickness of the sensor (meters).

Therefore, for a specified current and temperature, the voltage is proportional to B . If the current is dc, the voltage has the same frequency as magnetic flux.

Hall-effect sensors can be made by using metals or silicon, but they are generally made from semiconductors with high

Figure 20. A Hall-effect sensor makes use of Lorentz force. The response of electrons to Lorentz force creates the Hall voltage, which is perpendicular to both the external magnetic field and the direction of current flow. If the current is dc, the voltage has the same frequency as magnetic flux.

electron mobility such as indium antimonide. They are usually manufactured in the form of probes with a sensitivity down to $100 \mu\text{T}$. Silicon Hall-effect sensors can measure constant or varying magnetic flux having an operational frequency from dc to 1 MHz, within the range of 1 mT to 100 mT. They have good temperature characteristics from 200°C to near absolute zero.

MAGNETO-OPTICAL SENSORS

In recent years, highly sensitive magneto-optical sensors have been developed. These sensors are based on fiber-optics, polarization of light, Moire effect, and Zeeman effect, among others. This type of sensors leads to highly sensitive devices and is used in applications requiring high resolution such as human brain function mapping and magnetic anomaly detection. Here, because of the availability of space, only the polarization effect will be discussed briefly. Interested readers can find further information in the Refs. 1–6.

In the polarization effect, a plane of polarized light in a strong magnetic field rotates its plane of vibration. The per-unit angular rotation is related to the per-unit magnetic field in a given length of material by the Verdet constant. For example, terbium gallium demonstrates a Verdet constant of $50 \text{ min}/\mu\text{T}\cdot\text{cm}$, whereas bismuth-substituted iron garnet can have up to $0.04 \text{ min}/\text{T}\cdot\text{cm}$. This polarization effect was first noticed by Faraday in 1845; hence, it is generally known as the Faraday effect. Recently, this principle was applied to semiconductors and crystals, which have different physical properties such as interband effects, intraband free carrier effects, and absorption of magnetism by impurities.

MAGNETIC THIN FILMS

Magnetic thin films are an important part of superconducting instrumentation, sensors and electronics in which active devices are made from deposited films. The thin films are usually made from amorphous alloys, amorphous gallium, and the like. As an example of this use of thin-film technology, a thin-film Josephson junction is given in Fig. 21. The deposition of thin films can be done by thermal evaporation, electroplating, sputter deposition, or chemical methods. The choice of technology depends on the characteristics of the sensors. For example, thin-film superconductors require low-temperature operations, whereas common semiconductors operate at room temperature.

Figure 21. The magnetic thin films are made from deposited thin films from amorphous alloys such as gallium. This figure illustrates thin-film technology to form a Josephson. The deposition of thin films can be done by thermal evaporation, electroplating, sputter deposition, or chemical methods.

The magnetic thin films find extensive applications in memory devices where high density and good sensitivities are required. In such applications, the magnetic properties of the coating are determined by the magnetic properties of the particles that can be controlled before coating. The choice of available materials for this purpose is extremely large. Thin-film technology is also developed in magneto-optics applications where erasable optical media for high-density magnetic storage is possible. The miniature magnetoresistive sensors for magnetic recording and pick-up heads, the Hall-effect sensors, and other magnetic semiconductors make use of thin-film technology extensively.

AMORPHOUS MAGNETIC MATERIALS

The amorphous magnetic materials can be classified as amorphous alloys (Fe, Co, Ni), amorphous rare earths, and amorphous superconductors. Amorphous alloys have good soft magnetic materials and are extensively used in magnetic heads. They have high-saturation magnetization, high permeability, and flat high-frequency dependence. Amorphous alloys are produced in the form of $20 \mu\text{m}$ to $50 \mu\text{m}$ thick ribbons using rapid solidification methods. Nevertheless, thermal stability of these alloys is the major drawback preventing the wider applications. Many of the amorphous metallic films are based on rare earth 3D transition metal alloys, such as Gd_xCo_x . They are used in bubble domain devices.

On the other hand, the amorphous superconductors are a class of superconducting materials such as bismuth and gallium. They are manufactured in the form of powders, ribbons, or flakes by using evaporation methods, ion mixing or ion implantation, or liquid quenching. The vapor deposition technique is used in semiconductor-type sensors. These materials are used in high field magnets, memory devices, and other computer applications.

SHIELDING AND SENSITIVITY TO ELECTROMAGNETIC INTERFERENCE

Magnetic fields are produced by currents in wires and more strongly by the coils. The fields produced by coils are important as a result of magnetic coupling, particularly when there are two or more coils in the circuit. The magnetic coupling between coils may be controlled by large spacing between

coils, the orientation of coils, the shape of the coils, and shielding.

Inductive sensors come in different shapes and sizes. Even though some sensors have closed cores such as toroidal shapes, others have open cores and air gaps between cores and coils. Closed cores may have practically zero external fields, except small leakage fluxes. Even if the sensors do not have closed cores, most variable-inductor sensors have a rather limited external field, as a result of two neighboring sets of coils connected in opposite directions, thus minimizing the external fields. Because the inductive sensors are made from closed conductors, a current will flow, if the conductor moves in a magnetic field. Alternatively, a magnetic change produces current in stationary closed conductor. Unless adequate measures are taken, there may be external magnetic fields linking (interference) with the sensor coils, thus producing currents and unwanted responses.

Because of inherent operations, inductive sensors are designed to have a high sensitivity to magnetic flux changes. External electromagnetic interference and external fields can affect the performance of the sensors seriously. It is known that moderate magnetic fields are found near power transformers, electrical motors, and power lines. These small fields produce current in the inductive sensors elements. One way of eliminating external effects is accomplished by magnetic shielding of the sensors and by grounding appropriately. In magnetic shielding, one or more shells of high-permeability magnetic materials surround the part to be shielded. Multiple shells may be used to obtain a very complete shielding. Ends of each individual shell are separated by insulation so that the shell does not act as a single shorted turn, thus accommodating high current flows. Similarly, in the case of multiple shielding, shells are isolated from each other by proper insulation.

Alternating magnetic fields are also screened by interposing highly conductive metal sheets such as copper or aluminium on the path of the magnetic flux. The eddy currents induced in the shield give a counter mmf that tends to cancel the interfering magnetic field. This type of shielding is particularly effective at high frequencies. Nevertheless, appropriate grounding must be observed.

In many inductive sensors, stray capacitances may be a problem, especially at null position of the moving core. If the capacitive effect is greater than a certain value, say 1% of the full-scale output, this effect may be reduced by the use of a center-tapped supply and appropriate grounding.

HALL EFFECT TRANSDUCERS

Hall effect transducers belong to a family of semiconductors that produce an output voltage proportional to a magnetic field or magnetic induction. Initially, the Hall effect was a curiosity comparable to the Seebeck or Peltier effects, but soon it was realized that it could be used for the study of conduction mechanisms in semiconductors. From 1960 on, the first technical Hall effect applications were introduced—for example, the magnetic field measurement probe, magnetic multiplier, and current-to-voltage transducer. At present, a range of powerful Hall integrated circuits are available for magnetic field measurement purposes, the position control of objects, and angle position of wheels. The latest development was the discovery of the quantum Hall effect. This currently has no technical applications, but it has permitted electrical metrology to make considerable advances.

In 1879, E. H. Hall made the remarkable discovery (1) that a magnetic field perpendicular to a conducting foil deviates the charge carriers in a conductor in such a way that a voltage is generated transversally to the foil. The use and exploitation of this effect was, however, severely restricted to research purposes due to the shortage of good materials. Favorite materials during the exploration period were bismuth and even germanium, but the stability obtained with these elements was very disappointing due to their temperature characteristics. With the expansion of research on semiconductors after World War II, Hall measurements were refined with success for the determination of resistivity, carrier concentration, carrier type, and mobility in semiconductors. This research led to still better semiconductor materials; soon, the first industrial instruments for magnetic field measurements with sensitive calibrated Hall effect sensors were introduced on the market.

With the development of integrated circuits (IC) the applications domain of Hall devices was further extended because it became possible to integrate an amplifier with the Hall sensor in one unit. Such an IC can be used for several purposes: position detection, measurement of current, and electronic compass. In 1980, the German scientist Klaus von Klitzing (2) discovered a new effect that was strongly related to the classical Hall effect: the quantum Hall effect. By studying a two-dimensional electron gas at low temperatures in the presence of a very strong magnetic field (14.6 T), it was found that the ratio of the Hall voltage to the device current depends only on the Planck constant h (6.626×10^{-34} Js) and the elementary charge e of the electron (1.6021×10^{-19} C). The von Klitzing effect was very important to electrical metrology because it became possible to replace the material ohm standard in the same way as the volt standard was replaced by the Josephson junction.

HALL EFFECT

For the derivation of the classical Hall effect (3), a rectangularly conducting sample (Fig. 1) with width w , length L , and thickness t is considered. At the four side planes, the contacts 1, 2, . . . 6 have been added for the connection of a current source I (1, 4) and for potential measurements (2, 3, 5, 6). It is supposed that the width of the contacts is small in comparison with the distance l between (2, 3) and (5, 6). Also, the distances l_1 and l_2 are much larger than the width w . The sample is placed in a magnetic field with induction B perpendicular to its largest

Figure 1. (a) Hall bridge-type sample with four voltage contacts (2, 3, 5, 6) and current contacts (1, 4); (b) deviation of current lines due to an applied B -field. The contacts 1 and 4 are supposed ideal, and ℓ_1 , ℓ_2 , and ℓ are much larger than the width W of the sample. The carrier density at the left and right side will differ due to the Lorentz force F_y .

plane. Figure 1(b) shows that this plane is associated with a rectangular coordinate system with the x -axis in parallel with the length axis of the sample. As long as $B = 0$ in this system, the charge carriers in the sample move along the dotted straight lines between contacts 1 and 4.

The particular shape has the advantage that it can also be used for the determination of the classic resistivity of the sample material. The resistivity ρ_{xx} in the x -direction of the sample is determined with $B = 0$, by measuring the potential difference V_{23} (or V_{56}) between the contacts (2, 3) or (5, 6). It follows that

$$\rho_{xx} = \frac{V_{23}}{I} (wt/l)$$

If the contacts are symmetrically placed around the length axis of the sample, then we expect the voltage between contacts 2 and 6 (or 5 and 6) to be zero and in this case we also have $V_{23} = V_{56}$.

In the presence of a B -field, the moving charge carriers deviate from the straight lines due to the Lorentz force that the field exercises on the carriers. If the current flows in the x -direction, the carriers with an elementary charge q have a velocity v_x , and the corresponding force will be in the y -direction. The absolute value F_y of the Lorentz force is:

$$F_y = Bv_x q$$

As a result, the carrier concentration will be somewhat higher at the left-hand side than at the right-hand side of the sample [Fig. 1(b)]. It means that internally an electric field E_y counteracting the effect of the Lorentz force is generated. This field exercises a repelling Coulomb force qE_y on the carriers and in a steady-state situation both forces are equal and thus

$$E_y = Bv_x$$

The carrier concentration n (number of carriers per m^3) and the velocity v_x are related to the device current I , because the amount of charge displaced in 1 s is equal to the product $wt n q v_x$.

Therefore we have

$$v_x = I / wt n q$$

Because the field E_y is constant for all points between contacts (2, 6) or (3, 5), it follows immediately that the voltage V_H between (3, 5) or (2, 6) is equal to $w \times E_y$

$$V_H = BI / t n q = R_H BI / t, \text{ with } R_H = 1 / n q \quad (1)$$

The constant R_H is the Hall coefficient (independent of the width w), and it has the dimension $\text{m}^3 \text{C}^{-1}$. For the sensitivity of the device to be large, it is thus required that the sample is thin and the carrier concentration not too large. If these conditions are fulfilled, the mobility of the carriers (proportional to the carrier velocity) has to be large in order to give a reasonable conduction in the x -direction. This explains why in ordinary conductors the Hall effect is extremely small. From the foregoing derivation we can deduce some important facts.

1. Measurement of the Hall voltage permits determination of the average polarity of the charge carriers. It was indeed only supposed that the direction of the current was known, but this current could as well be established with holes or electrons depending on the type of semiconductor used. In the first case the left-hand side of the sample will have an excess positive charge and point 2 will become positive with respect to 6 (or 3 to 5). In the second case, 2 will be negative with respect to 6. For extrinsic p -type materials we find from R_H the carrier charge density (in C/m^3) $nq = 1/R_H$ and for the n -type this becomes $-1/R_H$.

2. From Eq. (1) of the Hall voltage we obtain the Hall resistance $R_{xy} = V_H / I$

$$R_{xy} = R_H B / t$$

This quantity increases linearly with the applied field B . The Hall effect device is also called a Hall transducer because it converts the value of the magnetic field into a voltage.

3. It can be seen that the current lines in the sample are slightly longer when the field is applied than when it is not. It can therefore be expected that the longitudinal resistivity

ρ_{xx} increases when the field increases; this is the magnetoresistance effect. In the Hall sample, however, the magnetoresistance effect is of minor importance because the ratio $L:w$ is large.

Until now it has been supposed that the contact pairs are symmetrically placed with respect to the sample. If this is true, no Hall voltage can be generated between the contact pairs when the field is zero. In practice there always remains a slight asymmetry and, because of the finite resistivity in the x -direction, a small offset voltage V_{os} will add to the Hall voltage. This offset voltage can only be eliminated by reversing the direction of B or by rotating the Hall device over 180° around its x -axis and combining the two resulting Hall voltages. The two voltages corresponding to this procedure are, respectively, $V_1 = V_{os} + V_H$ and $V_2 = V_{os} - V_H$. The Hall voltage thus is found from $(V_1 - V_2)/2$. For ac measurements, the offset can be eliminated by blocking the dc component of the output voltage of the Hall device.

QUANTUM HALL EFFECT

In order to observe the quantization of the Hall resistance, several conditions have to be fulfilled: the charge carriers have to behave like a two-dimensional electron gas (2DEG), temperature has to be very low (e.g., below 4.2 K) and a very strong magnetic induction has to be applied (4,5,6).

A two-dimensional electron gas is the special condition that occurs in strong inversion or accumulation layers at planar semiconductor-semiconductor or semiconductor-insulator interfaces. In the high electric field at the interface, the electrons are only allowed to move freely in a very thin layer in parallel with the interface. When a magnetic field is applied perpendicular to the interface, the electrons will tend to move along circular paths due to the interaction of the field and the electron charge e . The frequency ω_c of this rotation is called the cyclotron frequency and it can in a classic way be derived from e , B and the cyclotron effective mass m_e by equating the centrifugal force and the centripetal force due to the B -field. From this it follows that

$$\omega_c = eB/m_e$$

Under normal conditions the electrons are scattered before a full revolution occurs. However, if the electron mobility is very high, a number of revolutions can exist, and the effect is that an angular momentum quantization occurs that influences the density states of the 2DEG. The net effect is that the resistivity ρ_{xx} shows an oscillating behavior as a function of the magnetic induction (Shubnikov-Haas effect). A necessary condition is that the product of the cyclotron frequency and the scattering time τ of the electrons is much larger than one: $\omega_c \tau \gg 1$. Because the scattering increases with temperature and ω_c is proportional to B , the experiments have to be performed at low temperatures (<40 K) and in the presence of a high field (e.g., 15 T) in order to observe quantization. Figure 2 shows the resulting Hall resistance R_{xy} and the magnetoresistivity ρ_{xx} as a function of B under these conditions. As derived in the preceding, the Hall resistance increases linearly with B as long as the temperature is high, for example, above 40 K, and the magnetoresistance also increases with B . If temperature is low enough (about 1 K), ρ_{xx} becomes very small for certain

Figure 2. Hall resistance R_{xy} and longitudinal magnetoresistivity ρ_{xx} on an arbitrary scale and as a function of the induction B . The dotted lines correspond to temperatures above 44 K while the full lines are for less than 4.2 K. The Hall resistance shows quantized plateaus in this case.

ranges of B and the Hall resistance R_H becomes quantized following the relation:

$$R_H(i) = h/e^2, \quad i = 1, 2, 3, \dots \quad (2)$$

In the special case $i = 1$, the Hall resistance becomes the von Klitzing constant R_K

$$R_K = R_H(1) \quad (3)$$

For practical applications, the 2D gas can be implemented in Si-metal-oxide semiconductor field-effect transistors (MOSFET) or in a heterostructure with layers of GaAs and AlGaAs.

Because the quantified Hall effect is used in metrology, scientists have tried to detect deviations from the theoretical behavior by experiments or by extending the models for the samples in order to see whether or not $R_H(i)$ is universally valid.

Dependence on the Semiconductor Material

As the 2D gas can be implemented in MOSFET structures as well as in AlGaAs/GaAs structures, both materials have been carefully investigated (7,8). Measurements have confirmed that the value of R_H is with certainty independent of the material. The precision obtained with these measurements was at a relative error level 3×10^{-10} . A small number of researchers have found anomalies, but it has been shown that these can always be attributed to bad samples (9). It was possible to develop a test for the samples, in order to see in advance if the correct conditions for observing the quantized Hall effect are fulfilled.

Dependence on the Sample

Several heterostructure samples of the same material but with very different carrier mobilities have been studied (8) and it appears that the differences for R_H all fall within the uncertainty range of the measurement setup. On the other hand, the measurements also show that R_H varies as predicted with the integer i .

Width of the Sample

It is predicted by some theories (e.g., 10,11) that there could exist a relation between the width of the sample and R_H . However, studies performed on samples with widths of between 10 μm and 1 mm did not reveal deviations larger than the measurement precision (12).

Contact Resistance

For connection of the Hall sample to the outside world, metallic contacts are required. Good contact resistances are of the order of a few milliohms, but in some samples values in the kilohm range have been observed. If the latter is the case, relative errors of the order 1×10^{-7} can be observed. The effect of bad contacts can not be predicted due to their microscopic nature. The experiments (13,14) show that this behavior is strongly influenced by the device current or temperature. It is estimated that the error caused by a good contact lies in the range 1×10^{-11} . It has to be noted that the errors encountered for samples with bad contacts are not due to the loading of the device by the voltmeter circuit. If the device is bad, there is always a measurable longitudinal voltage V_{xx} associated with it. Finally, the most important electrical attributes of a good quantized Hall resistor can be found in Ref. 15.

APPLICATIONS OF THE CLASSICAL HALL EFFECT

The Hall effect can be used in semiconductor research as well as in technical applications.

Research Applications

The Hall effect is used intensively in semiconductor research for the determination of carrier concentration (n) and mobility (μ) in combination with the determination of conductivity (σ) or resistivity (ρ). In the first instance, it is assumed that the layers under study are uniform. If the magnitude of the carrier charge is q , then Eq. (1) for R_H gives the concentrations for p -type and n -type semiconductors, respectively

$$p = 1/qR_H \text{ and } n = -1/qR_H \quad (4)$$

For the case where two carrier types are involved, the general relation between the conductivity mobilities μ_p , μ_n and the conductance σ is given by

$$\sigma = q(n\mu_n + p\mu_p) \quad (5)$$

and, if $p \gg n$, this reduces to

$$\sigma = pq\mu_p = \mu_p/R_H \quad (6a)$$

For electron carriers the corresponding equation is:

$$\sigma = nq\mu_n = \mu_n/R_H \quad (6b)$$

In principle, it is possible to determine the mobility μ_p from this equation by measuring σ and R_H . Nevertheless, some problems that can arise require corrections.

A first problem is the occurrence of carrier scattering mechanisms that require a correction factor to be introduced when μ_p or μ_n are calculated from Eq. (6). A scattering factor r has

to be introduced in Eq. (6a) and its equivalent Eq. (6b) for the electrons as follows:

$$p = r/qR_H \text{ or } n = r/qR_H \quad (7)$$

Depending on the scattering mechanism, the scattering factor lies in the range 1 . . . 2. Therefore, the values of the conductivity mobilities derived from R_H have to be corrected with r

$$\mu_p = \gamma_H/r \text{ or } \mu_n = \mu_H/r \quad (8)$$

The mobility μ_H is derived from the Hall voltage and σ is the Hall mobility and μ_p and μ_n are the ordinary conductivity mobilities. Although the latter are more important, the Hall mobility is easier to determine and can still give comparative information about the material.

Second, R_H depends also on the B -field and, when both types of carriers are present as well as a B -field, the Hall coefficient becomes rather complex. In Ref. 16 the following equation is given:

$$R_H = r \frac{(p - b^2n) + (\mu_n B)^2(p - n)}{q[(p + bn)^2 + (\mu_n B)^2(p - n)^2]} \quad (9)$$

The coefficient b is equal to the ratio of the mobilities μ_n and μ_p or $b = \mu_n/\mu_p$.

For $B \rightarrow 0$ and $B \rightarrow \infty$, the general expression [Eq. (9)] can be simplified to a low-field and a high-field expression, respectively. Depending on the mobilities it is possible to have semiconductors which obey either the low- or high-field expression, or the general equation [Eq. (9)]. The low-field expression will be valid when $B\mu_n \ll 1$ if $p \ll n$ or $B\mu_p \ll 1$ if $p \ll n$. Likewise, the high-field limit is valid when $B\mu_n \gg 1$ if $p \gg n$ or $B\mu_p \gg 1$ if $p \ll n$.

For some semiconductors the conduction mechanism changes with temperature. For example, in HgCdTe one finds that for $T < 200 \text{ K}$. . . 300 K electrons are the main carriers. At the lower temperatures a mixed carrier conduction occurs and, as a result, R_H eventually can change its sign. Therefore, Hall measurements are always performed at different temperatures and induction in order to extract the necessary information from the measured data. An extra complication is the dependence of r on B .

In order to be able to determine the spatial resistivity and mobility profiles in nonuniform layers, it is necessary to remove small layers from the sample so that Hall coefficients can be measured as a function of thickness. This can be done by etching or, preferably, by anodic oxidation. In another method used for layers on an isolator, a pn -junction, a MOSFET or a moscapacitor is formed at its upper surface. If, for example, a metal gate layer is used, the penetration depth of the space-charge region can be controlled by means of the reverse bias of the junction and accurate measurements of the mobility and carrier concentration are the result.

In Ref. 3 one can find a review of the most common sample shapes used, and the precautions to be taken for the reduction of errors. Especially, if parameter estimation techniques are used the results can deliver much information about the material. Hall measurements on irregular sheets are also possible, provided some conditions are met. The theory for such samples was derived in 1958 by van der Pauw; see Ref. 17.

Technical Applications

Because it became possible to integrate the electronics and the Hall effect transducer on the same substrate, a number of important industrial applications have been demonstrated. The Hall transducer can be used for direct measurement of magnetic induction and power, switching applications, position control, and so on. A Hall device will not be destroyed by strong magnetic fields and when semiconductors of the III-V type (GaAs, InSb) are applied, it is possible to enhance the sensitivity and the allowable temperature range. With ion-implanted GaAs a temperature range of -40 to $+250$ °C is obtained. The advantage of using silicon lies in the fact that the integration of an amplifier with the Hall element is easy. However, sensitivity is lower due to the low mobility of the carriers in silicon.

In combination with magnets fixed on moving parts, the Hall transducer effectively becomes a position sensor. By monitoring the output, one can get an idea about the velocity or the acceleration of a moving object. Such a transducer will never wear out because there is no friction. Aging will also be very low because of the large mean time between failures (MTBF) of an integrated circuit. In contrast with optical devices, the operation of this transducer will not be disturbed by moisture, dust, or dirt except when the dust contains iron particles. The Hall device is also relatively fast: the rise and fall times are of the order $0.2 \mu\text{s}$ and magnetic ac fields with frequencies of up to 100 kHz can be detected. The substrate containing the transducer is either a ceramic material or a ferromagnetic substance. The latter is used if it is necessary to decrease as much as possible the permeability of the magnetic circuit in which the device is mounted.

Linear Hall Effect Transducers. The output of a linear Hall effect device is proportional to the product of the induction B and the device current I ; in this way, it performs an analog multiplication. It is also obvious that such an element can be dedicated to the measurement of magnetic fields if I has a constant value.

Measurement of Magnetic Fields. The instrument using Hall effect sensors for the determination of magnetic induction (18–22) is called a gaussmeter although it should be termed a teslameter, as the unit of induction is tesla (T) in SI units.

From the preceding it follows that the Hall voltage is due to the component of the field normal to the main sheet plane of the device. If the angle between the field B and the normal is α [Fig. 3(a)], then the normal component is $B \cos \alpha$. For maximum

sensitivity it is required that $\alpha = 0$ and if the field has an unknown direction it is necessary to search for maximum output by rotating the device in space. If three separate Hall devices are orthogonally arranged [Fig. 3(b)] so that their main planes coincide with the planes of a rectangular axis system, the outputs will be proportional to the spatial components B_x , B_y and B_z of B . The magnitude and direction of the vector B in space can then be derived from the three outputs. It is, however, required that the probes be carefully calibrated. This can be done by adjusting the individual device currents, or by measuring the three sensitivity factors and storing them in a memory for further use with the software calculations. If large spatial gradients exist in the field, then the device output represents a kind of average. This error can be reduced by using very small elements: mostly it is possible to adapt the magnetic circuit to minimize this effect.

As sensitivity depends on I it seems appropriate to take I as large as possible. However, this also increases both device dissipation and current consumption. Therefore the advantage gained by increasing I is rather marginal and it is better to amplify the Hall voltage electronically if a higher sensitivity is required. For spatial magnetic field measurements it is preferable that the Hall device has a ceramic substrate as this ensures that the field is not disturbed by the device. Due to the large field of applications of gaussmeters, several types of probes with a calibrated built-in Hall element are available on the market. For measurement of fields in air gaps, for example, in electrical machines or relays, thin probes are preferred but these probes are very sensitive to mechanical stress. The Hall device is mounted at the end of a long flat isolating stylus so that less accessible points can be probed as well. The transverse probe is sensitive for fields perpendicular to the stylus plane. The axial probe is cylindrical and the Hall device is mounted perpendicular to the axis of the cylinder; it measures fields parallel to the probe axis. Full-scale sensitivity can be as large as 15 T and rms readings of ac fields are also possible.

Measurement of Electrical Current. Although not strictly necessary, a magnetic circuit is commonly used with the Hall device for current measurement (19,23) purposes [Fig. 4(b)]. This has two advantages: the sensitivity of the measurement is increased, and the position of the current carrying conductor becomes unimportant. The magnetic field at a distance d of a straight conductor [Fig. 4(a)] carrying a current I , has a value $H = I/2\pi d$ and this is position sensitive. A Hall device at this position will give an output proportional to $\mu_0 H$. If the

Figure 3. (a) Component normal to Hall device for an arbitrary direction of the field and (b) setup with three elements for the determination of magnitude and direction of field.

Figure 4. (a) The radial field around a current-carrying conductor depends on the position of the Hall element; (b) magnetic circuit with a Hall device in the air gap. At low saturation all field lines in the core follow the magnetic path (1). When saturation occurs, some of the field lines (2) are lost for the air gap.

current encircles a magnetic circuit, the force lines [e.g., 1 in Fig. 4(b)] will concentrate in the magnetic material (mean length L , magnetic permeability μ) and in the air gap with width δ . The value B_g of the magnetic induction in the air gap becomes, with Ampère's law and because of the constant flux in the core and air gap section,

$$B_g = \mu \mu_0 I / (L + \mu \delta) \quad (10)$$

For $\mu = 10^4$, $L = 0.1$ m, $\delta = 1$ mm (10^{-3} m) the value $\mu \delta = 10$ and L can thus be neglected. It means that in the range where $\mu \delta \gg L$, the gap induction B_g can be approximated by $\mu_0 I / \delta$ and the sensitivity becomes independent of μ and yet can be very high because δ is so small. If the wire encircles the magnetic circuit N times, then B_g also becomes N times larger. The material properties of the core material barely influence the precision of the measurement, but a very stable air-gap width δ is required. Also, when the current increases, the core induction increases and the material has a tendency to saturate. As a result, some of the magnetic field lines can leave the legs of the core and pass through the window area [e.g., line 2 in Fig. 4(b)]. Because a part of the flux is lost, the air-gap induction becomes too low and a nonlinearity is introduced in the transducer characteristic. The existence of an air gap is favorable in this respect because it reduces the core induction at the cost of a lower sensitivity. The design of such a circuit is therefore a trade-off between sensitivity and full-scale behavior. The nonlinearity can remain below $\pm 1\%$ with ordinary core materials such as ferrite. Besides the electrical offset of the Hall device, a magnetic offset is caused by the core material. This is due to the remanent magnetism that remains after a heavy magnetization of the core. The remanent field gives an additional electrical output offset. Reduction of the remanent magnetism is done by choosing a very soft magnetic material. It is not possible to correct for this remanent field using software because its value depends on the history of magnetization and, as precise models for the core behavior are lacking, a precise offset error correction is unpredictable. In Ref. 24, one can find how the problem of the intrinsic Hall plate offset voltage can be alleviated by combining the output of several elements. The

simple circuit can still be very useful if the highest precision is not required because it requires only a Hall IC and a magnetic circuit, and power consumption is very low.

Closed-Loop Hall Effect Current Transducer. The linearity and offset problems can be reduced considerably by applying feedback (25) to the simple circuit (Fig. 5). In this case, the Hall voltage amplifier drives a second winding N_2 coupled with the core and a resistor R . The voltage drop RI_2 over this resistor is taken as the new output voltage. By choosing the correct winding, the amplifier output current I_2 can counteract the effect of the unknown current I_1 . The number of ampere turns generating the field is now equal to the difference of the ampere turns of the current and feedback windings. Equation (10) for the magnetic circuit becomes, with H_1 and H_g , respectively, the magnetic field in the magnetic circuit and in the air gap

$$H_1 L + H_g \delta = H_1 (\delta + L/\gamma) = N_1 I_1 - N_2 I_2 \quad (11)$$

The amplifier output voltage E_0 is proportional to the air-gap induction and with an induction-to-voltage gain K , we obtain

$$E_0 = K \gamma_0 H_g / R$$

As the corresponding current I_2 is E_0/R , the air-gap field becomes

$$H_g = N_1 I_1 / (\delta + L/\gamma + N_2 K \gamma_0 / R)$$

If the amplifier gain K is made very large, it is seen that $H_g \rightarrow 0$ and the field in the air gap disappears due to the feedback. It follows that $N_1 I_1 \rightarrow N_2 I_2$ and

$$V_0 \approx (N_1/N_2) I_1 \quad (12)$$

As is the case in every feedback system, the static error can be neglected if K is high enough. The output V_0 is a very accurate image of I_1 because the winding resistances, leakage inductances, and losses in the core, have no effect on accuracy. If the material is initially sufficiently demagnetized, the permeability will be very high and the magnetic offset error is reduced. In

Figure 5. Closed-loop Hall effect device in magnetic circuit. If the loop-gain is very large the primary and secondary ampere turns will cancel and V_0 becomes proportional to I_1 .

contrast with the open-loop system, the length of the gap barely influences the measurement precision; as a result, the temperature behavior is also enhanced. When the current I_1 exceeds the output current capability of the amplifier, for example, under short-circuit conditions, the core is likely to be saturated and, therefore, a means for demagnetizing the core is standard in such an instrument. Demagnetization is obtained by driving temporarily the winding N_2 with an exponentially damped oscillating (e.g., sinusoidal) current. If the initial value of this current drives the core into strong saturation, eventually the core will be demagnetized. For current probe applications the core is divided into two parts, which can be separated in such a way that the conductor can be enclosed by the core window without breaking the electric circuit. Especially, in this case it can be appreciated that the possible instability caused by imperfect core halves contact is eliminated by the feedback. The required current output capability of the amplifier depends entirely on the winding ratio N_2/N_1 and the full-scale current I_1

$$I_2 = I_1 N_1 / N_2 \quad (13)$$

For practical reasons, the winding ratio has to be limited. This means that the amplifier in general will have to deliver a much larger current than in the open-loop system and its power consumption will be large. Another problem is that additional circuitry is required for wideband measurements because the frequency response of the Hall device is limited to about 100 kHz. A solution is to split the circuit into two parts. First, the frequency response of the Hall amplifier will deliberately be limited to a few kilohertz by first-order lowpass filtering of the output V_0 . The purpose is to reduce the effect of the poles in the open-loop transfer of the Hall device. Next, for the higher-frequency part of the spectrum, the two windings can be made to operate as a current transformer. The signal obtained from this current transformer is also first-order high-passed, with the same 3 dB cut-off frequency and transfer gain as for the Hall device. By combining the two filter outputs a flat frequency characteristic is then obtained. Typical probes show a flat frequency response from dc to 20 or 100 MHz and have full-scale ranges from 1–10 A with a full-scale output voltage of 50–200 mV.

Multiplier Applications of the Hall Effective Device. Although ac power can be measured by sampling the current and the voltage of a consumer, in general, the potential drop, and, hence, the dissipation in the current shunt, are relatively large. Further, it is difficult to protect the electronics unconditionally against a short-circuit at the consumer side. On the other hand, when the load current flows through the magnetizing coil of Fig. 4, a short will not harm the Hall device or the magnetizing coil because the coil is very rugged. As suggested by Eq. (1) the Hall device output is proportional to the product of B and I . In fact, one of the first applications of the device was as an analog multiplier (19,20). Although this application has been superseded completely by the use of the Gilbert cell analog multiplier ICs, the device still has attractive features for power applications. For example, for determination of the power an ac load consumes, the product of the momentary voltage $v(t)$ and current $i(t)$ has to be calculated. The former current-measuring circuit can easily be adapted for this purpose. It suffices to vary the Hall current I proportional to the voltage $v(t)$ so that the output voltage $v_0(t)$ of the device becomes proportional to the momentary power. By filtering this voltage, a measure for the average

power is obtained. If $v_0(t)$ is fed to a voltage-to-frequency converter followed by a counter, the counter output will represent the energy consumed by the load. For household applications the preferable counter is a mechanical one because it gives a clear indication and holds the current value, even during a power loss. The advantage of using the Hall device lies in the fact that the current scale for the instrument can be adapted through a change of the winding N_1 in the same way as a classical Watt-hour meter with a rotating disk induction motor.

Clinical Hall Effect Devices as Position Sensors. A number of industrial applications require knowledge of the position of a mechanical part; the Hall effect ICs have been developed especially for this task (22). For example, in brushless dc motors the angular position of the rotor has to be known in order to activate the drive electronics of the field coils. More recently, the Hall sensor has been applied in magnetic bearings (26) for magnetic levitation purposes.

If there is no magnetic field available, the Hall devices will be used in combination with permanent magnets (27). Suppose the rotation angle α of a permanent magnet has to be determined [Fig. 6(a)]. If a linear sensor H_1 is positioned in a zone between the pole shoes, where the field of a rotating magnet is homogeneous and has a value B the output V_{H1} will be proportional to the cosine of the angle of rotation α on the condition that the rotation axis coincides with the length-axis of the Hall

Figure 6. (a) Hall device used as an angle sensor: a magnet is fixed on a turning axis and the Hall device is mounted between the pole shoes of the magnet. The output of V_{H1} is proportional to $\sin \alpha$ because for $\alpha = 0$ its plane coincides with the plane of the magnet. (b) A second device is necessary in order to remove all possible ambiguity from determination of α from the Hall voltages.

Figure 7. Internal circuit of a Hall IC with Schmitt-trigger and linear output. A comparator output is also useful for limit detection.

sensor plane. From output V_{H1} it is, however, impossible to obtain α , as there are two angle solutions for every voltage [α_1 and α_2 in Fig. 6(b)]. This ambiguity can be resolved by placing a second transducer H_2 (output V_{H2}) perpendicular to H_1 . From V_{H1} and V_{H2} , and taking into account the signs of both outputs, the position of the magnet can be determined in the whole α -range $(0, 2\pi)$.

A digital output can be obtained by including a Schmitt-trigger circuit (Fig. 7), driven by the analog output. Mostly, an open-collector transistor forms the output as this permits adaptation of the IC to the logic level of the system connected to it. Sometimes a small magnet is mounted close to the sensor in order to provide for a magnetic bias. The output can be made to react in two ways as shown in Fig. 8. In Fig. 8(a), the purpose is to discriminate between the presence or absence of a magnetic pole. Without field the output is at the logical level "1" (line 1). When the magnet approaches the device its analog output increases. At the trip point of the Schmitt-trigger corresponding to a field B_1 , the digital output falls to the logical level "0" (line 2). In a third phase, the magnet is removed from the device but output remains low (line 3) as long as B lies above the lower trip point B_2 . In Fig. 8(b), the lower trip point corresponds to a negative field, that is, the other pole of the magnet. Operated in these two ways, the Hall device acts like a switch. The hysteresis of the Schmitt-trigger reduces the effect of bouncing and noise. There exist three common ways for detecting the position of a moving magnet: Fig. 9(a–c). It is assumed that the magnet moves along the indicated x -axis in all three cases. In Fig. 9(a), the magnet moves in a direction perpendicular to the Hall device plane. The analog output falls continuously with increasing displacement x , and a digital action is possible if the circuit is followed by a comparator. In Fig. 9(a), the compara-

tor switches from low to high if the Hall voltage exceeds reference voltage V_d . The main drawback is the poor linearity of the analog output with respect to the movement of the magnet. In Fig. 9(b), the movement is along an axis in parallel with the device plane and the south pole is near the magnet. The output will be at maximum when the south pole is positioned at $x = 0$. The system can be used as a mechanical window detector: if the magnet is positioned within the range $(-x_1, +x_1)$, the comparator output is low and vice versa. The sensitivity is controlled by adapting the distance d between the magnet and the device. Linearity can be acceptable in a small part of the displacement curve around the point of the curve where the second derivative with respect to B vanishes. In the third case of Fig. 9(c), the magnet is turned over 90° and a linear device sensitive for negative and positive fields is used. Sensitivity can be controlled as in the former case and linearity can be extremely good but the sensitivity control will also influence the linearity. In the setup of Fig. 9(c), sometimes both magnet and Hall device are fixed but a high permeability screen moving between them can interrupt the field. Such a system can detect the teeth of a cog-wheel or it can replace the mechanical breaker of the ignition in a car.

Quantum Hall Effect in Electrical Metrology. In the International System of Units (SI) the four base units are the meter (length), kilogram (mass), second (time) and the ampere (current). The ampere is the current that generates a force of 1 N per length between a pair of very thin and infinitely long conductors. This definition is artificial and of little practical value, but it ensures that the mechanical and electrical units of force are the same. Apart from this, some of the mechanical units derived are introduced for practical purposes, for example, the Henry, coulomb. These secondary quantities can always be expressed in the base units. The magnitude of magnetic permeability in the SI system is fixed to $4\pi \times 10^{-7}$ H/m. The second is defined by means of the period of a well-defined transition in Cesium 133. The velocity of light (c) has a fixed value and the meter is the distance traveled in a vacuum by light during $1/299.792.458$ s. This makes the use of the material standard meter obsolete. All electrical units can be defined in this system if two of them, for example, the volt and the ampere, are related to the mechanical units meter, second, kilogram. This comparison can be implemented via a kelvin current or volt balance. In practice the ampere has been replaced by the ohm as the latter is related to the ampere by Ohm's law.

Because the realization of physical standards requires complex instruments, national metrology laboratories still possess

Figure 8. (a) Schmitt-trigger output for a unipolar sensitive Hall IC; (b) output for bipolar sensitive IC.

Figure 9. Three ways to detect a magnet movement: (a) magnet axis and movement normal to Hall plane and resulting linear (V_H) and comparator (V_C) output voltages; (b) movement axis parallel with Hall plane gives a window function for V_C ; (c) output is linear over a large displacement range.

material standards such as Weston cells and $1\ \Omega$ resistors for their electrical measurements. These standards are considered to be a kind of flywheel in which an image of the physical unit is conserved for a limited time. By regularly comparing the physical standards with the material standards, the correction for each of these is determined. The national volt (V_{LAB}) and ohm (Ω_{LAB}) of a nation is then defined from the average values of these material standards. Before the invention of the Josephson junction and the quantified Hall effect, it was imperative to perform regularly cumbersome international comparisons in order to determine the corrections between the national standards V_{LAB} and Ω_{LAB} of the different countries.

In 1956, Thomson and Lampard (28,29) derived a striking theorem concerning a special cylindrical four-electrode capacitor structure. It was proved that for the structure of Fig. 10(a), independently of the shape of the cross section of the electrodes A, B, C, and D, the capacities C_1 and C_2 per unit length (1 m) of opposite electrodes obey the expression

$$\exp(-\pi C_1 \geq 0) + \exp(-\pi C_2 \geq 0) = 1 \quad (14)$$

with ϵ_0 the permittivity of the absolute vacuum. The value of ϵ_0 is known because, in vacuum, the velocity of light is $c = (\mu_0 \epsilon_0)^{-0.5}$ and c as well as μ_0 are fixed. For a symmetrical capacitor Fig. 10(b), $C_1 = C_2 = C$ and from Eq. (14) we obtain $C = 1.953549043\ \text{pF/m}$. In practical applications, a capacitor with finite length is used and this length is varied by inserting a guard tube S in the space between the four electrodes (30–32). By careful construction it is possible to reduce the effect of the fringing fields at both ends of the capacitor. In this way, the physical length of the capacitor is changed by displacing the guard tube from l_1 to l_2 and the corresponding variation of capacity is $1.953549043 (l_2 - l_1)\ \text{pF}$. The capacity variation in this system is, therefore, only determined by one dimension; the displacement $l_2 - l_1$ of the guard tube can be measured very accurately with a laser interferometer. The very complicated setup for this system has been called the calculable capacitor because of its capacitance formula. By employing a chain of ac comparator bridges the material ohm standard can be related to the impedance of the calculable capacitor, and thus with the mechanical units.

Figure 10. (a) Calculable capacitor structure with four electrodes; (b) simplified system with four cylindrical electrodes A, B, C and D. The effective length is varied by moving a screen S in the opening between the cylinders. Not shown are a similar but fixed screen at the left side, the screen surrounding the tubes, interferometer, and trimming screws. The smaller part of the screen is the “spike.” It can be shown that this spike reduces the effects of irregularities in the cross section of the capacitor (Ref. 32).

Figure 11. Potentiometric setup for comparing the quantified Hall resistance with the laboratory standard resistor.

The quantum Hall effect has opened the door to a new material ohm standard, which is solely dependent on the universal physical constants e and h . On the other hand, it is generally accepted (33) that the von Klitzing constant R_K , that is, the value of R_H for $i = 1$, can also be calculated from μ_0 , c and the dimensionless fine structure constant α . This constant can be derived via complex quantum electrodynamic calculations from measurements of the anomalous magnetic moment of the electron. The relation between μ_0 , c , α , h and e is given by

$$R_K = R_H(i = 1) = h/e^2 = (\gamma_0 c/2)\alpha^{-1} \quad (15)$$

with a value $\alpha = 1/137.0359898$. Since μ_0 and c have well-defined values, the accuracy of R_K and α is the same in Eq. (15).

As it became clear that the quantum Hall effect could be used for definition of the unit of resistance, metrologists succeeded in refining the measurement procedures so that R_K could be expressed in Ω_{LAB} . It also became possible to compare the existing material ohm standards with a relative error of 10^{-8} . At that moment the reproducibility of the quantum Hall measurements was better than the implementation of the material ohm in the International System of Units (SI).

In 1990, the Comité Consultatif d'Electricité (CCE) decided, based on an analysis of all the known international comparisons of the material resistance standards by the Bureau International des Poids et Mesures (BIPM), to attach a conventional value to the von Klitzing constant

$$R_{K-90} = 25812.807 \, \Omega$$

The relative uncertainty for this value is 2×10^{-7} and this definition makes it possible to replace the maintained standards with the quantum Hall effect device. At the same time, for the second quantum effect used in metrology, that is, the Josephson effect, a conventional value K_{J-90} has also been assigned to the Josephson constant. The material standards for the volt and ohm are now replaced by the Josephson junction and the quantum Hall device; the outputs of these devices are independent of the site on earth and the shape or materials used for

their construction. Intercomparisons are therefore no longer as critical.

Measurement Setup. Comparisons of the Hall resistance with standard resistors can be performed in different ways: potentiometric or with a cryogenic current comparator bridge (CCC). Figures 11 and 12 show generic and simplified diagrams representative for various measurement setups. In the potentiometric method (Fig. 11) a reference resistor R_r of the same nominal value of $R_H(i)$ is used. As the plateau $i = 1$ is difficult to obtain with reasonable fields, often the integers $i = 2$ or $i = 4$ are preferred. Superconducting magnets that generate an induction of 15 T between its poles are commonly used. The value I of the dc current source is in the $50 \, \mu\text{A}$ range and this alleviates the work of the temperature controller because of the low power dissipation in R_r . Measurement of the voltage V_{xx}

Figure 12. Cryogenic current comparator setup for comparing the quantified Hall resistance with the laboratory standard resistor.

permits inspection if the correct conditions for the occurrence of the quantum Hall effect are met. The Hall plateaus will appear when V_{xx} is very small. A zero detector is lacking and, instead, a high-gain amplifier followed by a digital voltmeter (DVM) is used. A compensating source V_C is derived from a potentiometer fed with a second current source I_1 . By changing the position of S_2 , two voltage differences are measured: $\Delta_1 = V_H - V_C$ and $\Delta_2 = V_r - V_C$. From the Δ -values measured it is possible to calculate the current I and V_C and thus V_H . To eliminate the drifts of the current sources and the thermal emfs it is necessary to perform measurements over a longer period, for example, an hour, and calculate averages. Because all current sources can change direction (by turning over S_1) the effect of thermal voltages can be eliminated. If the CCC is used as shown in the simplified circuit of Fig. 12, it is possible to compare R_H with smaller resistors, for example, 100 Ω because the turns ratio N_2/N_1 can be varied. In Fig. 11, there are two balance conditions to be met: $V_H = R_r I_2$ for the zero detector balance, and $N_1 I_1 = N_2 I_2$ for the zero flux condition in the core. The magnetic flux is measured by the very sensitive superconducting quantum interference device (SQUID), and the output of this device controls the current source I_2 in such a way that the core flux becomes almost zero. If the balance of D is obtained by varying N_1 , then we find with $V_H = R_H I_1$, the quantum Hall resistance $R_H = R_1 N_1/N_2$. In order to increase the precision to the level 10^{-9} or better, a fixed ratio N_1/N_2 is more appropriate. In this case a third current winding N_3 is added to the comparator and a balance current I_b derived from the detector output performs the automatic balancing. This balance current is measured by means of a shunt resistor s and a DVM. The balance current is much smaller than the main current and, therefore, the limited precision of the digital voltmeter does not impair the measurement accuracy.

If the two methods are compared (Ref. 5), it can be calculated for a specific case that the potentiometric method generates more system noise than the CCC. In a typical case the CCC method is therefore almost 45 times faster than the potentiometric method. As a result, the measurement time is reduced to a few minutes and the random uncertainty still is at the level 2×10^{-9} .

PRESSURE SENSORS

Each physical quantity A can be measured by use of primary methods of measurement or by secondary methods, that is, by measurement of some other quantities W_i in physical relation with quantity A . Quantity A must be measured or must be controlled (regulated), but it is desirable to measure quantities W_i because of their advantages. There are many physical and technical possibilities for designing a specific device giving the relation between A and W_i . Such a device is called a transducer (measurement transducer, because the meaning of the word *transducer* is very wide and can mean any change-processing devices). A transducer is a device that provides a usable output signal in response to a specific measurand (a measurand is the physical quantity being measured). Transducers have their own internal structure. In the simplest case we can imagine some elementary transducers connected in linear order. Based on the physical background we can find a specific physical phenomenon, in our case, pressure that has a known, well-defined, influence on some quantities that characterize a specific body: volume, dimensions (linear and angular displacements, strain), resistance, sound velocity, density, dielectric constant, or other quantities whose variations allow determination of pressure. Let us call that body a *pressure-sensing element*, or *primary pressure transducer*. From a transformation theory point of view, it receives and transforms information by itself. A *pressure sensor* device, see Fig. 1, consists of the pressure-sensing element and at least one basic (secondary) transducer. This transducer converts a sensing-element signal into another quantity, one of the quantities W_i chosen as the most convenient, not only an electrical quantity. In this article only sensing elements (primary transducers) and basic (secondary) transducer systems are considered. Within the group of secondary transducers, capacitive, inductive, reluctance, strain gauge, resistive, potentiometric, and piezoelectric transductions are used for information processing in modern pressure sensors. Pressure sensors can have digital or analog output. In analog sensors output signals are voltage amplitude, voltage ratio, current, frequency, capacitance, and inductance.

FUNDAMENTAL DEFINITIONS

Pressure is one of the fundamental physical quantities that describes the thermodynamic state of a body. Pressure is an intensive type of quantity, that is, defined at points, it is a scalar parameter describing the “force side” of the body. Pressure characterizes the intensity of the internal effective repelling forces tending to increase the volume of a body. The intensity

Figure 1. Schematic representation of a pressure sensor.

of this force in every case is demonstrated as a continuously distributed force acting on a unit area. By this we mean the surface area of a vessel enclosing a defined body (for example, gas) or any virtual surface inside the body (gas). Pressure is not a basic physical quantity and therefore it is defined by other basic quantities resulting from the defining equation, that is, newton/m² (N/m²) or pascal (Pa). Let us interpret the pressure using the stress tensor σ_{ij} defined at each point in the volume of a concrete body. In the ideal gas no tangential component of the stress tensor exists. Normal and negative components are equal to each other so we can write $\sigma_{ij} = -p\delta_{ij}$, where δ_{ij} is a Kronecker delta and p is a parameter of state called pressure. In this case pressure can be expressed by the classical formula $p = 2n\langle E \rangle / 3 = \rho \langle v^2 \rangle / 3$, where n is the number of particles in a unit volume, $\langle E \rangle$ is the mean kinetic energy of the particles, ρ is the density of gas, and $\langle v^2 \rangle$ is the mean value of the square velocity of particles. Pressure in an ideal gas is associated only with the thermal motion of particles and therefore can be considered as fully “hot.” In the case of real gas the hot pressure is partially reduced by the so-called *internal pressure* caused by the some intermolecular attractive bond interactions. In the case of liquids the internal pressure makes the hot pressure practically “frozen.” “Cold pressure” can be produced in liquids by mass or in a closed volume by surface forces. In real liquids (e.g., natural water) in thermodynamic equilibrium at some place close to the Earth’s surface, the forces acting inside the liquid on a directed surface element dA are given by the formula $dF = -n p dA$, where n is an unitary vector of element dA and $p = \rho gh$, where g is the Earth’s acceleration, ρ is the density of a given liquid, and h is the distance between the free surface of the liquid and a specific point. This formula was given by Pascal, who defined p as the hydrostatic pressure. In the case of solids the correct interpretation of pressure and its effects is more difficult. The stress tensor σ_{ij} can be formally separated into two components: the axial stress tensor $A_{ij, i=j}$, with identical values of diagonal elements equal to $(\text{Tr } \sigma_{ij})/3$, and the deviatoric stress tensor D_{ij} , whose elements can be expressed as $D_{ij} = \sigma_{ij} - \delta_{ij} A_{ij}$. If all modules of deviatoric elements are small relative to the modules of negative-sign axiatoric elements, we define such a stress state as a quasihydrostatic pressure, which is the real situation. When the deviatoric stress tensor disappears and axiatoric elements are negative, hydrostatic pressure is acting in the solid. In the field of pressure measurement one should become familiar with the following definitions: *Absolute pressure* is pressure measured relative to zero pressure (MPa abs). *Zero pressure* is a state of vacuum. *Vacuum* is a state of space (a closed volume) in which pressure is reduced to a minimum that can be attained through practical means. *Perfect vacuum* is zero absolute pressure, resulting in the complete absence of any particles of matter. *Standard pressure* is the pressure of one normal atmosphere. *Gauge pressure* is the pressure measured relative to ambient pressure, usually relative to actual atmospheric pressure (MPa gag). *Differential pressure* is the difference (usually small) between pressures acting in two specific volumes (points) measured using one sensing element (MPa dif). *Stationary pressure* is pressure that is held constant long enough relative to the longest relaxation time of specific processes that take place in the liquids or solids under study. *Dynamic pressure* is a pressure generated by an impact wave causing a “jump” in the density (also internal energy) on a front of the impact wave. This phenomenon is fully nonreversible. We can speak also about *quick variable pressures*, which are gener-

ated continuously but the length of the pressure wave exceeds the dimensions of the container or the pressure sensor. With a pressure medium flowing in tubes, there is *static pressure* of the flowing fluid (the fluid is a liquid or gaseous substance), which can be measured normal to the direction of flow at the inner surface of a tube. *Impact pressure* is the pressure that can be generated in a moving fluid due to flow velocity. The *stagnation pressure* is the sum of the static pressure and impact pressure. *Partial pressure* is a pressure exerted by one constituent of a mixture of gases.

PRIMARY PRESSURE MEASUREMENTS

There are two primary methods for generation and measurement of pressure: using liquid manometers (1), which are the most accurate range from a few pascals to about 0.5 MPa, and using gas or liquid-operated dead-weight manometers (pressure balances or piston gauges) (2). For the first type of manometer the difference of pressure Δp between two levels h_2 and h_1 is given by

$$\Delta p = \int_{h_1}^{h_2} \rho(h, T) g(h) dh \quad (1)$$

where ρ is density of liquid (mercury in the most cases), known most accurately through the primary measurements of mass and length with temperature and pressure corrections and $g(h)$ is a local Earth acceleration known also on the basis of the most accurate primary measurements of time and length. In the second method, based on metrological properties of a quasisealed piston-cylinder system, the generated pressure is given by

$$p = Q_{\text{eff}} / A_{\text{eff}} \quad (2)$$

where p is a pressure generated just under the bottom surface of the piston and Q_{eff} is the effective weight of a standard mass used as a force generator. The acceleration of the Earth must be known at the specific location of the experiment with highest accuracy; air buoyancy, the surface tension effect, and other corrections should also be taken into consideration. The quantity A_{eff} is the effective area of the piston-cylinder system. At first approximation for low pressures it is equal to the mean values of the piston area and the inner-hole area of the cylinder. A_{eff} depends slightly on temperature and more strongly on pressure, and therefore its pressure dependence is a fundamental problem for designers of this type of pressure etalon (3). There are three fundamental types of piston-cylinder systems: simple-piston, reentrant-cylinder, and controlled-clearance systems. The last one is schematically shown in Fig. 2. The first and third systems have found wide applications in practice; the first for pressures below 1 GPa and the third for pressures up to 1.4 GPa are commercially available. The accuracy of pressure balance depends on its pressure range and is illustrated in Fig. 3 (2).

GENERAL CHARACTERISTICS OF PRESSURE SENSORS

A pressure sensor is normally designed to sense (measure) a specific measurand, pressure, and to respond only to this measurand according to the theoretical formula or to the pressure

Figure 2. Schematic of a piston gauge (pressure balance) with a clearance-controlled piston-cylinder system. On the right an initial clearance and on the left a reduced clearance at the measurement moment are shown.

scale. The pressure scale is given by several pressure values well established from primary methods of pressure measurements. Real metrological properties of sensors are described by the following characteristics [see, e.g., Ref 4]:

1. Measurand characteristics
2. Electrical design characteristics
3. Mechanical design characteristics
4. Static performance characteristics
5. Dynamic performance characteristics
6. Environmental characteristics
7. Installation (reinstallation) effects and mounting errors
8. Reliability characteristics (overload, life, and the number of operating cycles)

Measurand characteristics for pressure sensors is the *character* of pressure, which can be static, dynamic, or variable (quick-variable), and *range* of pressure defined by lower and upper limits. The range of pressure sensors is in principle unidirectional (e.g., from 0 MPa abs to 10 MPa abs) and asymmetrically bidirectional in the case of gauge pressures when the reference pressure is atmospheric pressure (e.g., from

Figure 3. Accuracy of pressure balances as a function of the maximum pressure range (2).

–0.1 MPa gag to 1.0 MPa gag) or expanded and suppressed-zero scale (e.g., from 0.3 MPa abs to 0.5 MPa abs). The algebraic differences between the limits of the range in the span of the sensor (for the preceding examples) are equal to 10 MPa, 1.1 MPa, and 0.2 MPa. Some electrical design characteristics are as follows:

1. *An excitation*, usually stated in terms of dc or ac voltage or of a current applied to the sensor (only piezoelectric pressure-sensing elements do not require external electrical excitation for operation)
2. *Output*, an electrical quantity produced by the sensor as a function of the measured pressure, in analog form as a continuous function of current or voltage magnitudes and also a continuous variation of capacitance, inductance, frequency. In the case of digital output, the system gives information in the form of discrete quantities coded in the specific notation, preserving the accuracy of the sensor throughout the measuring system.
3. *End points*, which are the output values at the lower and upper limits of the sensor range.
4. *Impedances* across the output terminals and across the excitation terminals, and load impedance presented to the sensor output by the associated external circuitry and transmission line (mismatching of output impedances can cause loading error).
5. *Demodulator and amplifier* characteristics and also *grounding*, which can be isolated or common for input and output, or floating when two or more portions of sensor are electrically isolated.

The main static performance characteristics of a sensor is usually determined by the test during which known values of pressure are applied to the sensor in an ascending mode and descending mode (a calibrating cycle), and corresponding output readings are recorded and correlated. The output of the actual sensor is affected by its real behavior, which causes the indicated pressure value to deviate from the ideal characteristic (true values). The algebraic difference between the indicated value and true value is a sensor error or sensor uncertainty (usually expressed as a percentage of full-scale output). The ratio of the error to the full-scale output is defined as the relative uncertainty or accuracy class. Pressure sensor errors can be considered in terms of maximum deviation over the range from known reference lines, but interpretation of individual errors such as nonrepeatability, hysteresis, zero and sensitivity drift, possible friction errors, and nonlinearity (when linear functions of output pressure can be accepted) are required. For high-pressure sensors hysteresis induced by sensing elements is the main source of measurement errors. Dynamic performance characteristics are characterized by a *frequency response*, that is, frequency dependence of the output to pressure amplitude ratio when the pressure varies sinusoidally. We can speak of $\nu_{\max}$ below which the response is correct within some percent of error and $\nu_{\min}$ above which the sensor response is correct, in the cases when a sensor is designed for quick variable pressure measurements. Another useful dynamic parameter is the *response time*, when a stepped change of pressure is applied to the sensor and its output reaches some arbitrary fixed level, say 90% of the final value. In most cases, when $p_{\text{step}} > 0$, the pressure change satisfactorily describes the relation

$p_{\text{read}} = p_{\text{step}} (1 - e^{-t/\tau})$ where τ is the time constant of the sensor. After that time the response of the sensor reaches about 63% of its final value or decreases by 63% of the p_{step} value when it has a negative sign. The upper limit of the frequency response and response time characteristics of the sensor are controlled by its energy-dissipating properties, that is, damping processes. Each oscillation process can be underdamped, critically damped, and overdamped. In an underdamped state of the sensor, an oscillation of the output is observed. In overdamped and critically damped states, the steady value is reaching monotonically with different values of τ . In the last situation (at critical damping) the time constant is smallest. The specific external conditions (temperature, shock, vibration, and humidity) to which a pressure sensor may be exposed during storage and operation constitute *environmental conditions*. The influence of temperature in the *operating temperature range* should be defined within specific error limits—a temperature error or temperature error band. The effect of temperature causes a thermal zero drift, thermal sensitivity shift, and temperature gradient error (a transient error). For the pressure sensors the knowledge of the influence of temperature on the sensor properties is very important because any change of pressure is connected with a change in temperature, especially for dynamic pressure. There are many scientific and industrial demands related to the pressure measurement at elevated or high temperatures (or cryogenic low temperature). For such demands a specific pressure sensor has been developed (5,6). Acceleration effects may be especially large when mechanical pressure-sensing elements are used. The error connected with this effect is usually more severe along one axis of the sensor than along the other axis, which depends on the sensing element's construction. Too large an acceleration (10g or higher) may lead to the failure of the sensor. For rocket technology, special pressure sensors are constructed. In some pressure-sensing elements such as the resistance pressure gauges, the sensitivity to acceleration is negligible. Vibration effects (vibratory acceleration) can affect pressure sensors in the same manner as constant acceleration does. The vibration effects may reduce static error connected with friction error and may induce resonance effects at some characteristic frequencies, with the largest effect connected with the main resonance.

Let us define *low pressures* as pressures for which the standard pressure is not negligible. Practically, we can accept it as 100 MPa, which makes the standard pressure 10^{-3} of the maximum value of the low-pressure value. For this range of pressure the differences among *absolute*, *gauge*, and *differential* pressures are essential. In Fig. 4 there are shown reference configurations adequate to low-pressure using diaphragms as pressure-sensing elements. The most commonly used classical, in principle mechanical, elastic sensing elements and the nature of their deflections are illustrated in Figs. 5 and 6.

DIAPHRAGM PRESSURE-SENSING ELEMENTS

Flat diaphragms are essentially circular, rectangular, or square-edge-clamped elastic thin plates (noncircular plates play an important role in silicon pressure sensors). Let us consider here the simplest situation, that is, a deformation state of a thin circular plate loaded on one side by measured pressure, which is a classical problem in the elastic theory of plates (7). Figure 7, in enlarged scale, shows a plate deformed by

Figure 4. Reference pressures: vacuum (for absolute pressure measurements), ambient pressure or normal pressure (for gauge pressure measurements), and basic, variable pressure (for differential pressure measurements).

pressure. The radial ϵ_r and tangential strains ϵ_t of the bottom free surface are given by

$$\begin{aligned}\epsilon_r &= 3(1 - \nu^2)(a^2 - 3r^2)p/8Eh^2 \\ \epsilon_t &= 3(1 - \nu^2)(a^2 - r^2)p/8Eh^2\end{aligned}\quad (3)$$

where a is the radius of the diaphragm, h a thickness, ν Poisson's ratio, E Young's modulus of the plate material and

Figure 6. Elastic pressure-sensing elements: (a) straight tube, (b) curvilinear (Bourdon tube) basic type, (c) spiral type, (d) helical type, and (e) twisted type.

r the local (optional) radius. At the center of diaphragm, that is, for $r = 0$, we have

$$\epsilon_r = \epsilon_t = 3(1 - \nu^2)a^2p/8Eh^2 \quad (\text{tensile, positive strain}) \quad (4)$$

and deflection

$$f = 3(1 - \nu^2)a^4p/16Eh^3 \quad (5)$$

On the edge of diaphragm, assuming perfect clamping, for $r = a$, we have

$$\begin{aligned}\epsilon_r &= 3(1 - \nu^2)a^2p/4Eh^2 \quad (\text{compressive, negative strain}) \\ \epsilon_t &= 0\end{aligned}\quad (6)$$

Figure 5. Elastic pressure-sensing elements: (a) flat diaphragms, (b) corrugated diaphragms, (c) capsules, and (d) bellows.

Figure 7. Pressure-loaded edge-clamped thin elastic plate (illustration of deformation in enlarged scale).

A good approximation of the fundamental resonant frequency of the diaphragm is given by

$$f_R = 0.47hE^{0.5}/a^2\rho^{0.5}(1-\nu^2)^{0.5} \quad (7)$$

So, one can see that the deflection at the center is proportional to the applied pressure (differential pressure across the diaphragm) and varies with the fourth power of its diameter. The preceding expressions are valid for small deflections only. With increasing pressure in the deformed diaphragm, tension stress starts to play an increasingly important role. The characteristic pressure or deflection for large deflections is therefore strongly nonlinear. The deflection at the center of a diaphragm for $f < 4h$ can be to a good approximation calculated from following expression (8):

$$pa^4/Eh^4 = 16f/3(1-\nu^2)h + 6f^3/7h \quad (8)$$

For the higher deflections, but not higher than $10h$, the following, simpler, formula can be used:

$$pa^4/Eh^4 = 3.45(f/h)^3 \quad (9)$$

Flat diaphragm pressure-sensing elements as primary transducers of the pressure-to-displacement or pressure-to-strain type are widely used in practice within the pressure range from some kilopascals to about 100 MPa and in special designs up to 1 GPa (high-pressure performance). Their typical accuracy varies from 0.5% up to 2%. *Corrugated diaphragms* contain a number of concentric corrugations of different shapes and dimensions. These increase the stiffness as well as the effective area of the diaphragm, the measurement of which is very important in the case of the pressure-to-force trans-

Figure 9. Different type of the capsule systems: (a) open forms for gauge pressure measurements, (b) closed form (aneroid) for measurements with a given reference pressure, if vacuum is used for absolute pressure measurements (typically for atmospheric pressure, and (c) double system of capsules.

ducer. The useful deflection is therefore larger than that of the flat diaphragms. The deflection can be a linear function of applied pressure with proper selection of corrugation and thickness of diaphragms. The coefficient of proportionality between pressure and deflection depends on the shape, location, and number of corrugations. In Fig. 8 examples are given illustrating this problem (8). Corrugated diaphragm sensing elements are typical pressure-displacement primary transducers, having a typical accuracy of 1.5% to 2.5%, and they can measure the pressure from some kilopascals up to some megapascals. Diaphragms made of very thin metal or nonmetallic materials (soft diaphragms) are called *membranes*. Membranes used as pressure-sensing elements are backed by a spring that provides necessary elastic properties. Typically membranes are used to isolate the pressure-sensing element from the pressurized chemically active liquid. As a pressure-transmitting medium a silicone oil with optimal properties from a metrological point of view is used. Pressure-sensing elements called *capsules* can have open or closed form [see Figs. 9(a) and 9(b)]. The closed-form element with vacuum as a reference pressure is frequently referred as an *aneroid* and is used in atmospheric pressure manometers. It consists of two corrugated metal diaphragms formed into shells of opposite curvature and fastened together with hermetically sealed joints around their peripheries, by (most preferred) inert-gas or electron-beam welding.

Figure 8. Illustration of the problem of obtaining of the linear dependence of deflection for corrugated diaphragm under pressure (8).

Factors influencing the deflection of capsules are the same as those that apply to corrugated diaphragms. The use of two corrugated diaphragms in one capsule nearly doubles the deflection obtained from each diaphragm. Capsules are often joined in double or triple systems [see Fig. 9(c)]. The *bellows* sensing element [see Fig. 5(d)] is usually made of a thin-walled tube formed in a large number of deep convolutions sealed at one end, which can translate axially when pressure is applied to a port in its opposite anchored end. Due to large numbers of their convolutions, bellows are frequently used when a large stroke is required. The number of convolutions vary from five to over twenty depending on pressure and displacement requirements and on outside diameter. Bellows are sensing elements that can work as a pressure-to-displacement transducer or pressure-to-force transducer. In pressure-to-force transducing the determination of the effective area of the bellows is very important. The effective area of the bellows is the effective area of the piston gauge in equilibrium with the force resulting from the pressure acting inside the bellows, which is equal to the pressure in the piston gauge. The effective area of the bellows is constant to a high degree. The pressure range covered by bellows sensors is typically from 0.1 MPa up to 1.0 MPa and the accuracy is about 1%. In the case of bellows, a large hysteresis up to 2% can be observed. Diaphragm and bellow sensing elements are made of high-elastic metal alloys such as brass, bronze, phosphor bronze, beryllium copper alloy, stainless steel, and alloys called Monel, Inconel, and NI-Span C. An important consideration in the selection of diaphragm materials is the chemical nature of the fluids that will come in contact with the diaphragm. Proper manufacturing methods include heat-treating and pressure-cycling to reduce elastic aftereffects like drift, creeping, and hysteresis in the diaphragms.

BOURDON-TUBE SENSING ELEMENTS

The Bourdon tube is named after the French inventor, Eugenie Bourdon, who patented it in June 1849, and has found very wide applications. The Bourdon tube is a curved or twisted tube, typically oval or elliptical in cross section, which is sealed on one end (tip) and rigidly mounted on the other. When pressure is applied internally to the tube, the tube tends to straighten. This phenomena can be easily but quantitatively explained as follows. When the Bourdon tube is subjected to an internal pressure, the cross section approaches a circle and the length of the tube increases slightly with pressure; hence the effect is to increase the radius of the tube. This results in a curvilinear tip deflection (tip travel) in curved tubes and an angular tip deflection in twisted tubes. The principle of action of this simple device is very difficult to describe in terms of elastic theory. For *C-shaped Bourdon* tubes (see Fig. 10), the initial total angle of curvature ψ_0 (typically of 180° to 270°) decreases by $\Delta\psi$ up to ψ as a result of the effective pressure (the differ-

Figure 10. C-shaped Bourdon tube main dimensions; various cross sections of tubes for low-pressure measurements (8).

ence between internal and ambient pressures). In the case of low pressure (thin-walled Bourdon tube, i.e., when the ratio of the thickness g of the tube to the minor dimension of its cross section b is smaller than 0.6) we have the following approximate expression defining the main characteristic of a Bourdon tube (8):

$$\Delta\psi/\psi = p(1 - \nu^2)R^2(1 - b^2/a^2)\alpha/Ebg(\beta + R^2g^2/\alpha^4) \quad (10)$$

where R is the mean curvature radius of the tube and α and β are parameters depending on the shape of the tube cross section the values of which are given in the Table 1. In the case of a high-pressure Bourdon tube (thick-walled tubes, $g/b > 0.7$) we can use following expression:

$$\Delta\psi/\psi = p(1 - \nu^2)R^2(1 - X)/Ebg(g^2/12b^2 + X) \quad (11)$$

where $X = (\sinh^2 c + \sin^2 c)/c(\cosh c \sinh c + \cos c \sin c)$ and constant $c = (3^{0.5}\alpha^2/Rg)^{0.5}$. The tip travel w can be described by two components, radial, w_r , and tangential, w_t as follows:

$$w_r = \Delta\psi R(1 - \cos \psi_0)/\psi_0, \quad w_t = \Delta\psi R(1 - \sin \psi_0)/\psi_0 \quad (12)$$

In practice the deflection of the free end of the tube is a linear function of the pressure. From Eqs. (10) and (11) we can see that the wall thickness, the a/b ratio Young's modulus, the radius of curvature and other parameters in the case of more complicated cross sections of the Bourdon tube determine the

sensitivity of the tube to pressure changes. For laboratory use, the precision of about 0.1% of full scale is attainable for pressures as high as 1 GPa. For pressures up to 2 GPa, the Bourdon tubes have been developed with an accuracy on the order of 1% to 2%. In many commercially available versions of Bourdon manometers the servo systems have been incorporated into the gauge mechanism, enabling automatic recording and regulation. Typical pressure ranges for this type of Bourdon manometers are from 0.01 MPa up to 0.6 MPa with typical accuracy of 0.2% to 2%. As an important extension of the simple Bourdon gauge, pressure-sensing elements in the form of spirally and helically wound tubes have been developed and also widely used. The *spiral Bourdon tube* amplifies tip travel due to its multiturns (usually 3 to 6 turns). Of course, its curvature radius increases with each turn from port to tip but the tube centerline is in one plane. In the case of the *helical Bourdon tube*, since it is coiled into multiturns, the total angle of curvature is typically between 1800° and 3600°. Its tip travel is proportionally greater than that of the tube with less than 360° curvature. For low-pressure applications (up to about 5 MPa) the pressure-sensing element is manufactured from quartz, and for higher pressures only high-strength elastic metallic materials are used. The *twisted Bourdon tube* is a strong flattened tube, twisted along its length. The total number of twists is usually between 2 and 6, but it can be less than one full turn. The twist rate (twists per unit of length) also varies within wide limits. The centerline of the tube is straight throughout its length under normal and pressurized states. The metrological deflection is an angle created by the rotating free end of tube in relation to its anchored second end (pressure port). In special cases prestressed twisted tube gauges do not show any deflection until a pressure close to the definite lower limit of its measuring range is reached. Then deflection occurs only over the narrow part of the pressure range, so zero suppression can be obtained for that kind of transducer. The deflection of this kind of Bourdon tube varies also with the ratio of its major to minor cross-sectional axes, the difference between internal and external pressure, the total tube length, and the rate of twist of the twisted tube. It also strongly depends on the wall thickness of the tube and the modulus of elasticity of the tube material. Materials used for fabrication of Bourdon tubes are practically the same as for diaphragm fabrication. More complicated is the process of its fabrication. The tubing can be machined from one bar stock or can be drawn. Tube fabrication begins with a regular shape and then flattening and forming into the desired configuration takes place. Machined tubes can have one or two ends integrally machined from the same bar stock. Drawn tubes are welded or brazed to the fittings or to the machined base port section of the transducer. Then the tip is sealed, welded, or brazed with great care to ensure leak-proof joints. After these operations the pressure and temperature cycling is performed.

STRAIGHT-TUBE SENSING ELEMENTS

Straight-tube sensing elements are used in an increasing number of pressure sensors. Based on the Bourdon idea it was suggested (9) to design a straight tube with an eccentric bore. When pressurized with liquid the tube will bend because there is a net force due to pressure in the bore acting on one side of the neutral axis of the tube (on the hole axis side). The resultant deflection can be recorded by means of any displacement transducer, for

Figure 11. Elastic pressure-sensing elements, short-tube types: (a) closed end, (b) open ends, (c) loaded open ends, and (d) short-tube type bulk modulus.

example a dial micron gauge. Not too high an accuracy from 1% up to 2% of this transducer has been reported. The design is rather easy to fabricate and is well suited to high-pressure applications. The second type of straight-tube element widely used in practice has a circular cross section. A differential pressure acting across its wall causes a very slight expansion or change of the tube diameter and length. These changes of tube dimensions can be easily detected by means of the proper displacement transducer or can be calculated based on knowledge of the longitudinal and circumferential strains of the open surfaces of the tubes. These tube elements being short tubes or cylinders, are divided into two groups: thin-walled cylinders and thick-walled cylinders. Each group can have closed-end or free-tube versions; see Fig. 11. Thin-walled cylinders are sensing elements for small pressures, and thick-walled cylinders are sensing elements for high-pressure measurements. With a strain gauge transduction system $\epsilon \rightarrow \Delta V$ many commercial types of low and high-pressure sensors were developed. In the case of thin-walled cylinders one obtains the longitudinal strains ϵ_l and circumferential strains ϵ_r from Laplace sheet theory (7) taking into account also the existing longitudinal stress due to the pressure acting on the closed end:

$$\epsilon_r = pD(2 - \nu)/4gE, \quad \epsilon_l = pD(1 - 2\nu)/4gE \quad (13)$$

where D is the inside diameter of a cylinder, g the thickness of a cylinder, E Young's modulus and ν Poisson's ratio of cylinder material. The classical tube sensing elements have some disadvantages: the influence of a closed end and the mounting stress in the open end of the tube on strains where the strain gauges are bonded, so in any case such pressure sensors must be tested. In the case of the free cylinder pressure-sensing element (10), that is, with a tube having two free ends, the longitudinal stress does not exist. In this case, for a thin-walled cylinder, from Laplace sheet theory, one can obtain

$$\epsilon_r = pD/2gE, \quad \epsilon_l = -\nu pD/2gE \quad (14)$$

The longitudinal strains are negative here and the results from Poisson's ratio contrast the classical case, where they are positive. This fact enables us to increase the bridge sensitivity by thermostating the strain gauge bonded along the cylinder. Further advantages of this solution are an exact expression for

strains and the lack of an influence of the mounting stress, except the small friction force due to o-ring sealing applied in this design. For high pressures the thick-walled cylinder must be used. Thus the calculations of circumferential and longitudinal strains can be based on Lamé's theory (7), which gives following expressions: For closed-end tubes

$$\epsilon_r = p(2 - \nu)/(W^2 - 1), \quad \epsilon_l = p(1 - 2\nu)/E(W^2 - 1) \quad (15)$$

and for free tubes

$$\epsilon_r = 2p/E(W^2 - 1), \quad \epsilon_l = -2\nu p/E(W^2 - 1) \quad (16)$$

where W is the wall ratio (the ratio of the outer to inner diameter of cylinder). When pressure is applied not only inside the tube but also on the end surfaces (10) one can obtain the following expressions:

$$\epsilon_r = p[2/E(W^2 - 1) + \nu/E], \quad \epsilon_l = -p[2\nu/E(W^2 - 1) + 1/E] \quad (17)$$

when $W \rightarrow \infty$, that is, a cylinder system with pressure acting on the open ends also becomes a free-rod system. When the pressure is applied to the outside of the measuring cylinder that system is called a bulk-modulus pressure sensor (11), and the circumferential and longitudinal strains measured on the inside diameter of the cylinder are

$$\begin{aligned} \epsilon_r &= -p[W^2(2 - \nu)/E(W^2 - 1)] \\ \epsilon_l &= -p[W^2(1 - 2\nu)/E(W^2 - 1)] \end{aligned} \quad (18)$$

The change of the length of this type of cylinder is a measure of pressure,

$$\Delta l = -p[l(1 - 2\nu)W^2/E(W^2 - 1)] \quad (19)$$

where l is the length of the straight measuring tube. From the data presented in Ref. 11, $l = 100 \text{ mm} \pm 0.05 \text{ mm}$, $\nu = 0.296 \pm 0.002$, $E = 186 \text{ GPa} \pm 2 \text{ GPa}$, $W = 2 \pm 0.005$, we obtain the following formula: $\Delta l = p(0.294 \pm 0.007) \mu\text{m} \cdot \text{MPa}^{-1}$. For the strain-gauge free active element pressure sensors the pressure characteristics can be calculated based on its dimensions and material data. With this estimate we obtain an accuracy of 2% to 4%, which is high enough for many industrial purposes.

STRAIN-GAUGE PRESSURE SENSORS

The conversion of pressure-induced strains in definitive elastic pressure-sensing elements (usually flat diaphragms or straight-tube elements) into changes of resistance using a different type of strain gauge has been used in commercial pressure sensors for many years. Two or more commonly used sensors with four active arms of a Wheatstone bridge with ac and dc excitations in special form that gauge ϵ (or $\Delta R/R$), appropriate for pressure measurements, have been developed. For straight-tube sensing elements described previously, using four active element arms of a Wheatstone bridge we have the following expressions for different types of *strain-gauge dilating cylinder* pressure sensors:

Thin-walled closed end cylinder	$\Delta V/V \cong kpD(1 + \nu)/2gE$
Thin-walled free cylinder	$\Delta V/V = kpD(1 + \nu)/gE$
Thick-walled closed-end cylinder	$\Delta V/V \cong kp(1 + \nu)/2E(W^2 - 1)$
Thick-walled free cylinder	$\Delta V/V = kp(1 + \nu)/E(W^2 - 1)$
Thick-walled open-end free cylinder	$\Delta V/V = kp(1 + \nu)[2/(W^2 - 1) + 1]/2E$
Free-rod approximation	$\Delta V/V = kp(1 + \nu)/2E$
Thick-walled bulk-modulus type	$\Delta V/V = kpW^2(1 + \nu)/E(W^2 - 1)$

where ΔV is a output voltage signal, V the excitation voltage of the bridge, and $k = \Delta R/R\epsilon$ the constant of the strain gauge equal to about 2 for metallic gauges and even more than 50 for semiconductor gauges. In the case of a clamped diaphragm, the opposite-sign strains in the center of diaphragm and on its periphery (on the same side) are induced by pressure. For the four active arms of a Wheatstone bridge the following expression for output voltage can be easily derived: $\Delta V/V = \frac{9}{8}k(1 + \nu^2)(a/h)^2(p/E)$. This expression is only an approximation of the real characteristic of the sensor because strain gauges cannot be fixed exactly in the center nor at the periphery of the diaphragm due to its finite dimensions.

RESISTANCE PRESSURE SENSORS

Resistance pressure sensors utilizing the change of the electrical resistance of a metallic wire (12) a semiconductor element (13) with applied pressure are widely used especially in scientific and industrial laboratories for elevated and high-pressure measurements. Pressure-sensing elements, usually in the form of small-coil, double helical coil, or hairpin elements, should be strain-free mounted in a pressure chamber having direct contact with a pressure-transmitting medium, or they can be separated from the chamber using soft bellow, diaphragm, or membrane systems. The pressure-sensing element located inside the high-pressure chamber is connected with the measurement system by a special leadthrough in order to isolate it from the body of the pressure chamber (see Fig. 12). In most cases, manganin wire is used. The relative change of resistance of the manganin sensing element with pressure (typical resistance of 100 Ω) is almost linear up to 1 GPa and can be characterized by the pressure coefficient $\Delta R/Rp$ equal to $(2.2 \text{ to } 2.5) \times 10^{-5} \text{ MPa}^{-1}$. Specialized resistance bridges, modern multimeters, and strain-gauge amplifiers are successfully

Figure 12. Resistance pressure sensor with a manganin hairpin form sensing element.

used. A resistance change corresponding to pressure changes of about 50 kPa can be attained. The heavily doped bulk n -type InSb single crystal as a semiconductor pressure-sensing element is widely used too (14). This type of gauge is characterized by high (but slightly nonlinear) sensitivity to pressure and low sensitivity to temperature and to the nonhydrostatic state of the pressure-transmitting medium. Typically the resistance of the gauge is below 0.2Ω , thus it is necessary to use a four-probe measurement system for its precise determination. The mean pressure coefficient of the relative resistance of this gauge is equal to about $0.7 \times 10^{-3} \text{ MPa}^{-1}$. Carbon resistors could be also used effectively as pressure sensors at pressures below 1 GPa (15). The variation of resistance is nonlinear, but thermal properties are sufficiently appropriate. Also, thin- and thick-film resistors can be successfully applied in some cases (15). The accuracy of this type of pressure sensor is typically 0.1% to 0.2%. In general, resistance pressure sensors have a number of advantages such as small volume, long-term stability, ease of manufacture, low cost, and need for conventional methods of measurements.

CAPACITIVE PRESSURE SENSOR

Classical capacitive pressure sensors (nonsilicon devices) can be divided into two groups. In the first group, for low-pressure measurements, the elastic diaphragm pressure-sensing elements and the capacitive method of transduction with standard methods of capacitance measurement are used. In the second group, for high-pressure measurements, pressure-sensing elements are the measuring capacitors with substances whose permittivity strongly depends on pressure and weakly on temperature. Here the sensing element is an axial capacitor, filled with a specific liquid dielectric under measured pressure, or has the form of a small, parallel-plate capacitor mounted directly in the high-pressure chamber using a special low-capacitance high-pressure leadthrough. In the first group there are two possibilities. In the first, applied pressure to the diaphragm deforms its center, which moves to and from a stationary electrode and changes the capacitance of the system; or a measured pressure and a reference pressure are applied to a diaphragm mounted between two stationary electrodes and results in changes in the capacitances of two capacitors connected in series in different directions. In the second possibility (see Fig. 13), dual stationary electrodes and a diaphragm create two arms of a four-arm

ac bridge circuit. The pressure-sensing element in most cases is used as a separate element. It is prestressed and clamped during the mounting of the sensor housing. The tension obtained in this way increases the diaphragms resonant frequency and reduces the vibration error of the transducer, which is important for vehicle applications. Prestressing also tends to shorten the transducer's time constant and lower its hysteresis. In the second group of sensors a pressure-measuring liquid polar dielectric or solid dielectric (16) can be used. There are some promising materials for wider application in pressure measurements using differential methods of measurement: First, using a combination of As_2O_3 and $\text{Bi}_{12}\text{GeO}_{20}$ sensing elements with pressure coefficients $110.6 \times 10^{-6} \text{ MPa}^{-1}$ and $-102.8 \times 10^{-6} \text{ MPa}^{-1}$ and temperature coefficients $76.7 \times 10^{-6} \text{ K}^{-1}$ and $73.7 \times 10^{-6} \text{ K}^{-1}$, or using a second combination of $\text{CaCO}_{3\perp}$ and $\text{CaCO}_{3\parallel}$ with pressure coefficients equal to $213.4 \times 10^{-6} \text{ MPa}^{-1}$ and $59.0 \times 10^{-6} \text{ MPa}^{-1}$ and temperature coefficients $3.6 \times 10^{-6} \text{ K}^{-1}$ and $3.6 \times 10^{-6} \text{ K}^{-1}$. The first combination gives a quite good temperature compensation effect and pressure sensitivity of $21.3 \times 10^{-5} \text{ MPa}^{-1}$, about 10 times higher than those of the manganin pressure sensor.

INDUCTIVE PRESSURE SENSORS

In inductive pressure sensors the self-inductance of a single coil is varied by pressure-induced displacement of a ferromagnetic diaphragm located close to the coil. So the motion of the diaphragm with respect to the iron core coil changes its inductance. In another solution of the inductive pressure sensor the inductance changes are produced by the large displacement of the ferromagnetic core within a long coil caused by the motion of bellows or the displacement of a Bourdon tube. In this type of sensor there are big difficulties in compensating for the environmental effects, especially the temperature effect. Therefore the reluctance pressure sensors are used much more frequently than the inductive types.

RELUCTANCE PRESSURE SENSORS

The reluctance changes in the magnetic circuit necessary to produce our output voltage signal in reluctant sensors are in most cases obtained by one of the following: (1) Utilize the pressure-induced deflection of a ferromagnetic diaphragm located between two ferromagnetic-core coils, connected as a two-arm inductance bridge. Then, the diaphragm displacement decreases the gap in the magnetic flux path of one coil while simultaneously increasing the gap in the second coil flux path (see Fig. 14). The output voltage is proportional to the ratio of the two inductances and is almost a linear function of pressure. (2) Use a twisted Bourdon tube with a ferromagnetic plate fastened to its end. The plate together with a two-coil magnetic E-shaped core element creates a magnetic circuit with two small gaps (see Fig. 15). The rotating plate decreases the flux gap of the one coil and decreases the gap of the other coil. Coil connection and production of output voltage signal are the same as those for the solution presented in item (1). (3) Use a differential transformer system with a ferromagnetic core whose displacement depends on pressure and is generated by pressure-sensing elements such as capsules, bellows, corrugated diaphragms, Bourdon tubes, or straight-tube bulk-modulus elements (4). Utilize the changes in permeability due

Figure 13. Dual-stator capacitive pressure sensor.

Figure 14. Relative differential pressure sensor with a diaphragm as the pressure-sensing element.

to a change in stress of a specially designed straight-tube sensing element to be a fixed core in the differential transformer circuit. The circuit operation is similar to that described previously but the decreases (or increases) in reluctance path occur in the fixed core proportional to the strain deformations due to the pressure. This method is used for elevated pressure measurements.

PIEZOELECTRIC PRESSURE SENSORS

Piezoelectric pressure sensors employing natural or synthetic quartz as a piezoelectrically active material have been used since 1900. The mechanical and electrical design has now been successfully developed such that they are capable of measuring pressures as small as acoustic pressure and as high as 1 GPa. The response time of a typical sensor is on the order of a few microseconds and resonant frequencies up to about 1 MHz. Piezoelectric sensors are extremely useful in dynamic and quickly-variable pressure measurements. Quartz is very stable, with a high mechanical strength (above 2 GPa) and high modulus of elasticity. The damping is very small and shows practically no hysteresis effect. Its piezoelectric and deformation response up to 2.5 GPa in the uniaxial compressive stress state is linear and can be used at temperatures up to 500°C. The quartz sensing element is a single plate, cut from a quartz crystal in the X-cut plane. Pressure is transmitted directly to the piezoelectric element by a flat diaphragm, producing in the crystal in the x direction a strain that gives rise to polariza-

Figure 15. Relative pressure sensor with E-shaped core and a Bourdon twisted tube as the pressure-sensing element (4).

tion of the crystal with the surface charge density proportional to the strain. The total charge on the surface is $Q = d_{11}Ap$, where d_{11} is the appropriate piezoelectric coefficient of quartz equal to 2.25×10^{-12} C/N and A the area of the crystal plate surface (17). For a plate of diameter 5 mm, the charge generated by a pressure of 10 MPa is equal to 0.44×10^{-9} C. For a typical value of thickness, $h = 1$ mm, the capacitance of the crystal capacitor is about 25 pF. Connecting the leads in the form of a coaxial cable would increase this value additionally by 75 pF, so the voltage generated by this pressure would be equal to 0.44 V. As a piezoelectric sensor is designed for dynamic pressure measurement, its frequency characteristics play an important role. The resonant frequency ν_{res} of a thin vibrating plate is given by the expression $\nu_{\text{res}} = c_1/2h$, where $c_1 = (E/\rho)^{0.5}$ is the velocity of longitudinal waves in the plate and ρ the density. So for typical values of h , for $c_1 = 5.5 \times 10^3$ m/s and $\rho = 2.655$ g/cm³ the resonant frequency is approximately 2.8 MHz. The matched diaphragm and quartz crystal form a single mass-spring system. This fact and the bonding will reduce this value to less than one half. While the lower-frequency response of the quartz sensor is governed by electrical characteristics, the upper-frequency response is the result of its mechanical characteristics. The best commercially available sensors cover a wide frequency range, from about 1 Hz up to about 1 MHz. Two types of specialized amplifiers for this kind of sensor are used: the voltage amplifier and the charge amplifier (voltage-mode and charge-mode operated sensor). The construction of the sensing element makes quartz sensors sensitive to acceleration. If a sensor is mounted on an accelerating surface (this is a real situation) additional, unwanted electric signals will be generated. This can be compensated for by using within the same sensor housing an acceleration-sensitive crystal, whose signal reduces the unwanted signal generated in the pressure-sensing element (see Fig. 16). Other piezoelectric materials are used such as tourmaline (for low pressure because of its low mechanical properties), piezoelectric ceramics [barium titanate (BaTiO_3)] and ferroelectric ceramics [(Pb)(Zr)(Ti) O_3 , known commercially as PZT]. These materials have piezoelectric coefficient 100 times as great as quartz but a much smaller maximal working temperature, which is determined by Curie points (300°C for PZT and 200°C for BaTiO_3).

Figure 16. Acceleration-compensated quartz dynamic pressure sensor.

Figure 17. Potentiometric low-pressure sensor with a capsule sensing element and lever system.

POTENTIOMETRIC PRESSURE SENSORS

Pressure sensors with potentiometric transduction elements are widely used in industry because of their simple operation principle, high-level output voltage signal, low cost, availability, and sufficient accuracy. A large number of designs and configurations by many producers have been developed for different measurement requirements. The most commonly used sensing elements are corrugated diaphragms, capsules (single or multiple), and all types of Bourdon tubes. A wide pressure range is covered by these sensors, for low pressure with capsules (see Fig. 17) and for high pressure with C-shaped Bourdon tubes.

OPTICAL PRESSURE SENSORS

An increasing number of optical devices are being used for pressure measurements. Most of them are still in a semicommercial form. They can be divided into two groups: with and without optical fibers used as transducing or pressure-sensing elements (light transmission by optical-fiber systems can be used in both groups but discussion of such systems is not in this article's scope). In the first group, such phenomena as a pressure-dependent refractive index, pressure translation of characteristic spectral lines (ruby high-pressure scale), or pressure-dependent light intensity in some pressure-metric media, as well as pressure deformation followed by detection by interferometric methods, are used.

In the second group, some pressure-dependent properties of multimode or single-mode high-refractive-index optical fibers and different devices for fiber-optic systems, where pressure-dependent deformation changes the light intensity, are widely used (18). The measured pressure range for this group is from acoustic pressure (10 kPa) up to pressures as high as 1 GPa to 2 GPa. For example, Fig. 18 shows the general construction of a pressure sensor based on a straight-tube sensing element

(primary transducer) [compare Fig. 11(d)], with a differential fiber-optic linear displacement transducer (the first secondary transducer in the sensor system) mounted inside the tube to measure pressure-induced changes in its inner diameter. Two receiving fibers, either single-mode or multimode (50 μm and 125 μm) were located on the moving ends of cantilever arm of special carriage. The ends of fibers were slightly prefused to create microlenses. Exactly on opposite sides of those fibers, in the same plane, on the stationary part of the carriage, was located a third fiber that illuminated the cores of the receiving fibers. So we have an input signal of intensity I_0 and two output signals of intensities I_1 and I_2 . In the null state of the transducer the illuminations of the receiving fibers are the same. In order to obtain a response to pressure, a special electronic photosensitive device, giving a voltage signal proportional to $I_1 - I_2$ [or to $(I_1 - I_2)/(I_1 + I_2)$], was used. In the case of 10 mm inner diameter of the tube, with the distance between emitter input and receiving output fibers was approximately 0.3 mm, and with a superluminescent diode emitting light at $\lambda_c = 810$ nm with spectral halfwidth 4 nm, the sensitivity of the displacement transducer was about 1 mV/ μm , so that the sensitivity of the device was 45 $\mu\text{V}/\text{MPa}$. The overall error was estimated as no larger than 1.5% (19).

The main advantage of optic pressure measurement systems is the elimination of any electromagnetic energy transfer through hazardous spaces, for example in methane-containing coal mines or in explosive-materials storage.

SEMICONDUCTOR DEVICES AS SILICON PRESSURE GAUGES

Silicon pressure gauges based on silicon chips etched to form a thin (2 μm to 5 μm for low pressure) or thick (20 μm to 50 μm for elevated pressure) diaphragms with a diffused, ion-implanted piezoresistor or with a capacitor or other diaphragm deformation detectors are widely used in a large number of applications such as altimeters, blood-pressure gauges, tire-leak detectors, pneumatics, hydraulics, and oceanography investigations (20). The main features of silicon pressure sensors are that they can be mass-produced in a variety of ranges, which lowers the cost. They could be smart sensors, are very small, and have good linearity (1% or better), stability, and sensitivity. The sensitivity can be varied from 10 mV/kPa to 1 $\mu\text{V}/\text{kPa}$ for high pressures. Moreover, their interfacing is convenient for signal processing. It is expected that in the next decade silicon pressure sensors within the pressure range up to 200 MPa will continuously replace conventional pressure-measurement devices and within the pressure range up to 1 GPa their industrial application will be much wider. In Fig. 19 a short presentation of

Figure 18. Schematic drawing of straight-tube pressure-sensing element with differential fiber-optic linear displacement transducer and its voltage-displacement characteristics (19).

Figure 19. Illustration of the evolution of silicon pressure sensors. On the left a preprototype of sensor is shown.

the development of this kind of sensor is given. Figure 19(a) shows a schematic of the preprototype of a silicon sensor, with a metal constraint and diaphragm but with a silicon strain gauge. Its overall dimensions of about 10 mm are macroscopic. Figures 19(b) and 19(c) present the initial state of silicon sensor technology with a diffused and ion-implanted strain gauge having typical overall dimensions of about 2 mm. The typical absolute pressure sensor with a silicon diaphragm sensing element for low pressure with ion-implanted strain gauges and overpressure protection is shown in Fig. 19(c). In Fig. 20 is shown the dependence of output voltage of the transducer versus pressure, with the upper limit of measuring pressure well represented and good linearity. In the case of the output voltage graphed against elevated pressure, a large nonlinearity can be observed. The large nonlinearity and much smaller sensitivity are disadvantages of this type of sensor for high-pressure measurements. Currently produced silicon sensors have sophisticated silicon technology and can have overall dimensions of about 1 mm. Different types of deflection diaphragm detection methods are used, such as the widely used capacitive method (21) or field-effect transistor method (22), the advantage of which is the direct displacement to voltage (or current) transduction (see Fig. 21), (23). In the case of capacitance pressure sensors we have to note that stray capacitances are of the same order as the sensor capacitance. In all silicon pressure sensors, temperature compensation devices must be added to circuits.

Absolute Pressure Sensors

When the reference pressure in silicon sensors is a vacuum pressure [see Fig. 18(b)] a specific sensing element will be

Figure 20. Low-pressure response of a pressure silicon sensor with overpressure protection (22).

under the influence of absolute pressure, but the operation principle of the sensing element does not change. Sensors can easily measure absolute pressures and are widely applied in the vacuum technology industry and space investigations. There are well-established technological procedures for fabrication of such sensors (24). For absolute pressure measurements, it is important to join a silicon diaphragm perfectly for a sufficiently long time to the sensor constrained under high vacuum with no leakage through the bonding surface.

Differential Pressure Sensors

The measurement of differential pressure plays a very important role for flow-parameter measurement, that is, the mass-rate or volume-rate measurement. It is especially important in the case of natural gas transportation, for example, in the case of intercontinental and international ventures. When the pressure difference between two pressurized volumes is small and the maximum pressure does not exceed some megabars the silicon sensor pressure is applied. Differential pressure sensors have the same configuration as gauge sensors, that is, sensors for which the reference pressure is an ambient pressure at the moment the reference cavity is hermetically sealed. In differential sensors the reference cavity is connected with a volume of smaller pressures. Zero deflection of a diaphragm is achieved at equal input pressures (from both sides of the diaphragm) but equilibrium of the measurement system may occur at a some value of differential pressure. In such cases the pressure sensor output is proportional not only to a differential pressure, but to a certain degree to a static pressure as well. This last effect is the static pressure sensitivity of the sensor, which depends on the design of the sensor and material used. The shape of

Figure 21. Schematic cross section of a pressure-sensitive field-effect transistor sensor (21).

Table 2. Commercially Available Pressure Sensors

Sensing Element and First Transduction Element	Pressure Range ^a	Calibration Accuracy	Producer
Diaphragm, strain resistance gauge	0–50 MPa (G,D)	0.5%–1.0% FS	Dimisco, West Wood, MN
Silicon, stainless steel diaphragms	0–50 MPa (G)	2.0% FS	Entran Sensors & Electronics, NJ
Diaphragm, thin resistance film	0–50 MPa (A,G,D)	0.5% FS	Statham, CT
Resistance, semiconductor <i>n</i> -type InSb single crystal	0–1 GPa (G)	0.5%–2.0% FS	High Pressure Research Center, Warsaw, Poland

Metal foil, semiconductor strain gauge	0–10 MPa (A,D,G)	0.5%–2.0% FS	Sensotec, Inc., OH
Bourdon tube	0–100 MPa (G)	0.1%–1.5% FS	Cole-Parmer Instrument Co.
Diaphragm	0–50 MPa (A,D,G)	0.1%–1.5% FS	Illinois
Bourdon tube, diaphragm	0–100 MPa (D,G)	0.5%–2.0%	Dwyer Instrum. Inc., Chicago, IL
Bourdon tube	0–0.4 GPa (G)	0.5%–1.0% FS	Nova Swiss, Nova Werke AG, Effreticon
Straight short tube, strain gauge	0–1.4 GPa (G)	0.5%–1.5% FS	Switzerland
Straight short tube bulk-modulus potentiometric	0–1.5 GPa (G)	1.0% FS	Harwood Engineering, MA

^a A, absolute pressure; G, gauge pressure; D, differential pressure; % FS, % of full scale.

diaphragms, especially their deflection, can be determined using conventional methods of calculation because of the small influence of static pressure on the elastic properties of silicon. The larger influence of pressure on a differential pressure sensor is connected with the pressure effect on the electronic properties of strain-sensing elements (for example, for the diffused strain gauge on the diaphragm surface). When the pressure is large and attains some hundreds of megapascals the effect of static pressure can be so large that differential pressure is more accurately measured as the difference between two absolute or gauge pressures.

ACTUAL MARKET INFORMATION

The designing and technological processes of modern pressure sensors are now in a strong development stage. Table 2 gives actual pressure-sensor producers, types, and main metrological properties of commercially available pressure sensors.

APPENDIX. REFERENCE TABLES

Tables 3 and 4 present respectively some common units of pressure and some values of the acceleration of gravity.

PIEZORESISTIVE DEVICES

Piezoresistive devices are devices whose functioning principle is based on the piezoresistive effect experienced by certain materials upon elastic deformation (discovered by Lord Kelvin, 1856). The word “piezoresistive” derives from the Greek “piezein,” which means “to press.” The piezoresistive effect involves a change in the resistance R of an electrical conductor [$R = \rho l/A$, where ρ is the material (Ω/cm), resistivity, l the conductor length, and A the transverse section area] as a consequence of a change in their geometrical parameters (at the macroscopic level) originated by an external stimulus. In certain materials, however, an equally important part of the piezoresistive effect is due to the change in resistivity ρ .

Piezoresistive materials are not themselves able to generate an electrical signal when strained; they need to be supplied with an external voltage source. If a voltage is applied between the extremities of a piezoresistive bar whose geometry is changing, the current also changes according to the change in resistance, in accordance with Ohm’s law. In this very elementary example, the current that flows through the piezoresistive bar is the output electrical signal directly related (by means of resistance variation) to the change of an external stimulus. Since piezoresistive materials upon deformation transform mechanical energy into electrical energy, they can be employed in the fabrication of transducers to make physical sensors. Piezoresistive sensors are called *active* sensors, in contrast with *passive* sensors, which themselves generate an electrical signal when stimulated and therefore do not need to be supplied with an external voltage source (1). Active sensors need specific supply circuits depending on the transducer technology.

Piezoresistive sensors are used to perform direct measurements of dynamic and geometric parameters (2) such as acceleration, cracks, creep, deformation, displacement, fatigue, flow, force, height, level, mass, pressure, and torque.

The fabrication of piezoresistive sensors involves the use of very different materials, such as conductive elastomers, carbon fiber, pure metals, or alloys (commonly with nickel and copper). More sophisticated processes are based on thin-film, thick-film, and solid-state technology (2).

BASIC THEORY

Let R be the resistance of an electrically conducting bar in the quiescent state at room temperature. By differentiating the expression

$$R = \rho \frac{l}{A}$$

we have

$$\begin{aligned} dR &= \frac{\partial R}{\partial \rho} d\rho + \frac{\partial R}{\partial l} dl + \frac{\partial R}{\partial A} dA \\ &= \frac{l}{A} d\rho + \frac{\rho}{A} dl - \frac{\rho l}{A^2} dA \end{aligned}$$

and dividing by R we finally obtain

$$\frac{dR}{R} = \frac{l}{A} \cdot \frac{d\rho}{R} + \frac{\rho}{A} \cdot \frac{dl}{R} - \frac{\rho l}{A^2} \cdot \frac{dA}{R}$$

which reduces to

$$= \frac{d\rho}{\rho} + \frac{dl}{l} - \frac{dA}{A} \quad (1)$$

Consider now a piezoresistive bar with cylindrical geometry (see Fig. 1), to which an electric field E_l is applied along the longitudinal direction, and suppose that, upon elongation, the initial value of the piezoresistor changes to the final value (the initial values of the length, the diameter, and the resistivity change too). As a consequence of the length increase a reduction in the cross sectional area occurs too, according to Poisson’s ratio $\nu = \epsilon_d/\epsilon_l$ (diametral strain per unit longitudinal strain).

It can be easily shown that the longitudinal gauge factor is given by

$$F_l = 1 + 2\nu + \frac{1}{\epsilon_l} \cdot \frac{d\rho}{\rho} \quad (2)$$

In the same manner also a transverse gauge factor can be defined.

Values of the longitudinal gauge factor for some commonly used materials are given in Table 1.

CONDUCTIVE RUBBERS

Conductive rubbers are commonly made by loading silicone-based polymers with conducting powder (preferably graphite)

Figure 1. Piezoresistive bar to which traction is applied.

or grains of small dimensions, depending on the applications. Polymer strain gauges are largely used in robotic applications for making highly robust and compliant prototype tactile sensors that resist damage and accommodate inaccuracy during the end-effector positioning and the grasp. Different arrangements have been proposed, including row-by-column matrices protected by Mylar films (Fig. 2) or silicone rubber skin. They use polyurethane foam to increase compliance, as well as conductive rubber wires for electrical connection with the acquisition electronic unit, preferably realized in hybrid technology (5).

On applying a force to the rubber matrix (5), the contact area between the rubber increases and the resistance R decreases. The maximum useful load reaches about 454 kg. At low loads, the sensor response follows the law $R = k/F$, where $k = 4 \text{ M}\Omega\text{kg}$ and F is the applied force.

METAL STRAIN GAUGES

The most popular and reliable technology, at very low cost compared with other technologies available today, is that of metal strain gauges. The transducers are usually made with a metal

stripe a few micrometers thick (6). The length l can be much larger than the width (see Fig. 3); a typical thickness is about $5 \mu\text{m}$, and typical values of the resistance range from 120Ω to 750Ω . The metal foil grid is backed by a plastic carrier with a thickness of about $25 \mu\text{m}$. The longitudinal and transverse gauge factors are about 2 and 0 respectively. Conventional metal foils of piezoresistive strain gauges are particularly suitable for mounting on bodies on which the strain must be measured. They are also called *bonded* strain gauges (3). (*Unbonded* strain gauges are made of several conducting wires suspended between two insulating pins; they are excellent force transducers, but they are cumbersome and also difficult to fabricate.)

Bonded gauges are placed directly on the surface of the body of which the strain is to be measured. The initial dimension can be carefully reduced by etching away very small parts of the backing polymer carrier. The surface must be clean and dry to ensure good adhesion of the special glues and catalysts used (3,7). Because of its geometry, the piezoresistor is mounted with the grid parallel to the direction of the dominant strain (*longitudinal strain*), although the body can also experience a secondary strain (*transverse strain*) in the orthogonal direction.

Table 1. Resistivity and Longitudinal Gauge Factor of the Most Common Materials for Piezoresistive Sensors

Material	Resistivity ρ ($\times 10^{-6} \Omega \cdot \text{cm}$)	F_1
Silver (Ag)	1.628	3.5
Aluminum (Al)	2.828	3.3
Gold (Au)	2.4	3.7
Copper (Cu)	1.724	2.9
Iron (Fe)	10	3.2
Nichrome V ($\text{Ni}_{80}\text{Cr}_{20}$)	7.1	101
Nickel (Ni)	6.84	-11
Platinum (Pt)	10	4.4

Figure 2. Conductive rubber tactile sensor.

A particular geometric disposition of more than one strain gauge, a *rosette* [see Fig. 1(c)] is used to sense nonuniform force fields involving multicomponent strains.

Metal strain gauges are not suitable for miniaturization.

THICK-FILM STRAIN GAUGES

Thick-film strain gauges consist of special resistive inks, loaded with submicrometer conducting particles and insulating glass parts suspended in viscous organic fluids (8). They are screened and fired on ceramic substrates. The strain sensitivity is strongly influenced by the resistivity, composition, structure, and nature of the conductive grains, and by the direction of the strain with respect to the electric field. The conduction mechanism and the strain sensitivity are dominated by the tunneling effect. A longitudinal gauge factor $GF_L = 13.8$ and a transverse gauge factor $GF_T = 11.6$ have been measured. Thick-film strain gauges are preferred for high-temperature operation (350°C) and in hostile environments (2). They are not satisfactory for miniaturization.

THIN-FILM STRAIN GAUGES

Thin-film strain gauges, usually made of SnO or SiO-Cr , are deposited on ceramic substrates by vacuum processes such as evaporation and sputtering. Device miniaturization is possible, and the maximum temperature of operation reaches about $+150^\circ\text{C}$.

SEMICONDUCTOR STRAIN GAUGES

In contrast with the previous technologies, which are largely employed for the fabrication of universal strain gauges in force field measurement, semiconductor monolithic sensors are limited to pressure and acceleration measurement.

Micromachining and integrated circuit (IC) technologies allow the fabrication of microsensors and microactuators for a temperature of operation not more than $+120^\circ\text{C}$. Semiconductors experience an additional piezoelectric effect, which leads to small differences in the gauge factor $GF = 2 - K$, where 2 is a pure geometrical factor and

$$K = -\frac{1}{\epsilon} \cdot \frac{d(n\mu)}{n\mu} \bigg|_{\epsilon}$$

takes account of the semiconductor nature of the material. In this expression ϵ can be the longitudinal or transverse strain, n is the number of the charge carriers, and μ is the mobility (2).

TYPES OF PIEZORESISTIVE DEVICES

Pressure Transducers

Pressure transducers convert pressure variations into resistance variations. Both unbonded and bonded metal strain gauges, and also sputtered thin-film gauges are used for this purpose. The transducers are usually located on the back side of a membrane, and the pressure is applied to the opposite side (9).

Force Transducers

Force transducers are realized by using metal, both unbonded and bonded, and semiconductor strain gauges. Force measurements are usually performed by combining shear stresses with cantilever beams of different configurations (9).

Accelerometers

Accelerometers, based on metal bonded strain gauges and semiconductor strain gauges, convert the displacement of a mass-spring system into a variation of resistance. In the most

Figure 3. Cross section of a planar strain gauge to which an electrical potential V is applied along the width w , while a traction is applied along the length l (orthogonal to the page).

common devices, the gauges are bonded to a cantilever beam terminated with a seismic mass (9).

Torque Transducers

Torque transducers sense the shear stresses in a torsion bar as a consequence of the applied torque. Usually semiconductor and bonded metal foil strain gauges, in a cruciform arrangement, are used for this application (9).

Displacement Transducers

Displacements are measured through the deflection of a bending beam. The strain gauges are mounted to sense both the tension and the compression of the beam. The beam is deflected by a sensing shaft (9).

STRAIN SENSORS

In recent years the area of sensors has become increasingly important because of their varied applications in many areas. The term sensor is a broad terminology which encompasses a wide variety of devices. The present article deals with one such type of sensor, namely the strain sensor. The alternative term commonly used for strain sensor is strain gauge. Basically, a strain gauge is a device used to measure the linear deformation (mechanical surface strain) occurring in a material during loading. In addition to their fundamental use for measuring strains as such, strain gauges are also used for measuring other physical quantities such as pressure, load, displacement, torque, and so on by employing them as sensors in other measuring systems.

Historically (1), the development of strain gauges has followed different paths, and gauges have been developed based on electrical, mechanical, optical, acoustical, and pneumatic prin-

ciples. Among these, the electrical strain gauges have become so widely accepted that they now dominate the entire strain gauge field except for a few special applications. In its widest sense, the electrical strain gauge includes many varieties, utilizing the full range of electrical quantities, that is, resistance, reluctance, capacitance, inductance, and others. However, over the years the electrical resistance type strain gauge has become the most widely used device, and this is what is usually meant when the term strain gauge is used. In this article, the term strain gauge refers to the electrical resistance type strain gauge.

ORIGIN OF STRAIN GAUGES

The origin (1) of the strain gauge goes back to Robert Hooke (1635–1703) whose famous law states that, within certain limits, stress is proportional to strain. Later, Robert Young (1773–1829) provided a quantitative relation between stress and strain in a bar under simple tension (or compression) by his modulus of elasticity equation,

$$\sigma = E \times \epsilon \quad (1)$$

where E is the modulus of elasticity σ the stress and ϵ is the strain.

Poisson (1781–1840), a French mathematician, extended the laws of elasticity from uniaxial to two- and three-dimensional aspects which involved another well known material constant, now named Poisson's ratio. Although mathematicians of the last two centuries worked out a great deal of theory, it is comparatively only at a later stage that strain measurement has been done on a large scale. This situation undoubtedly is because of the difficulty of making precise quantitative measurements on metals whose elastic strains are extremely small.

CONCEPT OF STRESS AND STRAIN

All bodies can more or less be deformed by suitably applied forces. As a result of this, forces of reaction come into play internally. This is due to the relative displacement of its molecules. This tends to balance the load and restore the body to its original condition. The restoring or recovering force per unit area set up inside the body is called stress. The deformation or the change produced in the dimension of a body under the action of external forces is called strain. It is measured by the change per unit length (linear strain), per unit volume (volume strain), or the angular deformation (shear strain) depending on whether the change is along its length, volume, or the shape of the body.

If a bar of length L is subjected to a direct load W (Fig. 1), and the resulting change in length of the bar is ΔL , then the strain produced is given by Ref. 2

$$\text{Strain } (\epsilon) = \frac{\text{Change in length}}{\text{Original length}} = \frac{\Delta L}{L} \quad (2)$$

Strain is thus a measure of the deformation of the material and is nondimensional; it is simply a ratio of two quantities with the same unit. In practice, the extension of materials under

Figure 1. Schematic of the bar subjected to load.

load are very small. Hence it is convenient to measure strain in units of 10^{-6} that is, microstrain ($\mu\epsilon$).

BASIC OPERATING PRINCIPLE OF THE STRAIN GAUGE

The discovery of the basic operating principle (3) of the strain gauge dates back to 1856, when Lord Kelvin reported that certain metallic conductors subjected to mechanical strain exhibited a corresponding proportional change in electrical resistance. This property, namely change in resistance due to strain, is referred to as the piezoresistive effect. Generally the term *piezoresistive effect* is used in connection with semiconducting materials.

STRAIN SENSITIVITY/GAUGE FACTOR

In general, all electrically conducting materials possess strain sensitivity. The dimensionless number F is variously termed the electrical resistance–strain coefficient, the strain sensitivity factor, or the gauge factor and is expressed mathematically (3,4) as,

$$F = \frac{\Delta R/R}{\Delta L/L} \quad (3)$$

$$\text{since } \frac{\Delta L}{L} = \epsilon,$$

$$F = \frac{\Delta R/R}{\epsilon} \quad (4)$$

where R and L represent, respectively, the initial resistance and length, while ΔR and ΔL represent the small changes in resistance and length which occur as the gauge is strained. The gauge factor of a strain gauge is thus an index of the strain sensitivity of the gauge. The higher the gauge factor, the more sensitive the gauge and the greater the electrical output for indication or recording purposes.

The major milestones/events in the history of strain gauge development are indicated in Appendix 1.

FEATURES OF AN IDEAL STRAIN GAUGE

An ideal strain gauge should possess the following characteristics. It should:

- Have high strain sensitivity (gauge factor)
- Exhibit linear response to strain
- Have a very low temperature coefficient of resistance (TCR)
- Be insensitive to humidity and other ambient conditions likely to be encountered
- Have good temporal stability
- Be suitable for use as the sensor in other transducer systems where an unknown quantity is measured in terms of strain
- Have low hysteresis effect

Although in practice it is difficult to meet all the requirements of an ideal strain gauge, a great deal of effort has been expended in making a strain gauge having the characteristics close to that of an ideal one.

GENERAL CLASSES OF STRAIN GAUGES

Broadly the types of strain gauges developed over the years are

- Unbonded—wire gauges
- Bonded—wire gauges
- Bonded—foil gauges
- Semiconductor gauges
- Thin film strain gauges

The unbonded wire strain gauge consists of a strain-sensitive wire mounted on a mechanical frame whose parts can have slight movement with respect to each other. This relative movement causes a change in tension of the wire resulting in a change in electrical resistance. The electrical resistance change produced is a measure of the relative displacement or strain. This type of gauge can be made of entirely inorganic and high temperature materials, so that operation of such sensors is possible even in high dose radiation and high temperature environments.

The bonded wire/foil strain gauge also consists of a strain-sensitive wire or foil, but is entirely attached by an adhesive to the member (component) whose strain is to be measured. As the strain-sensitive wire or foil are basically electrically conducting, they have to be electrically isolated from the component (especially if the component is made of conducting material). Usually the required level of electrical insulation in these gauges is provided by the adhesive and/or insulating backing material. The commonly used adhesive and backing materials are of the phenolic or epoxy resin type, some of which may resist the use of the bonded gauges in radiation and very high temperature environments. Also, as the adhesive and backing material are in the force path, the accuracy of measurement is limited by the characteristics of these materials. Normally the force required to produce the displacement in bonded wire/foil type gauges is larger than that required in the case of an unbonded wire gauge because of the

additional stiffness of the member. The bonded wire/foil type gauge can operate in tension, compression, or bending mode. Bonded foil type strain gauge is a by-product of precisely photo-etched printed electronic circuits by photolithography process. Foil gauges have undergone intensive development and are available in many grid configurations (Fig. 2) and a variety of different foil alloys. Foil gauges are thinner than wire gauges. It is easier to make complicated grid designs with these gauges and they conform more easily to curved surface components.

Generally, wire or foil type gauges made of metal and metal alloys exhibit a gauge factor value typically about 2.0 to 5.0. They are basically low signal devices and require signal amplification. Although their signal output is small, their linearity and hysteresis characteristics are generally good.

Semiconductor gauge development resulted from the intensive research in solid-state physics relating to semiconductors. Semiconductor gauges offer higher sensitivity than wire and foil type gauges. By controlling the type and amount of dopant in the semiconductor material, the strain gauge properties can be controlled effectively making them suitable for specific applications. In the case of semiconductor gauges, gauge factors of about 10 to 120 are typical, either positive or negative. Although the gauge factor values are numerically large, they are not linear and greatly affected by temperature variations above 70°C. However, because of their high sensitivity they are attractive for detecting very small strains.

As indicated earlier, the resistance change due to strain in the case of semiconductors is generally referred to as the piezoresistive effect. On the other hand, piezoelectric type strain sensors convert mechanical strain into electrical output and are based on the piezoelectric effect observed in certain nonmetallic and insulating dielectric compounds. However, these types of strain sensors are not usually preferred for static strain measurements. In cases of strain monitoring over a prolonged period of time, better accuracy and stability can be achieved with strain gauges made of metallic alloy materials.

An important development in the field of strain gauge technology is the introduction of thin film strain gauges (5). These gauges can be made of any desirable resistor metal, metal alloy, semiconductor, or a combination of metal and dielectric (called cermet which are basically metal-dielectric composites). Thin film strain gauges are prepared mainly by vacuum deposition processes. These techniques provide the greatest flexibility to control the major strain gauge properties. It is possible to optimize specific properties by controlling the deposition conditions such as pressure, temperature, rate of deposition, and so on. Significant research has been reported in the literature regarding the evaluation of the strain gauge properties of various materials in thin film form. The extensive effort in this direction resulted in the development of special alloy/cermet films which exhibit the necessary stability, gauge factor, and resistance characteristics. Figure 3 shows the broad classification (6,7) of the strain gauges.

STRAIN SENSITIVITY DEPENDENCE

In order to have an idea of how the strain sensitivity of the material depends on other basic parameters (7), we can consider a conductor of uniform cross-sectional area A and length

L , made of a material with resistivity ρ . The resistance of such a conductor is given by

$$R = \frac{\rho L}{A} \quad (5)$$

Considering all the parameters in this equation as variables, if we differentiate and substitute in the equation for gauge factor, we obtain (after simplification),

$$F = \frac{\Delta R/R}{\Delta L/L} = [1 + 2\nu] + \left[\frac{\Delta \rho/\rho}{\Delta L/L} \right] \quad (6)$$

where ν is the Poisson's ratio of the material. In Eq. (6), the term $(1 + 2\nu)$ represents purely a geometrical effect of deformation. The term $(\Delta \rho/\rho)/(\Delta L/L)$ represents a physical effect, namely the change in specific resistance with elastic strain (which is related to number and mobility of free electrons). In fact, in metals the dimensional change (or the geometrical effect) is the major factor, whereas in semiconductors the resistivity change is predominant. Vacuum deposited thin film materials may have additional contributions to their resistivity terms, because their structure (especially grain size and separation of grains) can be significantly different from that of the common bulk material specimens.

It is important to bear in mind that a high gauge factor is not the only criterion for selecting a suitable material for fabrication of strain gauges. In addition, the material must also possess low TCR values and exhibit excellent thermal and temperature stability. The data on the strain sensitivity of commonly used strain gauge materials (metals and alloys) are provided in Table 1. Table 2 contains data of different classes of thin film materials relevant to strain gauges.

USE OF THE WHEATSTONE BRIDGE

The Wheatstone bridge is one of the most common configurations used with strain gauges. This is because the resistance change of strain gauge is very small, and precise instrumentation is required to measure it accurately. Figure 4 shows the Wheatstone bridge in its simplest form. The condition for bridge balance is,

$$\frac{R_1}{R_4} = \frac{R_2}{R_3} \quad (7)$$

Any change in resistance of the arms will unbalance the bridge and produce a voltage V_{out} across the output terminals. In strain gauge related instrumentation, usually each arm of the bridge is used as a transducer or strain gauge. The general output Eq. (4) used in these cases is the following.

$$V_{out} = \frac{F \epsilon N V_{in}}{4} \quad (8)$$

where

F = Gauge factor

V_{in} = Bridge input voltage

ϵ = Strain

N = Number of active arms of the bridge

Figure 2. Foil type strain gauge configurations. (a) Single element. (b) Two element. (c), (d), (e) Three elements. (f) Four elements. Note: (1) All dimensions are in mm; (2) backing layer thickness 0.010 mm to 0.020 mm; (3) grid dimensions vary according to the type of gauge and application.

Figure 3. Broad classification of strain gauges.

The bridge output V_{out} obtained can be suitably amplified and processed. Details on bridge output voltage measurement, variations of wheatstone bridge configurations, bridge excitation, and associated aspects can be seen in Refs. 3, 4, 6, and 9–14.

Temperature Effects

Temperature is an important interfering input for strain gauges since resistance of strain gauges changes with both strain and temperature. Also, the material on to which the strain gauges are bonded/deposited will expand or contract with change in temperature. This causes an additional error resulting in apparent strain. Therefore, in order to carry out accurate strain measurements, temperature compensation must be employed. Several methods are available to compensate for temperature effects. One such method is to use a dummy gauge which is identical to the active gauge (in the Wheatstone bridge configuration) bonded/deposited on to a piece of similar

Table 2. Various Classes of Thin Film Materials and Their Characteristics Relevant to Strain Gauges (From Ref. 8)

Type and Class Film Material	Gauge Factor F	Temperature Coef cient of F (ppm/K)	Thermal Stability
Continuous, metals	2	400	Fair
Discontinuous, metals	Up to 100	~ -1000	Poor
Continuous, metal alloys	2	~ 100	Good
Discontinuous, metal alloys	Up to 100	~ 1000	Poor
Cermets	Up to 100	200–1000	Generally Good
Semiconductors	Up to 100	~ -1500	Good in some cases

material maintained at the same temperature. The dummy gauge and active gauge are placed in adjacent arms of the Wheatstone bridge, so that the resistance change due to the temperature and differential thermal expansion will have no influence on the bridge output voltage. Although in theory this is a simple and effective way of compensating, in practice because of inevitable differences from gauge to gauge and the fact that temperature of strain sensors is never precisely the same the inference is that it is possible to achieve superior performance with strain gauges having very low temperature co-efficient of resistance. It is important to note that, for the purpose of achieving very low temperature co-efficient of resistance for the strain gauges, thin film materials technology offers greater flexibility.

Another approach of temperature compensation involves the use of special gauges whose thermal properties are matched to the particular materials on which they are to be mounted—called self-temperature compensated (STC) gauges. STC gauges include those gauges made up of two parts; one with positive response to temperature and the other having negative response, and are so proportioned that the positive and negative responses essentially cancel each other over a given temperature range. STC gauges also include single element gauges made of various metallic or alloy materials which

Table 1. Strain Sensitivity of Various Materials (From Ref. 4)

Material	Trade Name	Typical Strain Sensitivity
Copper–nickel(55–45)	Constantan	+2.1
	Advance	
Nickel–chromium(80–20)	Nichrome V	+2.2
Nickel–chromium(75–20) plus iron & aluminium	Karma	+2.1
Iron–chromium–aluminium (70–20–10)	Armour D	+2.2
Nickel–chromium–iron –molybdenum (36–8–55.5–0.5)	Isoelastic	+3.5
Platinum–tungsten(92–8)	—	+4.0
Copper–nickel–manganese (84–4–12)	Manganin	+0.6
Nickel	—	–12.0
Iron	—	+4.0

Figure 4. Wheatstone bridge configuration.

have been classified according to their temperature characteristics. Another variation of STC gauges is to produce a sensing element alloy which, when subjected to certain heat treatment and mechanical processing, will match the properties of the material on which the gauges are to be used.

For several applications the STC gauges are adequate and save the cost of an additional gauge and its associated installation and wiring. In situations when self compensation is not good enough, for example at higher temperatures, the bridge compensation with external compensation network approach can be employed. Detailed information on temperature compensation can be found in Refs. 3, 4, 6, 9, and 13–18.

Transverse Sensitivity

Ideally, a strain gauge should respond to strains of a specimen along a specific direction. But most strain gauges exhibit some degree of sensitivity to strains along directions other than the one to be measured. The transverse sensitivity of strain gauges refers to the behavior of gauges in responding to strains which are perpendicular to the primary sensing axis of the gauges. Normally, strain gauges have very low response to transverse strains. Therefore, the errors in strain measurement due to transverse sensitivity of strain gauges are generally quite small. However, if utmost accuracy in strain measurement is needed, then transverse sensitivity of the gauges must be taken into account. Also, the effects of transverse sensitivity should necessarily be considered in the experimental stress analysis of a biaxial stress field using strain gauges.

In fact, one of the important aspects of strain gauge technology is that in many applications both the magnitude and direction of the strain need to be measured. In such cases, the information on the directional sensitivity (both longitudinal and transverse sensitivity) of the gauges will be very helpful. More detailed aspects of transverse sensitivity (including the mathematical formula) and related information can be found in Refs. 3, 4, 19, and 20.

THIN FILM TECHNOLOGY FOR STRAIN GAUGES AND STRAIN GAUGE BASED SENSOR DEVELOPMENT

Although foil gauges are being used widely, in recent years thin film strain gauges and thin film strain gauge based transducers are gaining increasing popularity because of their several distinct advantages (1,21,22). Some of the important advantages (in comparison with the bonded foil/wire gauges) are, (1) elimination of the glue between the strain gauge and the straining member, (2) easier thermal compensation with minimal interference with the mechanical properties of the component material, (3) larger operating temperature range, (4) mass production with considerable cost reduction, and (5) complete freedom from external strain gauge suppliers. During the last decade, a number of companies have started adopting thin films technology for strain gauge transducers development. This clearly indicates that thin film techniques will play a leading role in strain gauge based device technology.

In view of this, a concise description of thin film deposition techniques is given next.

Thin films can be deposited by a variety of methods (23–27). The important techniques commonly employed (useful for strain sensors development) may be broadly classified into two

categories, namely, physical vapor deposition and chemical deposition methods.

PHYSICAL VAPOR DEPOSITION

The term physical vapor deposition denotes those vacuum deposition processes such as evaporation and sputtering where the coating material is passed in to vapor transport phase by physical mechanisms, that is, evaporation, sublimation, or ion bombardment.

Thermal Evaporation

In thermal evaporation, the material to be deposited (evaporant) and the substrates on which it is to be coated are placed in vacuum. The evaporant is loaded in a heating element. The required vaporization temperature is achieved by resistance heating of the filament or boat, which conducts heat to the evaporant. At that point, the material evaporates and coats everything in its vicinity. The subsequent condensation process, consisting of nucleation and film formation, is strongly dependent on the thermal energy, the rate of arrival and the incident angle of the vapor particles, as well as the physical, chemical, and thermal conditions of the receiving surface. The resistance heating approach is a very convenient method and is widely used.

E-beam Evaporation

Some materials cannot be used as evaporants as they have high melting points or because they will react with any material used to support them in the chamber, making the deposited coating impure. Many of these materials, however, can be evaporated from an electron beam gun. In E-beam evaporation (28), the material is heated by electron bombardment. By controlling the kinetic energy of the electron beam, the depth of the melt area can be controlled. As a result, the molten evaporant material does not come into contact and alloy with the crucible (supporting material). Scanning the E-beam over the surface of the melt prevents the nonuniform deposition that would otherwise occur due to the formation of cavity in a molten source. A schematic of the general vacuum evaporation system is shown in Fig. 5.

Flash Evaporation

If the evaporant is not a pure element, it will fractionate upon heating. This makes it difficult to control the stoichiometry of the deposited film. In such situations, flash evaporation, in which a fine-sized powder of the alloy is dropped at a controlled rate on to a hot 'boat', is employed. The temperature of the boat is held well above the minimum vaporization temperature of the individual elements of the alloy; thus the arriving powder grain instantly flashes off (totally vaporizing) without fractionation.

Sputtering

Besides thermal and E-beam evaporation, vapor species may also be created by knocking out the atoms or molecules from the surface of a solid material by bombarding it with energetic ions. The ejection process, known as sputtering, occurs as a result of momentum transfer between the impinging ions and the atoms

Figure 5. A schematic of the general vacuum evaporation system.

of the target being bombarded. The sputtered species can be condensed on a substrate to form a thin film. Many different materials (including alloys or compounds) can be sputtered.

Ions for sputtering may be produced by establishing a glow discharge between the target and the substrate holder. This is referred to as glow-discharge sputtering. However, in case of ion-beam sputtering, a separate ion source is utilized. Depending on the geometry of the target-substrate system and the mode of ion transport, a large number of sputtering variants have been developed (29,30). These are briefly discussed next.

Direct Current (dc) Diode Sputtering

In this arrangement, a plasma discharge is maintained between the anode (substrate) and the cathode (target). The chamber is evacuated to about 10^{-6} torr and then backfilled to the sputtering pressure with an inert gas, usually argon. A potential applied to the electrodes gives enough energy to the electrons to ionize the argon molecules, creating a plasma. The ions in the plasma near the cathode get accelerated across the potential drop of the cathode dark space, and hit the target with enough energy to eject target atoms. These target atoms spray in all directions and coat everything in their path, including the substrates. There are three factors that characterize dc sputtering with planar diode arrangement: (1) the cathode current densities and sputtering rate are low, (2) the working pressures are high, and (3) the substrates are in contact with the plasma. A schematic of the dc diode sputtering system is shown in Fig. 6.

If the partial pressure of contaminants is higher than about 10^{-5} torr, sputtering can still be induced but the deposited films will be less pure. Oxygen, nitrogen, water vapor, and other constituents of the background gas will be incorporated in the films as they are deposited. If the base pressure is low and argon is pure, the only gas present will be argon. Very little argon will be incorporated in the films, however, because argon, as an inert element, has a low sticking co-efficient. Any incorporated argon will not form compounds with the target atoms. It is also unlikely that it will alter the properties of the deposited films to any great extent.

Figure 6. A schematic of the dc-diode sputtering system.

In a diode system, bombarding ion current density and bombarding ion energy cannot be varied independently because they both depend on the cathode potential. This inflexibility occasionally presents a problem. This problem can be overcome by using a triode system.

Triode Sputtering

In this configuration, sputtering rates are increased by supplying auxiliary electrons from a thermionically emitting filament. Both the total ionization and the ionization efficiencies are increased by accelerating the electrons by means of a third electrode and injecting them into the plasma. Consequently, triode sputtering system can be operated at low pressures. With this arrangement, the bombarding ion current density and the bombarding ion energy can be varied independently. The bombarding ion current density (the plasma density) can be adjusted by varying either the temperature of the thermionic cathode or the anode potential, whereas the bombarding ion energy can be adjusted by varying the negative potential on the target (Cathode).

Magnetron Sputtering

In magnetron sputtering system, the ionization efficiency of the electrons is increased by increasing their path length by applying a transverse magnetic field normal to the electric field. Magnetron sputtering makes it possible to utilize the cathode discharge power very efficiently to generate high current densities at relatively low voltages and lower operating pressure to yield deposition rates which are higher than those in the nonmagnetron sputtering systems.

BIAS SPUTTERING

The term *bias sputtering* is used to refer to the specific process of maintaining a negative bias on substrates during sputter deposition. In this case, the film is subjected to steady ion

bombardment throughout its growth, which effectively cleans the film of adsorbed gases otherwise trapped in it as impurities.

Radio Frequency Sputtering

Direct current methods cannot be used to sputter insulating targets due to the buildup of positively charged sputtering gas ions which repel the bombarding (sputtering) ions. This difficulty can be overcome by using radio frequency (RF) sputtering. In RF sputtering a high frequency alternating potential is used to neutralize surface charges periodically. RF sputtering apparatus can be used to deposit conducting, semiconducting, and insulating films. Therefore RF sputtering has found wide applications.

Ion Beam Sputtering/Deposition

This is a relatively newer technique. Ion beam sputtering permits independent control over the energy and current density of the bombarding ions. Ion beams are used for thin film deposition in a variety of configurations (31). Compared with other thin film deposition techniques, ion beams provide a controlled, collimated flux of energetic particles that may be directed at the substrate, a target material, or a growing film.

Ion Plating

Ion plating is the result of the combination of vacuum evaporation and sputtering. In this arrangement, the source of evaporation is placed in a vacuum chamber. Opposite to this source is placed a substrate holder. The high voltage applied to the substrate generates a discharge (plasma). When the evaporation source emits vapors, the vapor passes through a glow discharge on its way to the substrates. Ion plating technique combines certain advantages of both evaporation and sputtering.

CHEMICAL METHODS

Electrodeposition and chemical vapor deposition are the two important techniques that come under this category. These methods have a limited and specific usage. Chemical methods (32) require simple equipment, and thus may be more economical. These methods, however, are often complex and difficult to control. Also, some of these techniques demand that the supporting substrate withstand high temperature; others require that substrates be exposed to various solvents. A brief description of these methods is given next.

Electrodeposition is done in three ways, namely, electrolytic deposition, electroless deposition, and anodization. In the electrolytic deposition, two electrodes and a suitable electrolyte to pass a current are required. The deposition rate is dependent on the temperature of the electrolyte and the geometry of the cathode including other parameters.

In electroless deposition, the external potential source is replaced by a chemical reduction process. The deposition rate is highly affected by the temperature of the reaction which is rather difficult to control.

The production of a coating of metal oxide or metal hydroxide by the electrochemical oxidation of a metal anode in an electrolyte is called anodization. It is achieved by maintaining constant current or constant voltage. The sticking of oxide films on the parent metal depends on the nature of the metal. These metals are often referred to as "valve metals" because of rectify-

ing characteristics of their anodic oxides. The anodic films are invariably amorphous in nature, but crystalline structure may be obtained by suitably adjusting the conditions of anodization.

Chemical Vapor Deposition (CVD)

In this method, a volatile component of coating material is thermally decomposed, or it reacts with other vapors in the vapor phase or at the hot substrate surface so that the reaction product is deposited as a thin film.

Plasma Chemical Vapor Deposition

This method is also known as plasma assisted CVD (PACVD). In this technique for producing the glow discharge, radio frequency energy is used. Because the activation energy is provided by the plasma and not by heat, films can be produced at lower temperatures than with standard thermally activated atmospheric CVD (APCVD) and low pressure CVD (LPCVD).

Almost all the methods just outlined are useful for preparing the thin film strain gauges and strain gauge based transducers. In some cases of transducer development, more than one thin film deposition technique needs to be adopted.

METHODS TO DETERMINE THE GAUGE FACTOR OF STRAIN GAUGES

Normally the gauge factor of the commercially available strain gauges will be specified by the supplier along with the other parameters such as gauge resistance, TCR, STC number, grid dimensions, backing material, temperature range, fatigue life, maximum strain limit, and creep property. However, if the user desires to have an assessment about the suitability of the gauge for the specific practical applications and also to determine the gauge factor and resistance-strain characteristics of in-house developed gauges (especially true in the case of thin film strain gauges), it is necessary to measure the strain values by some other known standard method. A brief description of these methods is given here.

The methods to measure the gauge factor as well as the resistance-strain characteristics of the strain gauges/strain gauge materials can be broadly divided into (1) mechanical and (2) optical techniques. The mechanical methods are essentially based on the bending of beams in different configurations. They include:

- Four-point bending beam arrangement
- Beam supported at both ends
- Cantilever beam arrangement
- Beam bent over hard metal rods

In the four-point bending beam arrangement (33), the beam is held between four rolling pins, two at the top and two at the bottom (Fig. 7). This allows the application of the equal and opposite couples to both ends of a beam. As a result, the beam is subjected to pure end moments. The strain experienced by the strain gauge bonded to the surface of the beam at its center can be calculated, which involves measuring the maximum deflection at the center of the beam. This deflection measurement is possible by the use of a dial gauge or linearly variable differential transformer (LVDT).

Figure 7. Schematic of the four-point bending set-up (from Ref. 33).

In the case of beam supported at both ends, it is deflected by applying a force at its center (34). The strain experienced by strain gauge that is bonded on a convex surface of the beam can be calculated by measuring the thickness, length, and deflection at the center of the beam. As already mentioned, in this case the maximum deflection of the beam at its center also can be measured using either dial gauge or LVDT.

In the cantilever technique (35), a bending moment is applied to the beam by fixing one end and loading the other end with the weights (Fig. 8). Due to loading, a strain gauge cemented to the beam at a typical distance from the fixed end experiences a strain which can be calculated by knowing the dimensions of the beam, the Young's modulus of the material of the beam (E) and the weight (W) applied at the free end of the beam. It is important to note that while measuring the length of the beam, it is the length from the center of the gauge to the point of application of the load (W) which has to be taken into account for calculating the strain (ϵ).

In an arrangement (Fig. 9) in which the beam is bent over a hard metal rod (36) the strain experienced by the strain gauge (cemented at the top surface of the beam) can be calculated by measuring the thickness (t), length (L), and deflection (d) of the beam. In this case, the maximum deflection is obviously equal to the diameter of the rod on which the beam is bent. In order

Figure 8. Cantilever set-up.

Figure 9. Schematic of the beam bent over a hard metal rod (from Ref. 36).

to subject the strain gauge to different strain values, rods of different diameters are needed.

The optical methods which are adopted to estimate the value of the strain are based on interference and diffraction phenomenon. One such method which can be employed is the diffraction method.

Diffraction Method

In this method (37), a slit with independent jaws is cemented to the test member (say a metal bar) such that its jaws are parallel as shown in Fig. 10. A laser beam is made incident on the slit. The slit diffracts the beam into various orders which are observed on the screen located at a suitable distance. Any change in the slit width due to loading will result in the corresponding change in the diffraction pattern. A tensile strain will contract the pattern, whereas a compressive strain will elongate it. Hence, the strain experienced by the strain gauge (bonded to the test member) due to loading can be calculated by making measurements on the change in the diffraction pattern produced.

APPLICATION OF STRAIN GAUGES IN OTHER MEASURING SYSTEMS

Strain gauges find application as sensors in other measuring systems such as pressure transducers, load cells, displacement measuring devices, accelerometers, position sensors, stress-strain analysis systems, and so on. A brief description of some of these measuring devices is given in what follows.

Figure 10. Schematic of the diffraction set-up to estimate the value of strain. From Sirohi R. S. and Radhakrishna H. C., *Mechanical Measurements*, 3/e, Copyright © M/S Wiley Eastern, Ltd. Reproduced by permission.

Figure 11. Block diagram of the principle of strain gauge pressure transducer.

PRESSURE TRANSDUCER

Pressure transducers are basically the electromechanical devices which are useful for a number of applications. Typical applications of pressure transducers include measurement of pressure in process industries, automobile engines, depth study in oceanography, wind tunnel experiments, gas turbine systems, hydraulic systems, nuclear propulsion systems, mining safety, and nuclear and aerospace applications. The primary function of the pressure transducer is to sense fluid pressure and provide an electrical output proportional to the input pressure. A pressure transducer essentially consists of an elastic element such as a metal diaphragm which undergoes deformation due to applied pressure. This mechanical deformation of the diaphragm is converted into an electrical response by a strain gauge bonded to it. Schematically, the functioning of the pressure transducer is shown in Fig. 11. There are three types of pressure transducers, namely, absolute, relative (gauge), and differential pressure transducers (Fig. 12).

Absolute Pressure Transducer. This measures pressure referenced to vacuum, hermetically sealed at about 10^{-5} m bar of Hg. When the pressure port is exposed to the atmosphere, the transducer will indicate atmospheric pressure; approximately 760 mm of Hg or 1 bar. This occurs because there is a vacuum on one side of the diaphragm and atmospheric pressure on the other.

Relative or Gauge Pressure Transducer. This measures pressure referenced to local atmospheric pressure and is vented to the atmosphere. When the pressure port is exposed to the atmosphere, the transducer will indicate 0 mm of Hg or 0 bar. This occurs because the pressure on both sides of the diaphragm is the same and there is no net output. Venting is accomplished by means of a small hole located near the transducer's electrical termination-connector/cable. The vent hole contains a porous, stainless steel disk designed to filter out harmful air-borne particles from entering the transducer in order to

safeguard the strain gauges from contamination, corrosion, and hence resistance/output variation.

Differential Pressure Transducer. This measures pressure differential between two pressure P_1 and P_2 as shown in Fig. 12. When both the pressure ports (P_1 and P_2) are exposed to the atmosphere, the transducer will indicate 0 mm of Hg or 0 bar. In other words, if the pressures P_1 and P_2 are the same, the net output is 0 bar. If they are not the same, then the net output will be a reading other than 0 bar.

Application of pressure results in deformation of the sensing element (diaphragm or other type of elastic sensing elements) on to which strain gauges are bonded and wired in the Wheatstone bridge configuration. The change in the output of the bridge is related to the magnitude of the pressure. Since the resistance change of the strain gauge is a function of surface strain, this strain is directly related to the applied pressure. Hence, strain gauges form an important component of the pressure transducers.

A cross-sectional view of the complete absolute type strain gauge pressure transducer assembly is shown in Fig. 13. Either

foil type strain gauges or thin film strain gauges can be utilized in these transducers. The use of thin film strain gauges for the measuring systems of this type have the additional advantage that the gauges can be directly deposited (with a dielectric film for insulation) on the diaphragm. This process enables elimination of the likely limitation of accuracy in the case of foil type gauges, because of the presence of adhesive and backing material. A schematic diagram of the thin film strain gauge pattern (38) deposited on the diaphragm is shown in Fig. 14. It

Figure 15. Strain gauge based differential pressure transducer assembly. Reproduced from Sputtered thin film strain gauges for differential pressure measurement, M. M. Nayak et al., *IEEE Trans. Instrum. and Meas.*, 45 (1) February 1996, P 335–339. Copyright © IEEE, Inc. Reprinted with permission.

is possible to obtain the required strain gauge pattern by using precision mechanical masks or photolithography technique (especially for very fine line patterns). Referring to Fig. 14, it is important to note that the location of the strain gauges is such that the gauges C_1 and C_2 at the diaphragm edge experience a compressive strain and those near the center (T_1 and T_2) undergo tensile strain. All the four gauges are made active by connecting them in Wheatstone bridge configuration. Gauges C_1 and C_2 experience compressive strain whose resistance decreases with pressure will form one opposite set of arms. The strain gauges whose resistance increases with pressure form the other set. Pressure transducers are normally calibrated using standard dead weight pressure calibration set-up.

Suitability of the pressure transducers for a specific application can be assessed from their general specifications as well as output performance characteristics such as variation of output with pressure at different excitation voltages, nonlinearity and hysteresis, stability, repeatability, temperature effects, and so on.

Similar to absolute and gauge pressure transducers, *differential pressure transducers* are made using strain gauges. A differential pressure transducer gives an output with increasing difference between two pressures, both of which may vary. Normally, the lower or less varying pressure is termed as the reference pressure or the line pressure and the other pressure is called the measured pressure. When the measured pressure is always higher than the reference pressure, the transducer has a unidirectional range. When the measured pressure is either lower or higher than the reference pressure, the transducer is said to have bidirectional range. However, in either case, the measurement of differential pressure is of great value. Figure 15 shows the schematic of the strain gauge based on

Figure 17. Four active gauges on the sensing element of the differential pressure transducer connected in the Wheatstone bridge configuration.

differential pressure transducer assembly (39). It essentially consists of an H beam configuration with a set of bellows as a sensing element. The two thin walled bellows used on either of the H beams convert the pressure difference into a linear displacement.

Figure 19. Binocular type sensing element configuration for load cell.

As in the case of an absolute or gauge pressure transducer, in this case foil type or thin film strain gauges (two gauges on either side of the beam) also can be adopted for converting the linear displacement into a proportional electrical output. Figure 16 shows the schematic of the thin film strain gauges deposited on the H-beam sensing element. The Wheatstone bridge configuration with all the four gauges active is shown in Fig. 17. Calibration of the device can be done using a standard differential pressure calibration system (Fig. 18).

LOAD CELLS

Basically the load cells are the force transducers which are used for force or thrust measurement and weighing purposes. Like pressure transducers, load cells can be made using strain gauges (3,40,41). Typical common areas of applications of strain gauge load cells include on-board weighing for trucks, postal and shipping scales, crane and laboratory weighing systems, agricultural applications, thrust measurement in static testing of rocket motors, high altitude testing systems, and others.

The construction of strain gauge load cells is based on three types of strain fields, namely bending, shearing, and direct stress. Accordingly, the different types of sensing elements are adopted in load cells. Some of the commonly used sensing element configurations are hollow cylinder, slotted-cylinder, binocular type, ring type, wheel-shaped configuration,

Figure 20. Ring type sensing element configuration for load cell.

coupled dual-beam, and cantilever beam type. A typical binocular type and ring type configuration are shown in Figs. 19 and 20 respectively. Depending on the range of load, appropriate materials and configurations are chosen for the sensing element. Also overload protection will be normally provided in load cells.

As pointed out earlier, strain gauges find application in several other measuring systems. Information on these as well as related aspects including analysis of strain gauge data can be found in Refs. 3, 6, 37, 42, and 43.

SUMMARY

Strain gauges and strain gauge based sensors/transducers find a wide variety of applications in many branches of science and engineering. In this article, most of the important aspects of strain sensors are presented. However, for some of the related aspects such as surface preparation of specimens, bonding of strain gauges, soldering and wiring, providing moisture and environmental protection, output standardization, shielding and grounding, curing and post-curing, and so on each manufacturer recommends its own standard procedures. This information is available as "Technical Notes" from the manufacturers. Some of the known strain gauge/strain gauge based transducers manufacturers are: (1) Micro Measurements, U.S.A., (2) Hottingen Baldwin Messtechnik (HBM), Germany, (3) Kulite, U.S.A., (4) Motorola, U.S.A., (5) BLH Company, U.S.A., (6) Rosemount, U.S.A., (7) Transamerica Instruments, U.S.A., (8) Kyowa Electronic Instruments, Japan, (9) Tokyo Sokki Lenkyujo Company, Japan, (10) Dynisco, U.S.A. and (11) Sensotec Inc., U.S.A.

In addition to the general applications indicated in this article, in recent years strain gauge transducers have become increasingly important in areas such as biomedical instrumentation, robotics, and space and defence applications. It is possible that the combination of advanced thin film materials technology, improved design approach for sensing elements of the transducer, and compatible signal conditioning electronics will result in the development of high performance strain gauge transducers for many more important applications.

APPENDIX 1. A CHRONOLOGY OF THE MAJOR MILESTONES IN THE HISTORY OF STRAIN GAUGE DEVELOPMENT

1856	Lord Kelvin, England
1908	Investigated the variation in electrical resistance of wires with increasing strain.
1923	S. Lindeck, Germany
1938–1945	Development of a method of measuring high pressure (800 PSI) using fine manganin wire wrapped around a copper tube.
1950	P. W. Bridgman, Massachusetts, U.S.A.
Free-rod approximation	Confirmed Lord Kelvin's results in a series of tests involving wires under hydrostatic pressure.
Thick-walled bulk-modulus type	A. C. Ruge, Massachusetts, U.S.A.
	E. E. Simmons, California, U.S.A.
	Considered as the co-inventors of the bonded wire strain gauge.
	First patent issued to E. E. Simmons on April 13, 1943.
	Subsequent patents issued to A. C. Ruge on strain gauges and transducers.
	Technograph LTD, England
	Foil strain gauge introduced using printed circuit technology.
Around 1958–1960	Introduction of semiconductor strain gauges.
Around 1970s	Introduction of thin film strain gauges.

TEMPERATURE SENSORS

TEMPERATURE AS A PHYSICAL QUANTITY

Every object or phenomenon existing in the real world may be described by a set of properties. Some of these properties are physical quantities, while others are descriptive ones. Physical quantities must be measurable. In order to make a property measurable, one has to establish a method with which to detect whether a state of a property is higher than another state, to detect if two states are the same, to propose a measure of the state, and finally to find a scale which transforms a given level of the property into an abstract symbol in the form of a number and a unit of measure. Considering temperature as a property of an object, all the problems mentioned above are rather complicated from both theoretical and practical points of view. The human sense of touch enables us to distinguish between higher and lower thermal levels, over a limited range of temperatures and with very limited repeatability, but nothing more, and there was a long way to go from our "feeling of heat" to the definition of temperature and temperature scales. The popular and often-quoted definition of temperature as an "intensity of heat" does not lead directly to solving the problem because of its lack of clarity.

Only the discovery of the fundamental laws of thermodynamics in the middle of nineteenth century allowed us to answer the question, What is temperature? The first law of thermodynamics says that thermal energy transfer is possible only from a system with higher temperature to a system with lower temperature. By observing the direction of thermal energy transfer, we are able both to tell which system is the one of a higher state of temperature and also to confirm the existence of equilibrium of temperature states when the heat transfer between two systems declines to zero. Furthermore, the works by Carnot, Lord Kelvin, and Clausius resulted in the formulation of the laws concerning the reversible thermodynamic cycle, called the Carnot cycle. The Carnot cycle consists of two isothermal heat conversion processes and two adiabatic heat transfer processes as illustrated in Fig. 1. By transferring a heat energy from the system with a higher state of temperature to a system with a lower temperature state, it is possible to transform a part of that energy (although a relatively small one) into mechanical energy. This constitutes a theoretical principle for all heat engines. The theoretical efficiency of a Carnot cycle

Figure 1. The Carnot cycle for an ideal heat engine. The arrows indicate the subsequent thermal processes.

engine is

$$\eta = \frac{Q_1 - Q_2}{Q_1} \quad (1)$$

where Q_1 is thermal energy transferred from the system with higher temperature in the isothermal expansion process, and Q_2 is thermal energy transferred to the system with lower temperature in the isothermal compression process. The theory of the Carnot cycle does not depend on the medium used, and Eq. (1) is a universal one. The engine efficiency depends only on the ratio Q_2/Q_1 and this ratio was proposed by Lord Kelvin as the basis of a new "absolute" thermodynamic measure of temperature in the form

$$\frac{T_2}{T_1} = \frac{Q_2}{Q_1} \quad (2)$$

Such a measure is independent of the thermal properties of any material and requires only one fixed temperature point to create the temperature scale. Equation (2) indicates very clearly that temperature has no physical zero point. In creating any temperature scale the zero point is to be assumed arbitrarily. That is, temperature, in the same manner as time, can be measured only by the interval scale but not by the metric scale. The point defined as 0 K is only a mathematical point on the scale but not a physical null temperature. Even in outer space we are not able to achieve physical null temperature, because the insertion of any material body changes the state of the temperature previously existing.

In Lord Kelvin's lifetime the Celsius scale of temperature had been in use for 100 years, and the temperature differences (e.g., between the ice point and the boiling point of water) had already been expressed in Celsius degrees. Gay-Lussac's gas law had also been known for more than 100 years

and expressed as

$$V = V_0[1 + \alpha(t - t_0)]_{p=\text{const}} \quad (3)$$

where V and V_0 are the volumes of an ideal gas at temperatures t and t_0 , respectively. Equation (3) proved to give results fitting quite well to the experimental results, especially for rarefied gases at low pressure, and the numerical value of the coefficient α was known with a good accuracy. Taking a Celsius degree as a unit of temperature difference, assuming the ice point of water as a point of $t_0 = 0$, and accepting particularly for these conditions an experimentally obtained value of the coefficient $\alpha = 0.003661 \text{ } 1/^{\circ}\text{C}$, we are able to create a new temperature scale, with the zero value at the point when an ideal gas volume decreases to zero (Fig. 2). The scale is now known as the absolute or Kelvin scale and is shifted by a value of $1/\alpha = 273.15$ with respect to the Celsius scale. All currently used temperature scales are in linear relations with each other:

$$\begin{aligned} T[\text{K}] &= t[^{\circ}\text{C}] + 273.15 = (t[^{\circ}\text{F}] + 459.67) \frac{5}{9} \\ t[^{\circ}\text{C}] &= T[\text{K}] - 273.15 = (t[^{\circ}\text{F}] - 32) \frac{5}{9} \\ t[^{\circ}\text{F}] &= 1.8(t[^{\circ}\text{C}] + 17.778) = 1.8(T[\text{K}] - 255.37) \end{aligned}$$

It is evident that Gay-Lussac's law is an excellent basis for developing not only the scale but also a thermometer: a gas thermometer. There is only one problem, albeit a significant one: An ideal gas does not exist. This inconvenience may be overcome either by the use of gases with properties close to the ideal gas (^4He , H_2) or by the use of rarefied gases at low pressures and by applying a very special measurement procedure. It has to be pointed out that in Eq. (3) there is an implied condition that $p = \text{const}$. In practically built gas thermometers, however, it is easier to fulfill the requirement of

$v = \text{const}$ and to observe the changes in p , instead of v . Therefore the majority of gas thermometers work on the constant volume principle.

INTERNATIONAL TEMPERATURE SCALE OF 90

In spite of the great progress in measurement techniques achieved since the days of Lord Kelvin, the use of gas thermometers is not a way to establish a contemporary temperature scale because of the great difficulties regarding their performance. Absolute Kelvin temperature according to Eq. (2) remains the theoretical definition of temperature, but the temperature scale is reproduced with the highest accuracy by means of the International Temperature Scale (ITS) established first in 1927 and recently modified in 1990. Most high accuracy industrial temperature measurement requires the production of a reproducible temperature state rather than its value in terms of its absolute temperature value. ITS-90 allows this by setting up a scale that is highly reproducible but only approximates to an absolute Kelvin scale to the limits of technology available in the late 1980s. Temperatures corresponding to that scale are sometimes marked using the subscript 90 in order to distinguish the differences with respect to the former scales (1927, 1948, 1968) and to the theoretical values of the thermodynamic scale (T [K] and t [$^{\circ}\text{C}$] with no subscripts).

The ITS-90 describes a set of fixed temperature points (17 points) and the methods of measuring the temperature between these points. Fixed points are freezing or triple points of selected materials (except Gallium's melting point). The points and the methods have been chosen to ensure, according to the actual knowledge and technology, the best conformance to the absolute temperature scale. An additional document, "Supplementary Information for the ITS-90," gives a very in-depth and exhaustive description of the instruments and the procedures which ensure the highest accuracy and traceability of

Figure 2. The meaning of absolute temperature scale and its relation to the ideal gas law. The difference between ice point and triple point of water on the temperature scale is excessively enlarged in order to enhance clarity.

Figure 3. The differences in temperatures expressed by IPTS-68 and ITS-90. (After Ref. 1.)

temperature standard measurements. Figure 3 presents the difference in temperature values expressed by the previous IPTS-68 scale and by the present ITS-90. In some ranges, especially above 630°C, the differences are really great and are mainly caused by the incorrect reference function accepted by the IPTS-68 for the type S standard thermocouple. The correction of that reference function allows us to reduce the differences. Boiling points are rejected by the ITS-90 because of their poor stability and great sensitivity to pressure. The boiling point of water is no longer a fixed point. Some differences in standard instruments and methods have been introduced, too. The most important is that the standard platinum resistance thermometer now covers a much wider range of temperatures than previously, extending from about -260°C up to the freezing point of silver $+962^{\circ}\text{C}$. Above that temperature the Planck radiation law is used as a principle for standard measurements. Thus, the PtRh–Pt thermocouple is no longer a standard thermometer (1).

Extremely complex reference functions have been defined in order to express sufficiently precisely the ratio of the resistance at a given temperature T_{90} to the resistance at the triple point of water ($T_{90} = 273.16\text{ K}$) and vice versa, to express the temperature as a function of that ratio. The convenience of computerized calculations justify the complex forms of these functions.

They are not used, however, for numerical corrections of temperature values in the industrial, microprocessor-based instruments (e.g., for linearity correction). For that purpose much simpler, yet not so accurate, equations have been developed. Equation (4) is an adequate example.

ITS-90 serves as the best approximation of a realized temperature scale to the absolute thermodynamic scale and determines a highest level of the temperature standards. In every country, several levels of temperature standards are available, which are used for comparisons and to calibrate the thermometers in practical use. The uncertainty is higher as far as the calibration of the technical thermometers is concerned, and it ranges from a few millikelvin or less at the highest accuracy level and in the medium temperature range to the tenths of Kelvin for the case of industrial thermometers and thermometers used in everyday life. The uncertainty of both standard and practical thermometers in the higher temperature range (above 650°C) is always greater. According to the general idea of the ITS-90, it is evident that some modifications are inevitable in the future.

THE GENERAL PRINCIPLES OF TEMPERATURE MEASUREMENTS

The measurement of temperature differs from the measurement of other fundamental quantities such as mass, force, longitude, or voltage not only because of the lack of physical zero point of temperature, but primarily because of the inconvenience in direct comparison of the thermal state of the system of unknown temperature with the thermal state of the standard. The temperature is an intrinsic property of a material and hence does not permit scaling in the way of an extrinsic property such as length or mass. To measure temperature it is necessary to find an extrinsic property that varies in a predictable way with temperature and use this to construct a thermometer. That is why the practical measurements of temperature are always performed indirectly. The temperature sensor interfaces with the system whose temperature is to be measured. The interface may be realized by insertion, by point contact, or by visual contact with the system (Fig. 4). The sensor converts the thermal state of a system to a determined state of another quantity, which is defined as an output signal from the sensor. The output signal is then processed in the transducer T and finally presented in numerical form as a result of the temperature measurement. However, it is not the only function that contemporary transducers perform. They are more and more

Figure 4. Temperature sensors and transducers. The outputs are arbitrarily assigned to the transducers.

frequently equipped with microprocessors and constitute a system which controls the measurement process, controls range changes, performs the numerical result correction, presents the results in appropriate units, and controls the standard interfaces such as RS 232, IEC 625, or others. Many control systems work according to the two-wire 4–20 mA standard. Therefore it happens very often that a temperature-measuring transducer provides the 4–20 mA output too, or even has an incorporated PID or on/off controller. Sometimes sensors are integrated with transducers either mechanically only or both mechanically and electrically on the same chip. At a large enough scale of integration, the term *integrated sensor* (IS) is justified. (The reading of the acronym IS as “intelligent sensor” is a commercial and marketing abuse.)

It is not the aim of this article to describe transducers but sensors. Therefore only input stages of the transducers—those stages which are directly interfacing with the sensors—will be presented. They are usually analog parts of measuring circuits, because all temperature sensors are analog devices. The principle of sensor operation depends on the physical phenomena used for conversion of temperature to the output signal. There are a lot of physical phenomena where temperature plays a significant role, but only a few of them are used in temperature sensors because they have to meet some additional requirements. These are as follows:

1. The monotonic calibration curve—that is, the relation between the temperature and an output signal over a sufficiently wide temperature range.
2. Sensitivity to temperature that is much higher than the sensitivity to all other influencing variables.
3. The output signal easily measurable with sufficiently low uncertainty.
4. Interchangeability of the sensors at least within the same type or the same manufacturing technology.
5. Repeatability of the calibration curve over the whole range of operating conditions.

Repeatability is mainly disturbed by hysteresis, relaxation, and aging. Hysteresis is observed when the calibration curve taken for increasing temperatures differs from that taken for decreasing temperatures. Relaxation means a delay in approaching the stable value of measured temperature after a rapid change in the sensor temperature. Aging is a long time process which causes the shift of the calibration curve due to many, sometimes unknown, reasons. Recalibration reduces, at least for a limited period of time, the errors caused by aging.

The linearity of the calibration curve and a large output signal are no longer essential requirements because of the progress in signal conditioning technology.

In order to produce a good sensor, the above requirements have to be fulfilled, but they are not sufficient to ensure a proper temperature measurement. The quality of temperature measurement depends to a great degree on the design of the sensor adequate to the conditions where the temperature has to be measured and on a proper measurement procedure. These two aspects are general ones, and are valid for all measurement techniques, but for the temperature measurements their importance is particularly great. It is due to the fact that every temperature sensor measures its own temperature and, more precisely, the temperature of its own sensitive part (the

thermometric body). The designer and the user of a sensor have to ensure the sameness of that temperature with the temperature which is defined as a measurand (that one which has to be measured in the given particular circumstances). For that purpose the sensor should be brought into as close thermal equilibrium with the measurand as possible without disturbing the measurand's thermal state. It requires a good thermal connection to the thermometric body and a poor thermal connection to the environment. The difference in thermal conductivity between thermal isolating and conducting materials is not very high. This involves some difficulties in design of a good thermometer and leads to measurement errors. Errors and uncertainties in temperature measurements will be discussed in more detail in the last section of this article. The problem of the thermal burdening by a sensor does not exist in radiation thermometry, but other sources of errors occur in this case.

RESISTANCE SENSORS

In all resistance sensors the change of their resistance follows the temperature changes, but the way it happens is different in metal sensors and in semiconductor sensors. It is therefore reasonable to separate the considerations about those two groups of resistance sensors. Furthermore, within the group of metal resistance sensors there is a great difference in the design of precise and industrial thermometers. This difference justifies further subdivision of the discussion.

Precise Resistance Sensors

The resistivity of almost all metals depends on temperature, but only a few of them are used in resistance thermometers: those which meet the requirements listed in the previous section. Pure platinum is considered the best material for temperature sensors. It has a relatively high resistivity (15 times greater than copper); thus wires needed to form resistors do not need to be particularly thin. Platinum can be obtained in a pure form with few impurities ensuring repeatability and interchangeability of the sensors. However, the most important reason why platinum is so widely used for temperature sensors is its ability to withstand even severe environmental conditions at high temperatures. For this reason, only pure platinum is used in the standard temperature sensors.

The progress in the technology and in the design of platinum temperature sensors achieved in the past decades made it possible to eliminate the PtRh–Pt thermocouple from the list of standard thermometers, which define temperatures according to ITS-90. Now, the temperatures T_{90} in the range between 13 K and 1233 K (960°C: silver point) are defined by the standard platinum resistance thermometer (SPRT). SPRTs are situated at the top of the hierarchical system of propagation of standards and are used as a first tie, which links ITS with all other temperature standards. They are used only occasionally for measurement of unknown temperature but more frequently for calibration purposes only. It is evident that to satisfy such high demands the quality of SPRTs must be the highest one. The purity of platinum used is secured by meeting two requirements: $R_{\text{Hg}}/R_{\text{TP}} \leq 0.844235$ and $R_{\text{Ga}}/R_{\text{TP}} \geq 1.11807$, where R_{Hg} , R_{Ga} , and R_{TP} are resistances at Hg point, Ga point, and triple point of water, respectively. These requirements are much greater than those required for industrial thermometers. In order to achieve such high values, the purity of platinum

has to be greater than 99.999%. The influence of impurities is much stronger at lower temperatures, limiting the temperature range of SPRTs. The next limitation is a very low resistance at 13 K with respect to the resistance at the triple point of water, R_{TP} (approximately one-thousandth), which makes the calibration process more complicated and results in decreasing sensitivity.

Standard resistors are always wire-wound, but the cores differ according to the temperature range. For the lowest temperatures, resistors are encapsulated in a hermetically sealed platinum sheath filled with helium under the pressure of 30 kPa. Such a design makes the sensor short and vacuum-protected as required for calibration in cryostats used for realization of ITS-90 fixed points. For higher temperatures, SPRT sensors are fixed at the end of long Inconel or quartz glass tubes, because of the necessity of providing a deeper penetration in the calibration device. For temperatures above 650°C, some special materials such as silica, alumina, or sapphire must be used. The wire diameter of high-temperature SPRTs is greater, exceeding 0.5 mm, resulting in a lower resistance of 2.5 Ω or even 0.25 Ω as compared with 25 Ω for SPRTs used at lower temperatures and wound from 0.05 mm wire.

Industrial Metal Resistance Thermometers

The industrial resistance thermometers used for measurement and control purposes in manufacturing plants, in the automotive industry, in housekeeping equipment for environmental measurements, and for many other everyday purposes are much less accurate than standard resistive thermometers. Industrial thermometers differ from SPRTs not only by design, technology, and material used, but also by the idea of its implementation. For the purposes of the ITS and of the calibration performed with SPRTs, the ratio of two resistances at two different temperatures is taken as a measure of the temperature. In “normal,” not standard, temperature sensors the value of the resistance of the thermometer becomes a measure of temperature. In other words, the output of a standard thermometer is the resistance ratio, and the output of an industrial thermometer is its resistance. The abbreviation for industrial thermometers is PRT (without “S”) or more frequently RTD (resistance temperature detector), indicating that sensors in use are not only platinum. Most of the RTDs all over the world are adjusted to the nominal value equal to 100.00 Ω at 0°C,

and hence termed as Pt-100 or Ni-100. The relationship between resistance and temperature for platinum RTDs is much simpler than for SPRTs and may be expressed in the form of the following equation:

$$R(t) = R_0[1 + At + Bt^2 + Ct^3(t - 100)] \quad (4)$$

where $A = 3.90802 \times 10^{-3} \text{ } 1/^{\circ}\text{C}$, $B = -5.802 \times 10^{-7} \text{ } 1/^{\circ}\text{C}^2$, $C = -4.27 \times 10^{-12} \text{ } 1/^{\circ}\text{C}^3$ for $t < 0$, and $C = 0$ for $t > 0$. However, it is not the equation but the values of resistances corresponding to appropriate temperatures that are the subject to national and international (IEC) standards, in the form of reference tables. Sometimes a distinction is introduced between “European” sensors with $R_{100}/R_0 = 1.385$ and “American” sensors with $R_{100}/R_0 = 1.392$. Furthermore, the uncertainties allowable for those sensors are also set in national standards, which are normally very close to the international IEC standards (Fig. 5). Standardization secures the reproducibility and hence interchangeability of RTDs, which is one of the most significant advantages of these sensors over all other temperature sensors.

It is a common practice that the repeatability of each individual sensor—especially over a limited temperature span—is in fact much better than the standard uncertainty limits. Therefore the individual recalibration of RTD sensors is recommended, because it allows further improvement of the accuracy. Due to the cost and available technical equipment, such calibration is commonly performed at one or two fixed points only. One-point calibration enables us to take into account an additive component of the difference between the nominal and the actual value of the resistor (i.e., additive error). Two-point calibration enables us to account for the sensitivity difference (i.e., the multiplicative error too). Nonlinearity error remains unknown. If the range of measured temperatures is limited (as is usually the case in practical situations), the nonlinearity of the RTDs has little influence on the total uncertainty and may be neglected. For wider temperature ranges the reference tables or appropriate $R(t)$ equations like Eq. (4) are useful for identifying the nonlinearity component and for applying it for the correction of the measurement result, together with the correction of the additive and multiplicative errors determined during the two-point calibration.

Besides platinum, some other metals and alloys are also used for temperature sensors. Nickel and copper are utilized

Figure 5. Comparison of allowable uncertainties of RTD Pt-100 after IEC Publication 751 and thermocouple type S after IEC Publication 584. Higher accuracy of resistance thermometers at lower temperatures is evident.

Figure 6. Immersion-type thermometer (a) and four types of sensors: ceramic sealed type (b), free wire type (c), thick film (d), and thin film (e). Types b and c are commonly used in industrial thermometers.

for temperature measurements over a narrow range. The sensitivity of nickel sensors is higher than that of the platinum sensors, but their nonlinearity is greater. Copper sensors are known to be extremely linear, but due to their low resistivity, it takes very long and thin wires to produce a 100 Ω resistor. Therefore, lower nominal values of copper sensors are also allowed by standards.

With the wire wound sensors two designs are usually used. In the first one the wire is bifilarly wound on a glass, quartz, or ceramic rod or pipe and coated with fired glass layer [Fig. 6(b)]. Glass other than quartz glasses is unsuitable for sensors above about 250°C as electrical insulation properties begin to deteriorate rapidly. For sensors working at temperatures above 600°C, glass is not a proper material and is replaced by alumina (Al_2O_3). The difference in the thermal expansion coefficient of core and platinum causes stress, which influences the long-term stability of the sensors. The second design is stress-free because the helical winding is placed in two holes drilled along the ceramic core and only sealed at the both ends of the core [Fig. 6(c)]. Often, two independent sensors are placed in four separate holes in the body. One of them may be replaced by the second in case of damage, or, more frequently, one serves for measurement and recording purposes while the second serves as a control. It is also very important to ensure the high shunting resistance from the internal mounting structures of the RTDs.

Sensors are protected from mechanical and chemical influences by metal tubes of different length (up to 2 m) made of stainless steel, nickel alloys, and sintered alumina and equipped with fixing elements for fastening them to the objects where the temperature should be measured [Fig. 6(a)]. The choice depends on the kind of object and the range of measured temperatures, pressures, and other environmental conditions. Because the sensor is placed at the bottom of the tube, it is convenient to lead out all the wires from one end of the sensor. In fact, this is the reason why the bifilar winding is used. It

protects against the induced noise voltage too. The best thermal contact between the sensor and the protecting tube is highly recommended.

Besides wire-wound RTDs, a group of sensors exists where a metallic layer is deposited on a flat or cylindrical core. The core material most frequently used is alumina, and a metal layer is deposited either as a thick film (5 μm to 10 μm) in a screen printing process [Fig. 6(d)] or as a thin film (1 μm) by sputtering [Fig. 6(e)]. The laser cutting provides the adjustment to the required resistance value. Sensors are coated with a thin protective layer of overglaze. Short response times of such sensors result from the small dimensions and small mass of the sensors. Long-term stability is a bit worse, and the temperature range is restricted to 500°C, but it probably will change with the advances in technology. Deposited RTDs are used in laboratory and service hand-held thermometers and in instruments requiring relatively accurate but small sensors for thermal control or correction. Psychrometric humidity sensing instruments also use deposited sensors. The electric signal which is obtained from these sensors is smaller than the one from traditional sensors because of the lower magnitudes of applied supply current.

SEMICONDUCTOR SENSORS

Semiconductor material may be used in resistance thermometers such as negative temperature coefficient thermistors, linear KTY sensors, and germanium resistance sensors used in cryogenic temperatures, but also in semiconductor devices such as diodes, transistors, and integrated circuits, the operation of which is related to the properties of p - n junction being the essential part of each semiconductor device. Classification and terminology are not established, but for the purposes of this article the distinction will be made between semiconductor resistance sensors and semiconductor active sensors.

Thermistors

Negative temperature coefficient (NTC) thermistors are prepared from a mixture of powdered metal oxides such as MgTiO_3 , MgO , CuO , NiO , and CoO , along with others sintered at the temperature of 1300°C . During that process, some p - and n -type semiconductor centers are created, thus enabling resistance–temperature relations to be described as semiconductorlike. In semiconductors, both electrons and holes are responsible for the conductivity.

$$s = \frac{1}{\rho} = \frac{ne^2\tau_e}{m_e} + \frac{pe^2\tau_p}{m_p} \quad (5)$$

where: s is the conductivity, reciprocal to resistivity ρ ; n and p are the numbers of electrons and holes in the valence band, respectively; τ_p and τ_e are their relaxation times; and m_e and m_p are their effective masses. In the semiconductors, τ_p and τ_e remain constant but n and p values change with temperature according to the relationship

$$n = p = 2 \left(\frac{kT}{2\pi h} \right)^{3/2} (m_e m_p)^{3/4} e^{-E_g/2kT} \quad (6)$$

where E_g is the energy of the band gap, and k and h are Boltzmann's and Planck's constants, respectively. From Eqs. (5) and (6) we obtain

$$\rho = CT^{-3/2} e^{E_g/2kT} \quad (7)$$

In the range of temperature in question (250 K to 400 K), the last term of Eq. (7) dominates. This fact leads to the well-known relationship between temperature and resistance of NTC thermistors in the form of

$$R = R_\infty e^{B/T} \quad (8)$$

R_∞ has a very small value and no physical interpretation. More practical therefore is the equation

$$R = R_{25} e^{B(T-25)/298} \quad (9)$$

where R_{25} is the thermistor resistance value at 25°C (500 Ω to 20 k Ω are typical values), and B is a material constant (Fig. 7). The value of B does not correspond strictly to $E_g/2k$ because many other factors influence the resistivity of the semiconductor, and additionally other mechanisms of conduction exist in the thermistor structure. Therefore the value of that constant depends on the material and manufacturing technology of the thermistor, and normally we obtain $B \approx 3000$ K to 5000 K. By describing the relative sensitivity of the thermistor in the same way as for the metal sensors, one obtains

$$S = \frac{1}{R} \frac{dR}{dT} = -\frac{B}{T^2} \quad (10)$$

from which the value of $S \approx -0.03 \text{ K}^{-1}$ at 25°C is approximately 10 times greater than that for metal sensors.

There are two principal types of thermistors commercially available. The first is the bead type, where the sintered material is formed into a bead of 0.1 mm to 1 mm diameter and sealed

Figure 7. Calibration curves of an NTC thermistor, a KTY temperature sensor, and the output voltage of linearized circuit according to Eq. (15) for temperature span -25° to $+75^\circ\text{C}$. The sensitivity of linearized NTC sensor is twice the sensitivity of KTY which does not need any linearization procedure.

in glass stick or epoxy sheath together with two platinum connecting leads. The second and cheaper type is a disk thermistor, where the metal oxides are pressed at 1000°C into the forms of disks, tablets, and bars. Disk-type thermistors are less stable and are used for temperature compensation in electronic circuits. Only bead-type thermistors may be used as temperature sensors because their stability is much better, and after annealing at 60°C repeatability level of ± 10 mK may be achieved. Unfortunately, the interchangeability of thermistors is rather poor. Both parameters R_{25} and B differ for individual thermistors, even taken from the same batch (3). This is of particular importance because of the nonlinearity of the thermistors calibration curves. The methods of matching the $R(t)$ characteristics are much more complicated for nonlinear characteristics than for the linear ones. The International Standardization Organization (ISO) has attempted to unify thermal calibration curves by introducing the so-called ISO curve thermistors. The standardization concerned the R_{25} value (0.5, 1, 2, 4, 15, 100 k Ω), the shape of the calibration curve, and the admissible limits of interchangeability (from $\pm 0.25\%$ to $\pm 5\%$ of resistance span). Such thermistors are much more expensive than the ordinary ones.

Positive temperature coefficient (PTC) thermistors are used as switching elements rather than as temperature measuring sensors, because of their bistable calibration curve.

Bulk Silicon Sensors

Extremely low doped bulk silicon material shows a different mechanism of conductivity. At temperatures above 100 K, all free electrons become ionized and the temperature influences only the relaxation times, which decrease with the increase of temperature. As a consequence, the resistivity of doped silicon increases, creating a positive slope of the calibration curve of a respective sensor. At higher temperatures, however, the process of thermally excited electrons dislocating from the valence band to the conductivity band becomes more evident and stops the increase in resistivity. The mechanism described above may be practically used only when no p - n junction is created in the bulk material. This is why a special technique of resistance measurement has to be used. The technique is based on a great difference in size between the electrodes used for the measurement.

Figure 8. The design of a KTY sensor.

One electrode is only micrometers in diameter, while the other covers the whole counter surface of the semiconductor piece (Fig. 8). This creates a great difference in the electric field density at both electrodes, and therefore only the part of the material with high field density is responsible for the measured resistance R . The relationship between the resistance and the semiconductor resistivity is given in the form

$$\rho = \frac{R}{\pi d} \quad (11)$$

where d is the fine electrode diameter.

The commercially available temperature sensors, which work according to the described principle, are known as KTY linear sensors. In fact there are two small electrodes of $22 \mu\text{m}$ diameter, and the “back side” of the bulk silicon material is coated by a conductive layer. Such a design makes the sensor insensitive to the current direction. The very precise doping control of the material is realized by means of neutron implantation in which the silicon atoms are replaced by phosphorus atoms with excellent homogeneity over the whole bulk material. The resistance of KTY sensors at ambient temperatures is about $1 \text{ k}\Omega$ to $2 \text{ k}\Omega$, their sensitivity is about $1\%/K$, and the operation temperature ranges from -50°C to $+125^\circ\text{C}$ (Fig. 7).

Active Semiconductor Sensors

Active semiconductor sensors are those whose operating principle relies on the potential barrier between the conducting layer and the valence layer in a semiconductor, as in diodes and transistors. The simplest semiconductor device is a diode. According to the Shockley theory, the relationship between current I and

voltage V in the forward polarized diode may be expressed as

$$V = V_B + \frac{kT}{nq} \ln \frac{I + I_S(T)}{I_S(T)} \quad (12)$$

where V_B is a barrier voltage, n is a coefficient (not considered in the simplest form of the theory), and $I_S(T)$ is reverse saturation current, many times smaller than forward current I , but very strongly dependent on the temperature. Every temperature increase by 10 K results in its value doubling, and this behavior determines the temperature properties of the diode. In the temperature range of 150 K to 400 K the thermometric calibration curve of the diode is nearly linear, with the negative slope of approximately 2 mV/K to 2.3 mV/K . Unfortunately the I_S value depends not only on the temperature but also on many factors hardly controllable in the manufacturing process. Therefore, the diode sensor's interchangeability is poor. A single diode is the cheapest temperature sensor, but each one has to be individually calibrated at one or better at two points. Even in that case the uncertainty, including nonlinearity and hysteresis, is at the level of $\pm 2 \text{ K}$. In order to improve the properties of diode temperature sensors, two integrated diodes fed from two different current sources I_1 and I_2 should be used (Fig. 9). The difference in voltage drop over these diodes is

$$\Delta V = V_1 - V_2 = \frac{kT}{nq} \ln \frac{I_1}{I_2} \quad (13)$$

and does not depend on the reverse saturation currents because of their similarity due to the integration. Furthermore, the output voltage bias is significantly reduced, which leads to simpler measuring circuits.

Transistors are often used instead of diodes, and the base-emitter voltage difference is the output signal of the sensor. Integrated circuit (IC) technology allows us not only to produce temperature-sensitive pairs of transistors but also to include amplifiers and signal conditioning circuits on the same chip. In this way, integrated sensors with precisely trimmed output signal can be produced. The most popular are IC temperature sensors with $1 \mu\text{A/K}$ output (e.g., Analog Devices AD592), but sensors with voltage output of 1.5 mV/K or even 10 mV/K are manufactured too. The LM75 temperature IC sensor, produced by National Semiconductor, has a silicon band gap sensing element and is equipped with a sigma-delta A/D converter, programmable alarms, and a two-wire I^2C interface. The operating temperature span of diode- or transistor-based IC sensors ranges from -55°C to $+125^\circ\text{C}$.

Figure 9. Diode and transistor temperature sensors: simple diode sensor (a), double diode sensor (b), double transistor sensor (c), and simple integrated circuit (d).

THE MEASUREMENT OF SENSOR RESISTANCE

Common Problems

The first stage of every transducer consists of the measuring circuit, directly connected to a temperature sensor. A few different measuring circuits are used to transform the resistance changes $R_x(t)$ to the output signal V . $R(t)$ forms that part of the sensor resistance which changes its value according to the measured temperature: $R_x(t) = R(t) - R_0$, where R_0 is a constant value of the sensor resistance corresponding to the reference temperature. Three problems seem to be common for all those circuits. These are (1) sensor self-heating, (2) lead resistance, and (3) linearity.

Self-heating of resistance sensors is unavoidable because the flow of the current creating the output signal causes automatic heat dissipation in the sensor, subsequent increase of its temperature, and consequent measurement error Δt :

$$\Delta t = P k_w = I^2 R(t) k_w \quad (14)$$

where k_w is a dissipation factor. The dissipation factor depends on the design of the sensor and on its materials, dimensions, and shape, but it depends primarily on the environment of the sensor. Its magnitude changes dramatically with the kind of medium surrounding the sensor and with the velocity of that medium, as presented in Table 1. Theoretically, the error due to self-heating can be removed from the measurement result by means of a correction procedure, but our knowledge about the value k_w is insufficient to calculate the correction value because of the unstability of the environmental conditions. It is sometimes possible to correct for self-heating effects by measurement at two currents and extrapolating to zero current. The best way, however, is to limit the error due to self-heating by keeping the current at the allowable level, but it results in lowering of the output signal.

The second problem is the change of lead resistances with temperature. The problem becomes serious when the distance between the sensor and the transducer reaches up to hundreds of meters and the long leads are exposed to great temperature differences (e.g., outdoor temperatures in summer and winter). For a 10 Ω copper lead the temperature change of 60 K (from -30°C to $+30^\circ\text{C}$) causes a 2.4 Ω resistance change which is observed as a 6 K temperature error if a Pt 100 sensor is used. The best way to avoid this kind of error is to feed the sensor from a current source by one pair of leads and to sense the voltage from the sensor by another pair of leads. This solution is called a four-wire line and is commonly used in transducers with standard analog 4–20 mA output and in all high

accuracy transducers. A three-wire line instead of a four-wire line is also used, especially in bridgelike measuring circuits. Three-wire installation cancels the additive errors caused by the thermal change of lead resistance, but the multiplicative part of the error remains. The higher the sensor resistance, the lower the influence of the lead resistance. There is no need to use four- or three-wire lines for thermistors or KTY sensors.

The third problem, linearity, is common for all transducers working with more or less nonlinear sensors. While most transducers are equipped with microprocessor-controlled systems, the linearity corrections are commonly performed numerically. The look-up table method is preferred. In that method, appropriate corrected values or the values of corrections which have to be added to the directly measured uncorrected results are written in memory. The linearization algorithm consists of a simple readout from the memory. At 0.1% resolution the method requires only 1 kB of memory. Some other methods of numerical linearity correction, utilizing the reduced tables containing only node point correction values, are also used. The correction data for all the results falling in between the node points are calculated by linear interpolation.

When the numerical linearization is performed together with other numerical corrections realized by the microprocessor system, the procedure becomes complicated and needs multidimensional tables. In that case the possibility of analog linearization ought to be considered. Two extremely simple methods may be used for that purpose. The methods are different in their principles, but both lead to the same results because of the same mathematical model.

The first method is based on the use of voltage controlled current sources in the structure presented in Table 2, part E. The supply currents depend linearly on the output voltage $I = I_0(1 + \alpha V)$. Linearization is performed by the proper selection of the coefficient α according to the sensor nonlinearity. The relation between V and R_x is then nonlinear and enables a successful linearization of NTC thermistors and nickel RTD sensors while choosing at positive α coefficient and of platinum RTD sensors while choosing it negative. The magnitude of α coefficient depends on the kind of the sensor and on the temperature range.

The second method is even simpler, because it does not require the voltage controlled sources. It depends on the proper choice of the Thevenin equivalent resistance R_{Th} seen from the sensor terminals, that is from the virtual terminals of the effective part of the sensor $R_x(t)$. According to such a definition of R_{Th} , the R_0 component of the sensor belongs to R_{Th} . The method is based on the theorem that any voltage between two points of each linear electrical circuit containing one variable parameter $R_x(t)$ may be presented in a form

$$U = \frac{U_0 R_{Th} + U_\infty R_x(t)}{R_{Th} + R_x(t)} \quad (15)$$

where U_0 is the voltage at $R_x = 0$, U_∞ is the voltage at the open circuit $R_x = \infty$. Some examples of linearizing circuits are presented in Table 2, A to D.

The above described methods do not lead to the canceling of the nonlinearity but only to its reduction (11). In practice more complicated circuits are used in integrated temperature measuring transducers like AD1B41 or B-B IXR 100, but the idea of linearization procedure depends on the above given principles.

Table 1. Dissipation Factors of Resistance Sensors Without Protective Sheath

Sensor	Environment	k_w (mW/K)
Wire-wound RTD ^a	Still air	3–5

NTC bead-type thermistor	Still air	1
	Stirred oil	8

^a RTD, resistance temperature detector.

^b NTC, negative temperature coefficient.

The Most Popular Measuring Circuits for Resistance Temperature Sensors

Generally the resistance sensors are manufactured with high accuracy. Transducers have to be matched to the sensors in order not to increase the total uncertainty. It is evident that for SPRTs the most accurate methods and instruments should be used for measuring the resistance and more exactly the resistance ratio. Costs and compactness are less important. The uncertainty of modern precise resistance ratio measurements is as low as a few parts per million, but only with very special apparatus used in advanced well-equipped laboratories. Such measurement circuits will be not presented here. However, with conventional temperature measuring transducers the accuracy of resistance measurements has to be high too. Let us note that according to IEC 751 standard, the Pt-100 uncertainty at 0°C is only ± 0.1 K, which means ± 0.04 Ω . In order to protect the sensor accuracy, the uncertainty of the transducer ought to be less than, say, ± 0.01 Ω , which gives 0.01% with respect to a 100 Ω sensor. For resistance-measuring instruments in common use, it is a rather high requirement and a bridge circuit is therefore the one which has to be primarily considered as the input stage of the transducer.

Balanced bridges are contemporarily used almost only in self-balancing chart recorders or x - y - t recorders. The complicated mechanical design of such instruments together with the need for the precise potentiometer, makes these instruments rather expensive. Such instruments have been formerly widely used not only in industrial applications, but also in laboratories and research. High cost and the absence of an electrical output signal (which may eventually be obtained from an additional potentiometer) make those instruments not very suitable for modern instrumentation systems.

To the contrary, unbalanced bridges are very often used as the first stages of contemporary transducers working with resistance temperature sensors [Fig. 10(a)]. The differential structure of any unbalanced bridge circuit enables easy adjustment to the desired temperature range. The output voltage is not strictly proportional to the resistance, because the unbalanced bridge belongs to the class of the circuits described by Eq. (15) and presented in Table 2 as cases B and C. Therefore, an unbalanced bridge may also be used as a linearizing circuit for some types of sensors. To do that, an appropriate matching of the bridge branches have to be performed. Unbalanced bridges are supplied either from a voltage source or from current sources. The constant current supply is preferred especially for low-resistance sensors, as Pt-100 or Ni-100, where the three-wire connection between the sensor and the transducer is needed in order to reduce the line temperature error. The reduction is twice better using a current source than using a voltage source.

The output voltage from a bridge is fed to a direct-current (dc) differential amplifier. The signal is usually high enough for a conventional low-noise operational amplifier with a proper compensation of bias currents. In some extremely precise instruments the switched-capacitor-based instrumentation amplifiers are used (i.e., Linear Technology LTC 1043). The aim of the amplifier is not only to increase the signal but also to allow the transition from differential to a single-ended signal. It is a general requirement, especially in the industrial measuring systems that the sensor must be grounded. When the three-wire configuration is used, two of them are close to ground

Figure 10. The measuring circuits which reduce the influence of the leads resistances R_L . (a) Three-wire bridge circuit makes it possible to connect one lead to the sensor and the second to the resistor in opposite bridge arm and then to reduce their influence. (b) Four-wire circuit with the current source enables canceling of the lead resistance influence. (c) The implementation of an A/D converter in the four-wire circuit provides direct conversion of the analog signal to the digital one.

potential, but according to the principles of noise protection they must not to be grounded at two points (at sensor's side and at transducer's side) in order to avoid the ground loop which introduces additional unknown voltages. The circuit with floating voltage supply and grounded one-amplifier input is less convenient because of the limitations in scaling the circuit parameters. The greatest comfort in circuit parameters scaling is provided by a four-wire installation because it consists of two almost separated circuits [Fig. 10(b)]. The only problem to solve is the subtraction of that part of voltage which corresponds to the low limit of the measured temperature. It may be done either by a bias voltage or by another differential structure containing a sufficiently stable voltage source. Integrated circuits, which incorporate a controlled gain amplifier, a linearization circuit, and isolated output (i.e., Analog Devices 1B41), facilitate the design of the measuring system. A/D converters with reference input may be used for direct four-wire connection to the sensor supplied from the voltage source instead of a more complicated current source [Fig. 10(c)].

Some completely different temperature measuring circuits—that is, circuits with frequency output, where the sensor resistance influences either the oscillator frequency or the duty cycle of square-wave output voltage—are also known. The practical implementation of such circuits are limited mostly to those in a form of integrated circuits—for example, the SMT 160-30 produced by Smartec.

RESISTIVE SENSORS FOR LOW TEMPERATURE RANGES

The range of temperatures below 20 K becomes more and more interesting not only for the researchers but also for

Table 2. Some simplified examples of linearizing circuits for resistance sensors. Circuit A (potentiometric), B (bridge circuit) and C (active bridge circuit) are for NTC thermistors or RTD nickel sensors. Circuit D (positive feedback circuit) is for RTD platinum sensor. Circuit E (with controlled current) can be used for all sensors regarding the proper sign of α coefficient. The balance state of bridge circuits is assumed at $R_x(t) = 0$, ($R_1 = R_2 = R_3 = R_0$).

 (a)	 (b)	 (c)	 (d)	 (e)

			$V = \frac{I_0 R_x}{1 + \alpha I_0 R_x}$	

the technologists. The practical use of the superconductivity requires the precise temperature measurements and control of temperatures as low as 4 K. In some cryogenic technologies the high magnetic fields and nuclear radiation are simultaneously present. Temperature sensors destined for low-temperature applications have to be resistant to those environmental conditions too. It is reasonable to distinguish a special group of sensors working at low temperatures in spite of their different principles of operation and design.

As stated before, a platinum resistance thermometer does not work properly at temperatures below 10 K. For that range a different alloy has been developed, namely rhodium with 0.5% iron (2,3). The technology of preparing thin, 0.05-mm-diameter rhodium-iron wires is complicated. It includes chemical iron deposition on powdered rhodium and then a series of metallurgical processes. The helically wound sensor is hermetically encapsulated similarly to SPRT sensors. The most useful operating range is 0.3 K to 30 K; but due to its relatively low slope of resistance versus temperature, it may be used up to the normal ambient temperatures too. The stability of an Rh-Fe sensor is relatively good, much better than that of low-temperature semiconductor sensors. Semiconductor sensors, however, are much simpler and smaller, and for that reason they are used too.

Some specially prepared and composed thermistors, usually made from iron oxide, are able to measure temperatures as low as 5 K. According to Eq. (8), thermistor sensitivity and nonlinearity increases dramatically at lower temperatures, creating problems with covering a wider range of temperatures. This is a common problem of all low-temperature sensors related to the "wrong" representation of temperatures on the linear scale, as discussed in the first section of this article. The greatest advantage of thermistors is their low sensitivity to the magnetic fields. Germanium was previously used in

electronic semiconductor devices to the same degree as silicon. The physical principles of its conductivity remain the same as those described for silicon. Germanium temperature sensors have been used for measurement purposes for a much longer time than bulk silicon sensors. Their operating area, however, is shifted toward the very low, cryogenic temperature range. The bulk germanium with a very small amount of added impurities forms a low-temperature sensor which may be used down to 1.6 K; but due to the very strong dependence of its properties on the amount of the impurities introduced, the individual calibration of each sensor is necessary. The calibration process at extremely low temperatures is always a complicated and expensive one. Other problems related to the use of the germanium sensor are (1) rapid and unexpected changes in resistance of the magnitude corresponding to a few millikelvins, (2) high sensitivity to the mechanical stress, and (3) a strong Peltier effect causing an additional heat distribution along the sensor. The instability exhibited by many low temperature Ge resistance thermometers is thought to be due to the difficulty of attaching leads in a way that defines the resistor without subjecting it to strain effects. A long-lasting experience with this kind of sensor (since 1960) has resulted in gathering a considerable amount of information, which enables us to reduce the effects of all inconveniences listed above. Specially doped germanium resistors are insensitive to magnetic fields (3).

Individually calibrated diode sensors may also be used in the very low temperature region, down to 10 K. Sensitivity is not the same as at medium temperatures, and it increases rapidly below a certain temperature (approximately 25 K for silicon diodes), but the sensor calibration curve remains repeatable with the uncertainty of ± 10 mK. Commercially available diode sensors are produced with a wider uncertainty span, exceeding ± 0.25 K but with quite good reproducibility of ± 50 mK (4).

THERMOCOUPLE SENSORS

Physical Principles

A temperature difference between two points of a conducting wire forces free electron diffusion from the point of higher temperature to the point of lower temperature. Such dislocation of electrons produces a voltage difference, which forces the electron flow in the opposite direction. In the state of dynamic equilibrium, both processes are in balance. A voltage difference caused by the temperature difference is known as thermal electromotive force (emf), and it provides a measure of temperature difference between any two points of the wire. Thermal conductivity of the metal wire causes temperature distribution along the wire, and hence the thermal emf may be considered as continuously distributed along the wire too. The problem of how to measure the thermal emf arises because each electrical contact of the connecting leads with the heated wire is also a thermal contact and generates subsequent thermal emf corresponding to the temperature difference at the ends of the connecting leads. If the materials of the heated wire and connecting leads are the same, two emfs appear in the loop with the opposite signs and are reduced to zero. However, the magnitude of the thermal emf depends on the material; and it is possible to find a pair of materials (A and B) with essentially different emfs, thereby generating relatively high voltages in the loop (Fig. 11).

By denoting the thermal emf sensitivities to the temperature of both wires as $S_A(t)$ and $S_B(t)$, one obtains

$$E_{AB} = \int_{t_1}^{t_2} [S_A(t) - S_B(t)] dt = \int_{t_1}^{t_2} S_{AB}(t) dt \quad (16)$$

where $S_{AB}(t)$ is the sensitivity of a thermocouple known as a Seebeck coefficient or “thermoelectric power.” In other words, a temperature difference produces thermal emf, and the inhomogeneity of the materials in the loop allows us to detect it. The greatest inhomogeneity appears at the contact points of two different materials. These points constitute “hot junction” and “cold junction,” or more properly, a measuring junction and reference junction. Any other material (C in Fig. 11) included in the thermocouple loop but not exposed to the temperature difference does not produce any additional emf in the loop. Otherwise, each unexpected inhomogeneity, caused not only by inclusion of any additional material D but also by chemical reactions or annealing processes in the material under temperature difference, is a source of additional thermal emf. Therefore the whole of the thermocouple loop ought to be considered as the sensor not just the tip and this makes the consideration of sources of uncertainty much different to most other temperature sensors.

The thermal emf effect discovered by Seebeck in 1821 is superposed by two other effects related to the current flow in the

Figure 11. Temperature difference measurement by a thermocouple circuit. Temperature difference $t_m - t_0$ corresponds to the emf difference Δemf .

Table 3. Thermocouple Data

Type	+Wire	−Wire	Long-Time Temperature Span (°C)	Short Time Allowable Temperature (°C)	Thermal emf Span at 0°C Reference Junction (mV)	Allowable Uncertainty (IEC)				Properties

E	NiCr	CuNi	−270 to +700	1000	−9.8 to +76.4	1.5	3.2	2.5	6.75	High thermal emf, also at low temperatures.
—	WRe5	WRe26	0 to +2400	2700	0 to +40.7	No standards				For highest temperatures. For neutral and reducing atmospheres only.
—	NiCr	Au	−273 to 0	—	−5.3 to 0					Linear for low temperatures, also below 4.2 K.

loop: (1) Thomson effect and (2) Peltier effect. In the Thomson effect an additional emf is induced by current flow in the presence of a temperature difference in the conductor, involving heat liberation or absorption by the conductor at the rate

$$Q = \int_{t_1}^{t_2} S_{TA} I dt \quad (17)$$

where S_{TA} is a Thomson coefficient of the particular material A. For the same reason as with Seebeck effect, the Thomson emf in the whole loop is different from zero only in a case when two different materials make two branches of the loop. The Peltier effect reveals in the additional heat absorption or heat generation forced by the current flowing through a junction of different materials $Q_P = V_{PAB} I$, where V_P is called the Peltier coefficient (Peltier emf).

Three effects described above are interrelated according to the equation

$$E_{AB} = V_{PAB}(t_1) - V_{PAB}(t_2) + \int_{t_1}^{t_2} S_A(t) dt + \int_{t_2}^{t_1} S_B(t) dt \quad (18)$$

Because of the low currents flowing in the temperature-measuring thermocouple loops, the effects of additional heat emitted in the Thomson and Peltier effects may be normally neglected.

Thermocouples

It is evident that a thermocouple has to be composed of thermowires with very different thermal emfs. In measurement practice, however, a lot of additional requirements are of a great importance. Most of them stem from the fact that thermocouples are usually used at high temperatures. Therefore the wires themselves have to be resistant to high temperatures. Their

melting points must be at least by 150 K higher than the upper temperature of the measuring range. At high temperatures the atmosphere is usually corrosive and hence much more aggressive than at low temperatures. The degeneration of the lattice structure and the chemical changes observed at the surface of the wires cause the inhomogeneity of the wire materials and lead to the successively arising measurement errors. This is a reason why thermocouple wires are rather thick, and the upper temperature limit for continuous work case depends on their diameters. The cost of wires, especially those made of noble metals, is important too. Very special alloys have been developed in order to meet the above-mentioned requirements. The work in this area is still going on, and the result has been continuous improvements and modifications of the thermocouple wires. Table 3 presents the most popular thermocouples and their essential properties.

The calibration curves of some thermocouples are subject to standardization in the form of reference tables, similar to the corresponding tables for resistance sensors. Worse stability of thermocouples results in their much greater uncertainties as compared to resistance sensors (see Fig. 5). When a lower uncertainty is required, the individual calibration of thermocouples is not recommended because the validity of the results is rather short-lived.

Thermocouple Sensors

A great variety of thermocouple sensors with different sizes and designs are destined for a wide range of applications, such as power plants, nuclear plants, metallurgy, chemical reactors, and the glass industry, as well as laboratories, research works, and communal applications (5).

Industrial-immersion-type thermocouple sensors look like thick resistance sensors because they are manufactured in a similar form, with a long protective pipe and a head on one

end. The sensor element (wires with the junction) are mounted inside and may be replaced if necessary. However, the materials used for shields differ considerably. For high-temperature sensors a conventional carbon steel protective pipe is insufficient. Either stainless steel (18% Cr, 8% Ni), inconel (NiCr, 15% Fe), hastelloy, or bronze has to be used depending on the environmental conditions. Sometimes there is a need for molybdenum or tungsten sheath (for highest temperatures). Noble metal thermocouples have to be additionally protected by means of an internal ceramic (alumina Al_2O_3) coating, against the contamination of the thermocouple wires by the particles of pipe material that occurs at high temperatures. Some outer porous ceramic protection tubes are used with the sensors for open fire furnaces.

A special type of sensor is produced in the form of a metal shielded double thermowire cable with MgO or Al_2O_3 insulation. These are called shielded thermocouples or mineral insulated metal sheathed (MIMS) sensors. The same type of insulation is used in resistance heaters. The thermocouple junction is formed by connecting the both wires. The external diameter of the MIMS may be as low as 0.25 mm (more commonly 0.6 mm to 3 mm), and the bonding radius allowed is normally twice that of the diameter. This constitutes a great advantage of the sensor, being an ability to penetrate hardly accessible spots. This kind of sensor is now obtainable in lengths of up to a tenth of a meter, with the sensing junction, as well as the plug on the opposite end, formed and sealed by the manufacturer. Former MIMS were produced in a form simply cut from one piece of cable, but the hygroscopic properties of the insulation material made it very hard for the user to provide the proper hermetic sealing.

The next group of thermocouple sensors are those designated for the measurements of moving surface temperatures and designed as free thermowires or thermostrips, either suspended on elastic arms or shaped into a form of an elastic arch. The measuring junction is situated in the middle of the free part of the thermostrips and should be pressed to the surface during measurement. The smoothness of the thermojunction allows the measurement of the moving or rotating elements without heat generating by friction. The elasticity of the sensor ensures a good thermal contact with the surfaces of different shapes (e.g., with rollers of different diameters).

In metallurgy, two kinds of immersion-type sensors are commonly used for measurement of the molten metals temperature. Both kinds work under the transient state conditions. The construction must be strong enough to pierce the layer of the blast furnace slag. In the first design, two sharp-cut thick bars from thermocouple materials are placed near each other at the end of a long handle. The stick is immersed in the molten metal, thereby creating a junction. In the second design the

exchangeable cap with very thin thermocouple wires (50 μm to 100 μm) and a protective cover is placed at the end of the handle. The cover is damaged when immersed in the molten metal, and after each measurement the cap is replaced by the new one.

Many other thermocouple sensors are present on the market or are custom-designed for particular purposes. The use of a thermocouple sensor instead of another sensor type is recommended in a case when most important are (1) high temperature range, (2) small dimensions of the sensor, and (3) relatively low cost.

Thermocouple Measuring Circuits

At a first glance, the task seems to be easy: Create a reference junction and measure a dc voltage. However, some problems arise particularly in the industrial environment and at high temperatures. In the large area plants the distance between the sensors and the transducers is long, and at high temperatures the sensor head temperature is usually unstable to such a degree that it is impossible to treat it as a reference junction. Therefore, the thermocouple wires have to be brought to the place where the temperature is constant, say in the transducer (6,7). For evident reasons it is not a good solution, especially if noble metal wires are used. In such a case, extension wires are used as a connection between the sensor head and the reference junction. These are special compensation leads having the same thermal emf as the thermocouple wires, but with a much lower temperature range, namely that expected to occur at the sensor head (Fig. 12). Compensation leads have to be matched to the thermocouple; and in order to avoid misconnections, the colors of their insulation are subject to standardization. Compensating wires are much cheaper than thermocouple wires. A special noble metal thermocouple has been developed (Type B, Table 3), which does not require any compensation leads because its thermal emf at temperatures up to 50°C is practically equal to zero and with temperatures up to 120°C it is very low. For that thermocouple, neither a reference junction nor the compensating leads are needed, assuming that the ambient temperature of the transducer and the sensor head temperature do not exceed 50°C and 120°C, respectively.

For all other thermocouples, however, the reference junction is necessary. In laboratory practice ice-water baths, and in industrial measurements, thermostats may be used. Both are impractical. Instead of stabilizing the temperature of a reference junction, it is more convenient to measure it and to introduce a compensating voltage into an emf measurement loop. Such a method is now used in almost all instruments and transducers. The most common compensating circuit is shown in Fig. 12. At nominal temperature of the reference junction (say 25°C),

Figure 12. Basic thermocouple circuit with compensating leads which eliminate the influence of the head temperature variations and with reference junction temperature compensation circuit. Resistances R and supply current I are matched according to the type of the thermocouple.

$R(t) = R$ and $V_C = 0$. As the reference temperature increases, $R(t)$ increases accordingly, producing a compensating voltage V_C , equal to the change of the thermal emf corresponding to the difference between the actual temperature and 25°C. The supply current I is matched according to the sensitivity of particular thermocouple. There exist also a great number of integrated circuits for compensation of the reference junction temperature where a diode sensor is used instead of the temperature-sensitive resistor (i.e., Linear Technology 1025). The amplification of a thermocouple signal, together with the reference junction compensation and with some additional functions, is performed by integrated circuits such as Analog Devices AD594, or Linear Technology LTK001.

A method of reference junction voltage correction instead of compensation is also used. It is based on the measurement of the reference junction temperature (for example, by means of a semiconductor sensor), followed by a numerical calculation of the correction value. There is also a common need for the numerical correction of a result in all instruments working with thermocouples, because of the nonlinearity of these sensors. The correction is usually performed by the look-up table method described before.

Another problem is caused by the noise superposing on a relatively weak dc signal transmitted over long compensating leads. In order to avoid the electromagnetically induced voltages, the wires in the compensating leads should be twisted. The protection against the common mode noise is provided by shielding the wires and connecting the shield to a guard terminal of the instrument or transducer. In this way the current flowing through the stray capacitance between the leads and the supply power lines or induced by any source in the grounding loop is shunted and does not affect the measured voltage. The noise voltage may also be suppressed by filtering of the output signal.

A very successful method eliminating all problems due to long compensation leads is to place the whole transducer in the thermometer's head. The current developments in electronic components technology enables design of the compact and temperature-resistant transducers comprising all compensating and linearizing elements and delivering the standard 4–20 mA output signal. Many companies offer such a solution now, and this design seems to be very promising for all immersion-type thermocouple thermometers.

QUARTZ TEMPERATURE SENSORS

The piezoelectric properties of quartz crystal (SiO_2) are applied in the design of extremely precise, stable, and relatively cheap oscillators. The applications of those oscillators are very widespread, from counters and frequency meters to precise timers in clocks and computers. The most important requirement for all those purposes is temperature stability. It is achieved by appropriate cut of the oscillator plate from the quartz crystal. For temperature-invariant oscillators the so-called AT cut is used with the cutting plane inclined to a z axis (optical axis) of the crystal at $+35^\circ$. Any other cut results in a smaller or greater dependence of the oscillator frequency on the temperature. This very property is used in quartz temperature sensors. A plate obtained by a Y cut with the inclination of -4° called HT cut has the highest value of temperature coefficient. The relation between the frequency and temperature may be

Figure 13. An equivalent circuit of a piezoelectric resonator. C_0 is a geometrical capacity between two electrodes and L_1 , C_1 , R_1 are quartz plate parameters which depend on its mechanical properties. C_L is a load capacity for tuning of the resonance frequency.

written as

$$f(t) = f_0(1 + 90 \times 10^{-6} \Delta t + 60 \times 10^{-9} \Delta t^2 + 30 \times 10^{-12} \Delta t^3) \quad (19)$$

where f_0 is frequency at temperature $t = t_0$ and $\Delta t = t - t_0$. The third and the fourth terms in parentheses introduce nonlinearity, which in this particular case is a great disadvantage because a conventional frequency meter cannot be used as a temperature indicating instrument. Therefore, the LC cut, instead of the HT cut, is used for quartz temperature sensors. The LC cut of a quartz crystal with the cut plane inclined at $+11^\circ 10'$ to the x axis and at $+9^\circ 24'$ to the z axis forms an oscillator with frequency linearly depending on the temperature but with a lower sensitivity (35×10^{-6} 1/K instead of about 100×10^{-6} 1/K with HT cut).

A quartz plate with two electrodes forms a resonator which may be presented in the simplest form as an equivalent electrical circuit, as shown in Fig 13. In the circuit, C_0 is a geometrical capacity between two electrodes and L_1 , C_1 , and R_1 are quartz plate parameters, which depend on its mechanical properties. Two resonance frequencies exist for this circuit: Serial resonance frequency $f_S = 1/2\pi\sqrt{L_1 C_1}$ and parallel resonance frequency $f_G = 1/2\pi\sqrt{L_1 C_E}$, where $C_E = C_0 C_1 / C_0 + C_1$. Both frequencies have close values, because the capacities C_1 and C_E are of the same order. Using of an additional load capacity C_L , the resonance frequency of the plate may be tuned in a limited range between f_S and f_G . Two opposite surfaces of the resonator are coated with thin gold layers. The resonator is mounted in a hermetical case protecting it from atmospheric air moisture. Spring contact elements ensure a low level of mechanical damping. The oscillator frequency f_0 depends on the dimensions of the resonator. It is very convenient to adjust that frequency to such a value that the relationship between the frequency and the temperature may be obtained by simply shifting a decimal point on the frequency meter. Hence if the sensitivity coefficient α is equal to 35×10^{-6} 1/K, the condition is fulfilled for $f_0 \approx 28.6$ MHz, because in that case $f_0 \alpha = 1000$ Hz/K. The tuning feature of the oscillator allows us to meet the above requirement in spite of some differences in individual plates parameters (3). The connection between the sensor and the oscillator must be performed by high-frequency coaxial cable. By the use of frequency meters with high resolution, high resolution of temperature measurements may be achieved too. Much better solution, however, is application of a differential structure of the measuring circuit (Fig. 14) where a mixer forms a low-frequency signal Δf , which corresponds to the difference between the measured temperature t and a reference temperature t_0 : $\Delta f = f - f_0 = f_0 \alpha (t - t_0)$. In such a state the resolution of the frequency meter may be much more

Figure 14. The differential structure of a quartz thermometer.

effectively used. Taking as an example the temperature range from 0°C to 200°C, the value of $f_0\alpha$ equal to 1000 Hz/K, and the 61/2 digit resolution of the frequency meter (which is a common practice), a 0.1 mK temperature resolution is achieved. This extremely high resolution is a reason why quartz thermometers are commonly equipped with two sensors allowing the measurement of temperature difference. In many practical cases, it is not the absolute value of temperature but the difference of temperatures that has to be known with a great accuracy. A double quartz thermometer is an excellent instrument for this purpose. Please note that the meaning of the term “absolute value” is used here differently than “absolute temperature scale.” The uncertainty of the quartz thermometers depends primarily on aging and relaxation. Single-point recalibration from time to time and avoidance rapid temperature shocks are therefore highly recommended. With these conditions met, the uncertainty of ± 50 mK may be sustained for a long time.

RADIATION THERMOMETRY

The principle of radiation thermometry is the measurement of the thermal energy emitted by radiation from the object under inspection. It is not the whole energy that is measured but only its very little part, corresponding to the radiation focused on the radiation-sensitive element placed in the thermometer. The essential difference between the radiation thermometry and all other methods of temperature measurements is the lack of the thermal equilibrium between the object and the sensor. With radiation thermometry the only way of thermal energy transfer from the object to a sensor would be electromagnetic wave propagation in the range from ultra-violet radiation (0.2 μm wavelength) through visible spectrum (0.38 μm to 0.78 μm) up to far-infrared radiation (50 μm). Thermal energy transfer does not lead to equalizing of the temperatures but only excites the sensor. The excitation level, and consequently the output signal of the sensor, depends on the portion of the received energy. Proper design, together with the proper use of a radiation thermometer, ensures a strictly defined dependence of that portion of energy and the temperature of the object. All other object properties and radiation parameters such as emissivity, dimensions, the distance to the sensor, atmosphere composition and temperature, and radiation of other objects including the thermometer body and many others, either have to be kept at the same level as during the thermometer calibration or must have no influence on the sensor. These requirements seem to be more serious than in conventional thermometers since they are related to the environment in which the measurement is performed, rather than to the sensor and the instrument themselves.

In order to answer the question of how to meet the above requirements, some essential properties of thermal radiation have to be considered. The spectral density of heat energy emitted by a black body is given by Planck's law

$$M(\lambda) = C_1 \lambda^{-5} \frac{1}{e^{C_2/\lambda T} - 1} \quad (20)$$

or in a simplified (but sufficient for our discussion) form of Wien's law

$$M(\lambda) = C_1 \lambda^{-5} e^{-C_2/\lambda T} \quad (21)$$

In both equations, $C_1 = 37.4 \text{ mW} \cdot \mu\text{m}^4/\text{cm}^2$ and $C_2 = 14,388 \text{ K} \cdot \mu\text{m}$. The lower the temperature of the radiation source, the longer the wavelength of the emitted radiation (Fig. 15). The product of the temperature and the wavelength corresponding to the maximum of spectral density remains constant, according to Wien's law of displacement: $T\lambda_{\text{max}} = 2899 \text{ K} \cdot \mu\text{m}$. The measurement of low temperatures requires the use of the sensors and of the methods which detect the radiation in far-infrared spectrum.

Figure 15. Spectral heat radiation density. Dotted line indicates the Wien's law. After Ref. 8. The radiance energy declines dramatically with the temperature. It is the main reason why low temperature radiation thermometers were developed many years later than high temperatures ones.

The total thermal energy emitted by a surface of a black body with the area F is an integral of the Wien's equation:

$$E_{BB} = F \int_0^\infty M(\lambda) d\lambda \quad (22)$$

The black body is defined as an object which does not reflect thermal radiation and therefore, according to Kirchhoff's law of radiation (absorptive power = emissive power), emits the whole radiant energy relative to its temperature. The emissivity factor ϵ of a black body is equal to 1. To simulate a black body (e.g., for the calibration of radiation thermometer), a closed cavity with a relatively small aperture may be used. The inner surface of the cavity has to be specially shaped. In the radiation thermometry practice, only some objects (such as a hearth of a furnace) may be treated as black cavities. All other objects, and especially all objects in the air, have the emissivity ϵ smaller than 1, and their radiation density has to be multiplied by ϵ . The magnitude of emissivity depends on the material, surface finish (polishing, oxidization, roughening, deadening), its temperature, incident and viewed angles of heat flux direction, and polarization of radiation. Furthermore, the emissivity depends on the wavelength too. Therefore, the whole heat energy emitted by a uniform surface F observed by the radiation thermometer may be expressed as

$$E = F \int_0^\infty \epsilon(\lambda) M(\lambda) d\lambda \quad (23)$$

where $\epsilon(\lambda)$ is usually known with a very poor accuracy.

Next we take into consideration the properties of the atmosphere that the radiation is passing through. Application of radiation thermometers with high-temperature objects is always disturbed by the presence of smoke and dust particles absorbing the radiation. The blow of purging air is used to clear the optical path between the object and the thermometer and to protect the optical parts from contamination with dust. Nevertheless, the outer surface of the instrument optics has to be cleaned from time to time.

In measurements performed in open air the concentration of absorbing gases is considerably lower, but the distance between the object and the instrument is much greater so the absorption plays a significant role too. The contents of CO, CO₂, and water vapor in the air are most significant. The spectral distribution of the absorption caused by these gases is not uniform and shows extremely great variations. Only two bands of thermal radiation wavelength may be indicated as almost free from absorption. These are 3.5 μm to 4.5 μm (near atmospheric window) and 8 μm to 13 μm (far atmospheric window). Hot gases disturb the measurement process by their own radiation too. According to Kirchhoff's law, the spectral distribution of emissivity is the same as the distribution of absorption, and it declines in the spectral ranges of atmospheric window. For these two reasons, it is highly recommended that radiation thermometers operate within one of those windows.

Considering the spectral disturbances, two additional aspects must not be overlooked: (1) the spectral transmittance of the materials used for optical parts of the thermometers (lenses, windows, and filters) and (2) the spectral sensitivity of radiation detectors. Glass optic elements may be used in the range of visible and near-infrared radiation up to 2 μm

wavelength that corresponds to measured temperatures over above 500°C. Quartz lenses enable slight widening of that range (up to 3.5 μm). For these thermometers, however, which cover a much lower temperature range, very special materials have to be used. These are ZnSe (0.6 μm to 16 μm), GaAs (1.2 μm to 12 μm), or CdTe (1.7 μm to 25 μm) and some other materials, such as Chalcogenid, KRS-5, or specially prepared ZnS. All of them (except ZnSe) are not transparent to visible light, and therefore the optical path for visual radiation must be simultaneously used to aim at the target.

Infrared Radiation Detectors

Two groups of infrared (IR) detectors are presently used in radiation thermometry. These are thermal detectors with low but spectrum-independent sensitivity and semiconductor photon detectors (IR diodes and IR photovoltaic sensors), much more sensitive but working in the limited spectral zones. Thermopiles, bolometers, and pyroelectric detectors are the thermal detectors.

Thermopiles consists of a large number (of up to 66) of thermocouples with hot junctions concentrated on a small surface and exposed to the thermal radiation flux, along with reference junctions kept at a temperature close to the ambient temperature (Fig. 16). The thermocouple materials are Bi-Sb or Ag-poly Si, with a hot junction deposited on a very thin (0.7 μm to 1 μm) silicon membrane isolated with an SiO₂ layer and with a reference junction deposited on bulk silicon material, which forms a frame around the membrane. A low thermal conductivity of the thin membrane secures proper thermal insulation between hot and reference junctions. The detector is fabricated by Micro Systems Technology (MST) and may be integrated with signal conditioning elements or even A/D converters on one chip with dimensions not exceeding a few millimeters. These thermocouples possess a very high thermoelectric power of approximately 100 $\mu\text{V/K}$, comparing with a few $\mu\text{V/K}$ for conventional metal thermocouples. This ensures high sensitivity of the detector expressed in volts per watt of thermal energy:

$$S_D = \frac{V_{\text{out}}}{E} \quad (24)$$

Thermal noise is the factor limiting the possibilities of thermal energy measurement. The Johnson noise equivalent voltage is given by

$$V_N = 2\sqrt{kTR\Delta f} \quad (25)$$

where k is Boltzmann's constant, R is the detector resistance, T is the detector temperature, and Δf is the bandwidth of the associated amplifier, determined either by the chopper frequency or by the detector speed. Substituting Eq. (24) in Eq. (25), one achieves the noise equivalent power (NEP) in the form

$$\text{NEP} = E_{N\text{min}} = \frac{2\sqrt{kTR\Delta f}}{S_D} \quad (26)$$

The reciprocal of NEP is called detectivity $D(\lambda)$. Hence the sensitivity S_D is proportional to the square root of detector area A , and the frequency band Δf is determined by the amplifier rather than by the detector itself. The properties of the detector are better described by specific spectral detectivity $D(\lambda)$,

Figure 16. Thermopile manufactured in Micro Machining Technology.

defined as

$$D^*(\lambda) = D(\lambda)\sqrt{A\Delta f} \quad (27)$$

Thermopile specific spectral detectivity is usually about $10^8 \text{ cm}\cdot\text{Hz}^{1/2} \text{ W}^{-1}$ (Fig. 17).

Bolometers with thermistors used as temperature-sensing elements have the same detectivity but are less frequently used. Pyroelectric detectors where the electrical charge evoked on the piezoelectric plate follow the temperature changes are a few times more sensitive, but they do not work at steady-state conditions and the thermal flux must be mechanically modulated by means of a rotating disk with slots or holes. Mechanical chopping enables the use of alternating-current (ac) amplifiers; this is more convenient than using direct-current (dc) ones and additionally cuts off a large portion of low-frequency noise (red noise), thus increasing the specific spectral detectivity. For this reason, the chopping technique is in common use now.

Photon detectors are much more sensitive than thermal detectors and are mostly used when the limited range of wavelength is preferred. They are manufactured as semiconductor photodiodes or photovoltaic elements. The most sensitive Si detectors [$D(\lambda) = 10^{13} \text{ cm}\cdot\text{Hz}^{1/2} \text{ W}^{-1}$] are suitable for visual spectra only; PbS, InAs, and InSb detectors [$D(\lambda) = 10^{11} \text{ cm}\cdot\text{Hz}^{1/2} \text{ W}^{-1}$] cover the range up to $3 \mu\text{m}$ to $5 \mu\text{m}$; and only an Hg–Cd–Te detector may be used up to the $20 \mu\text{m}$ range, achieving its maximum detectivity [$D(\lambda) = 5 \times 10^{10} \text{ cm}\cdot\text{Hz}^{1/2} \text{ W}^{-1}$] in the far-infrared radiation region. Cooling of detectors in order to improve their detectivity by noise reduction results sometimes in shifting of the spectral characteristics toward longer wavelengths. This effect is observed in particular for Ge detectors. Therefore, in comparing the spectral detectivities of various

detectors, precise specification of their operating temperatures must be taken into account (8). Detector cooling is frequently performed by single-stage or multistage Peltier coolers, which are compact and easy to use. The only problem to solve in their

Figure 17. Specific spectral detectivity of thermal and photon infrared detectors. The design of low temperature radiation thermometers is more complicated not only because of the lower radiance energy but by the lower sensitivity of the photon detectors working in the far IR region.

design is providing quick dissipation of the heat to enable the continuous cooling of the detector. Stirling coolers which require pumps are seldom used. It is quite possible, however, that in the near future, micropumps for that purpose will be produced by Micro Machining Technology.

Wide-Band Radiation Thermometers

Conceptually the simplest method of radiation thermometry is to detect the thermal energy emitted by an object toward a sensor regardless of its spectral distribution. This energy depends on the temperature according to the Stefan–Boltzmann law:

$$E = \epsilon_0 \sigma T^4 - \epsilon_t \sigma T_t^4 \quad (28)$$

where σ is the Stefan–Boltzmann constant, T and T_t are the object and thermometer temperatures, respectively, and ϵ_0 and ϵ_t are the emissivities of the object and the thermometer, respectively. The exponent 4 in Eq. (28) makes the calibration curve nonlinear and increases the uncertainty at the lower range of measured temperatures where the sensitivity is also low. This form of relationship, however, decreases the influence of the object emissivity ϵ_0 . The thermometer calibrated with the use of a black body ($\epsilon_0 = 1$) always indicates lower temperature T_{in} than is actually existent at the observed surface with the emittance ϵ_0 . By the comparison of equal states of the detector output signals during calibration and measurement, and assuming that all other factors are the same, one obtains

$$T = \frac{1}{4\sqrt{\epsilon_0}} T_{in} \quad (29)$$

[The second term in Eq. (28) has been neglected, which is allowed in case of higher object temperatures.] For example, taking $\epsilon_0 = 0.5$, the real temperature is not twice the indicated temperature but only 19% higher, as expressed in kelvins. Nevertheless, such a great difference is not negligible and has to be corrected. The simplest and the most common way is to adjust the emissivity value in the instrument which calculates and introduces the appropriate result correction. It would be a good method if the values of ϵ_0 were known with sufficient accuracy, but usually this does not take place. Furthermore, ϵ_0 is used here in the meaning of average emissivity over the whole spectral range. It has been shown before that for many reasons the heat flux incident at the sensor is spectrally disturbed, and hence the averaging should be weighted with regard to all these disturbances. Calculations become complicated to such a degree that their practical usefulness becomes questionable. The only way is then to calibrate the thermometer at the same environmental conditions as its operational conditions. The calibration is more effective when influence variables are stable. Higher stability may be achieved by narrowing the wavelength band. For this reason the class of wide-band thermometers includes not only total radiation thermometers but also thermometers with intentionally limited spectral bands. Total radiation thermometers are commonly equipped with thermal detectors and are used for measurements inside closed cavities as tanks or ovens where the emissivity is equal to 1 and the distance to the target is relatively low and stable. For applications in open air the thermometers with narrowed band and adjustable emissivity are used. They work in the first atmospheric window (for higher temperatures) or in the second atmospheric window

(for lower temperatures). For lower temperature ranges the compensation of ambient temperature [T_t in Eq. (28)] is commonly performed. Some of the devices are referred to as “near touch” radiation thermometers, in which an infrared detector is placed immediately over the surface, and the mirror optic is used to focus the radiant energy at the detector.

The majority of wide-band radiation thermometers are produced as hand-held or tripod-based instruments, commonly equipped with optical or laser aiming facility. Because of the progress in noiseless amplification of weak electric signals, the lowest temperature range of the discussed instruments has been pushed down to the level of -50°C or even -100°C . It is no longer true that those radiation thermometers are destined for high temperatures only, as it was in the past. It still remains true, however, that accurate measurements may be obtained only in the case of sufficiently stable conditions. The responsibility for ensuring repeatable conditions is with the user. The accuracy of the measurement depends rather on his skills and experience than on the quality of an instrument.

Monochromatic Radiation Thermometers

The name for the device derives from the times when radiation thermometers were used in the visual band only and indicates that a very narrow spectral band $\Delta\lambda$ of emitted heat flux is used for measurement purposes. In optical pyrometers the narrow band was being filtered using colored windows. Now the infrared interference filters are used for that purpose. Interference filters consist of a number of thin transparent layers deposited on a substrate. The optical properties and the thicknesses of the layers are specially matched to transmit through only a desired wavelength band $\Delta\lambda$ with the middle wavelength equal to λ_1 , as well as to reflect all higher and lower band frequencies. The filter remains cool because the undesired heat energy is reflected and not absorbed. The filtered bands are matched first of all with respect to the temperature range of the thermometer, but also with respect to the atmospheric windows. The part of energy emitted in wavelength band $\Delta\lambda$ may be described as

$$E_{\lambda_1} = \epsilon_{\lambda_1} C_1 \lambda_1^{-5} e^{-C_2/\lambda_1 T} \Delta\lambda \quad (30)$$

where ϵ_{λ_1} is the emissivity at wavelength λ_1 . The volume of energy incident at the detector is much lower than that in wide-band thermometers, but narrow-band photon detectors with much higher detectivity may be used in this case. Assuming the same calibration procedure as described before for wide-band thermometers, one obtains the relationship between the real temperature T and indicated temperature T_{in} in the form of

$$\frac{1}{T} = \frac{1}{T_{in}} + \frac{\lambda_1}{C_2} \ln \epsilon_{\lambda_1} \quad (31)$$

and for the small differences between T and T_{in} in the form of

$$T \approx T_{in} \left(1 - \frac{T_{in} \lambda_1}{C_2} \ln \epsilon_{\lambda_1} \right) \quad (32)$$

The differences between real and indicated temperatures are lower than in wide-band thermometers [Eq. (29)]. However, it is more important that the value of ϵ_{λ} be better defined and more stable than an average emissivity ϵ_0 which has been used

for calculations in the case of wide-band thermometers. Furthermore, all disturbances such as atmospheric absorption, hot gas radiation, contamination of optical parts by dust particles, and variations in detector properties have no influence on the output signal so far, because they do not concern directly the filtered band $\Delta\lambda$. The maintenance of the monochromatic thermometers is therefore simpler and their stability is much better, but the problem of emissivity correction remains.

Radiation Ratio Thermometers

The idea of radiation ratio thermometers is based on simultaneous measurement of radiation in two narrow wavelength bands followed by calculating the temperature from the ratio of the results. Both bands have to be chosen on the “increasing” part of the Wien’s spectral energy distribution curve (see Fig. 15), and they differ for each temperature range. Denoting the energy ratio at wavelength λ_2 and λ_1 by R , one obtains

$$T = \frac{\lambda_2 - \lambda_1}{\lambda_2 \lambda_1} C_2 \left[\ln R \left(\frac{\lambda_2}{\lambda_1} \right)^5 \right]^{-1} \quad (33)$$

for all gray bodies independent from their emissivity. For nongray bodies, like all metals, in which the emissivity is a function of wavelength, a very small correction is needed:

$$T \approx T_{\text{in}} \left(1 - T_{\text{in}} \frac{\lambda_2 \lambda_1}{C_2(\lambda_2 - \lambda_1)} \ln \frac{\epsilon_1}{\epsilon_2} \right) \quad (34)$$

where ϵ_1 and ϵ_2 are emissivities for wavelength λ_1 and λ_2 , respectively. The difference between ϵ_1 and ϵ_2 is very low, even in metals, which causes, according to Eq. (34), a very little difference between T and T_{in} . The ratio thermometers may be considered emissivity-independent instruments. The design of radiation ratio thermometers is much more complicated than other radiation thermometers, and special requirements for low chrominance optic elements have to be fulfilled. Therefore this kind of instruments is rather expensive.

In summary, it is worthwhile to point out that in the last decade an intensive progress in radiation thermometry has been achieved. The basic ideas remain unchanged, an optical pyrometer with disappearing filament remains a prototype of narrow band thermometers, and a two-color pyrometer is an ancestor of the ratio thermometers, but the progress in detector technology, the introduction of interference filters, the possibilities of low noise signal amplification, and numerical result corrections make the use of these instruments simpler and allow moving the operational temperature range toward lower temperatures. The use of fiber optics to transmit the thermal energy from hardly accessible places or through the areas with nuclear radiation or strong electromagnetic fields creates the next step of development which cannot be underestimated. Up to now the optical fibers work at short wavelengths only (up to $2.5 \mu\text{m}$), but with low distances the temperatures as low as 100°C may be measured; further progress in that field is expected.

ERRORS AND UNCERTAINTIES

First of all we have to distinguish between errors and uncertainties. According to its definition, an error is a difference

between a result of the measurement and a measurand true value. Errors always have certain values and a sign, but they remain unknown. In order to determine an error, we can try to calculate it or to measure it. Errors are measured in the calibration process. A determined error added to the result with the opposite sign as a correction makes the result free from that particular error. Many errors exist which are very hard to determine, even if their sources are theoretically known. In radiation thermometry we know exactly how the emissivity influences the result, but we do not know the particular value of the target emissivity. We are only able to estimate the range of results which is affected by more or less unknown sources of errors. It is a range of uncertainty, and the most probable value of the result is commonly (but not always) placed in the middle of this range. Therefore, uncertainty is denoted as $\pm\Delta t$, where Δt is half of the estimated range.

All predictable errors in sensors or transducers are normally accounted by the producer by means of compensations and corrections. The accuracy data which are found in transducer specifications or in standards are uncertainty limits. ISO Guide For Expression of Uncertainties (10) distinguishes two kinds of uncertainties: type A and type B. Type A uncertainties are easy to detect and estimate by repetition of measurements performed in the same conditions and then by calculating the standard deviation of the results (classical random uncertainties). Type A uncertainties dominate in high accuracy measurements. Random effects observed in industrial measurements are caused by measurand instability and environmental variations rather than by measuring instruments themselves. Type B uncertainties are those which remain constant by repetition of measurements. They may be caused by residuals remaining after nonlinearity compensation, hysteresis effects, or they may be caused by the influence of variables such as pressure, nuclear radiation, electromagnetic fields, humidity, dust, lead temperature variations, ambient temperature variations, velocity of the medium under measurement, aging, and many others. Type B uncertainties dominate in medium accuracy thermometers. Estimation of type B uncertainties needs some investigations performed either by the manufacturer of the thermometer or by the user, and some amount of experience too. It is a more complicated task than a type A estimation but the uncertainty data given in thermometer specification may be adequately used here. The calibration of a particular sensor or transducer transforms some uncertainties into errors, allowing us to account for them in a form of correction. All the rest remains as a part of a type B uncertainty. Laboratory calibration of temperature sensors is expensive, but calibration performed at the site of thermometer installation is more expensive and sometimes even impossible. On the other hand, it is impossible to restore all measurement conditions during laboratory calibration, and thus the improvement of accuracy by the recalibration is always limited.

Two remarks dealing with specification sheets ought to be pointed out here. In thermometry the uncertainty data referred to as “% of reading” or “% of full scale” (%FS) have no sense because temperature scales have no physical zero, and $\pm 2\%$ of 273 K gives $\pm 6 \text{ K}$ but $\pm 2\%$ of 0°C gives $\pm 0^\circ\text{C}$. All uncertainties have to be referred to in temperature units.

The next remark is concerned with resolution. Resolution is not a measure of accuracy and normally has nothing to do with uncertainty. It is only the ability to indicate small differences in temperature. High resolution may sometimes be very useful,

but we ought to have in our minds that by the use of numerical result display the resolution is commonly 10 times better than the uncertainty involved.

In the sensor-transducer pair the uncertainty of sensor usually dominates. Excluding standards from our considerations, it may be stated that of all temperature sensors, metal resistance thermometers are the ones with the lowest uncertainty. In the temperature range of -50°C to $+150^{\circ}\text{C}$, quartz thermometers are much more accurate and stable than all semiconductor sensors (the fact is reflected in their price). Traditional NTC thermistors seem to be less attractive in comparison with modern linear semiconductor sensors and more and more cheap integrated sensors which have the advantage of standardized calibrated output signal. However, the uncertainty of all semiconductor sensors is not better than $\pm 0.5^{\circ}\text{C}$ to 1°C . Thermocouples are the less accurate sensors. Their uncertainty is rapidly increasing, with the measured temperature reaching up to ± 10 K at temperatures above 1000°C . This is a much higher value than for radiation thermometers where the uncertainty is rather optimistically referred to as ± 1 K to 2 K. The advantage of thermocouple sensors is their lower cost, but the costs of transducers are comparable now. Some radiation sensors are equipped with such a signal conditioning system that their output signal fits to conventional thermocouple transducers. The thermocouples, however, are the unique sensors which have to be immersed in the high-temperature medium.

The discussion presented above deals with the instrument uncertainty, but more serious sources of uncertainty are related to the methods of temperature measurement. Generally, the problem is in the difference between the temperature of a sensor and the temperature which ought to be measured. This problem will be considered separately for steady-state conditions and for dynamic conditions.

Steady-State Errors of Temperature Measurement

In order to provide the same temperature of an object and of a sensor, the conditions for easy heat transfer from the object to the sensor and simultaneously for the difficult heat transfer from the sensor to the ambient environment should be created. For immersion-type sensors the length of the immersed part should be as large as possible because the heat runs away from the sensor through the protective tube, and a higher temperature gradient along the shield facilitates the transfer. Thermal insulation of the tank or pipe line where the temperature is measured lowers the gradient, and therefore the error too. The problem is much more serious in the case of gas media because of their low heat transmission coefficient and the possibility of heat escape to the pipe walls by radiation. The problem weight increases with the measured temperature, not only because of the higher temperature gradient but also due to the need for increasing shield thickness and for better thermal insulation of the sensor by protective ceramics.

The measurement of surface temperature is the best case for obtaining a false result. The sources of errors are the same, but the available remedies are very limited. The typical situation is schematically presented in Fig. 18. The sensor ought to have the best thermal contact with the surface but simultaneously should be insulated from the environment. The thermal insulation provides protection from the temperature decrease at the point of measurement, but perhaps it may cause a local increase

Figure 18. The measurement of surface temperature. The heat is accumulated in the silver plate with high thermal conductivity in order to equalize the surface and sensor temperatures. The air gap between the surface and the plate ought to be filled with silicon gel. The connection leads act as radiators and therefore run along the surface to a distance far enough to avoid the surface temperature disturbance near the sensor.

of the temperature especially when the surface was intensively cooled. Touching of the surface by the sensor involves thermal effects which are different in each particular case and practically unpredictable. From this point of view, the advantage of radiation thermometry for surface temperature measurements is evident.

Dynamic Errors

Dynamic errors are caused by the thermal inertia of the sensors and become important while transient temperatures have to be measured. The dynamic properties of a sensor are described by the response time of the output signal after a rapid change of sensor temperature, or by the time constant. The response time is usually defined as the time elapsing between 10% and 90% of the output signal change, but other definitions are also used. The response time depends on the sensor properties such as its material, shape, and dimensions, but depends first of all on the environment surrounding the sensor, characterized by the heat transmission coefficient. That coefficient is a few times greater in liquids than in gases, and it increases with the velocity of the medium. With any comparison of the sensor dynamic properties, exactly the same conditions have to be secured.

Assuming the linearity of the thermometer the idea of Laplace transformation and transfer function may be used for describing the thermometer dynamic properties. The simplest model of the dynamic behavior of a sensor may be presented in a form of the first-order transfer function:

$$K(s) = \frac{T_T(s)}{T_O(s)} = \frac{1}{1 + s\tau_1} \quad (35)$$

where $T_T(s)$ is the Laplace transformation of thermometer temperature, $T_O(s)$ is the Laplace transformation of the object temperature, s is the Laplace operator and τ_1 is a time constant. The model is valid for nonembedded sensors only, which are rather seldom used. Two other models are also used. The second-order

model

$$K_{II}(s) = \frac{1}{(1 + s\tau_1)(1 + s\tau_2)} \quad (36)$$

accounts for the delay of the output signal and better describes the thermometer with the shielded sensors. A model with the differential action

$$K_{III}(s) = \frac{1 + s\tau_D}{(1 + s\tau_1)(1 + s\tau_2)} \quad (37)$$

may in turn be used for surface temperature thermometers.

All those models may be treated as rough approximations because in fact the dynamic properties of temperature sensors are nonlinear. The experiment has shown that even for a nonembedded thermocouple sensor the time constant at 400°C has been three times larger than at that 1200°C (5). Also the warming curves and quenching curves always differ from one another.

For dynamically nonlinear sensors, it is not so easy to transform the results from one operating condition to other. One of the methods for estimation of dynamic behaviors of a sensor under its operating conditions uses an intentionally generated self-heating impulse in order to record the thermometer answer and then to calculate its dynamic parameters.

The dynamic behavior of the radiation thermometers depends on the dynamic properties of the infrared sensors which are rather slow, with the response time varying from 0.2 s to 2 s, and which are dynamically nonlinear too.

THERMISTORS

In the conventional Ohm's law equation

$$v = Ri \quad (1)$$

it is well known that the resistance value R corresponds to a specific temperature. Every two-terminal resistor invariably possesses a resistance–temperature (R – T) characteristic. Three typical shapes of such a characteristic are shown in Fig. 1 over a temperature range 0° to 100°C (273.15 to 373.15 K). In curve (a), the resistance is almost invariant with temperature, this property being exhibited by materials like manganin or constantan. Curve (b) corresponds to a material having a positive temperature coefficient of resistance. Examples of such materials are metals like platinum, copper, nickel, and others. A characteristic as in curve (c) is indicative of a large negative temperature coefficient of resistance and is encountered with resistors made out of semiconducting materials such as Mn_2O_3 , Co_2O_3 , and NiO (1–2). Thermistors belong to this class of resistors and derive their name from the phrase “thermally sensitive resistors.” Their properties and applications are discussed in greater detail in the following sections.

TEMPERATURE-DEPENDENCE OF RESISTIVITY: METALS AND SEMICONDUCTORS (3)

The value of the resistance R referred to in Eq. (1) depends on the physical dimensions of the resistor and the resistivity ρ of the material used. The change in resistance with temperature is due mainly to the change in ρ or its reciprocal, the conductivity σ . The nature of the change is different for metals and semiconductors. A given solid is classified as a conductor if, in its atomic model, the energy gap between the valence and the conduction bands is absent, with the two bands overlapping. For semiconductors, however, there exists an energy gap ranging from 0.1 eV to 3 eV between the two bands. The value of σ depends on the number of charge carriers n_c available in

Figure 1. Typical shapes of R – T characteristics of resistors: (a) with negligible temperature coefficient of resistance, (b) with positive temperature coefficient of resistance, (c) with negative temperature coefficient of resistance.

the conduction band and the velocity with which these carriers move under the application of an electric field. The latter is directly related to the mobility μ of the charge carriers. In the case of metals, n_c does not vary appreciably with temperature. The contribution to the change in resistivity comes from a change in μ . As temperature is increased, the enhanced thermal agitation of the atoms in the crystal lattice decreases the mean free path of a charge carrier between two successive collisions. This causes a decrease in μ and a consequent increase in the resistivity ρ . For semiconductors, on the other hand, an increase in temperature causes a large number of charge carriers to move into the conduction band. The resultant increase in n_c more than offsets the effect of the decrease in μ . Semiconductors thus exhibit a negative temperature coefficient of resistance, whose magnitude is several orders higher than that observed in the case of metals. The temperature coefficient of resistance of a semiconductor would lie between -1 and -5% per K, compared with a value of around $+0.4\%$ per K for copper and platinum.

CONSTRUCTION OF THERMISTORS

It is only through special processing that germanium or silicon can be had in pure form. Such intrinsic semiconductors, no doubt, possess a large temperature coefficient of resistance. Their conductivity at ordinary temperatures is, however, too low for practical resistors to be made out of them. Commercial thermistors are therefore basically compound semiconductors, which are made of oxides of cobalt, copper, manganese, nickel, tin, titanium, and others. While the R - T variation of a compound semiconductor is similar to that of intrinsic germanium or silicon, the increase in number of charge carriers is traceable in this case to a different phenomenon involving oxygen atoms (1).

Thermistors are manufactured in different shapes such as disk, rod, bead, and washer (1,4). A few sample shapes are illustrated in the sketches of Fig. 2. The various stages involved in the manufacture of thermistors are:

- Mixing of the various ingredients (metallic oxides) and grinding of the mixture to obtain a fine homogeneous powder.
- Binding of the powder by using a suitable organic chemical and shaping to the required form.
- Sintering at a controlled temperature. (Sintering is a process in which a powder mix of various ingredients is heated to a temperature below the melting point of the major constituent to achieve inter-particle bonding).
- Fixing of connecting leads and encapsulating in glass, epoxy, or a ceramic sheath.

Table 1. Typical Parameters for a Few Commercial Thermistors

Type of Thermistor	R_0	A	B
Siemens K 19	10 k Ω	9.754 m Ω	3440 K
Omega 44005	3 k Ω	5.586 m Ω	3934 K
YSI part No. 44033	2.25 k Ω	3.817 m Ω	3958 K

Figure 2. Various types of thermistors.

The nominal resistance of the thermistor, its temperature sensitivity and other relevant properties depend on the proportions of the constituents, the size, and the sintering temperature.

A QUANTITATIVE RESISTANCE-TEMPERATURE RELATIONSHIP WITH SIMPLIFIED THEORY (1,5)

The charge carriers contributing to current in a semiconductor include both electrons and holes. The conductivity due to each type of charge carrier is proportional to the product of its concentration (number of charge-carriers per unit volume) and mobility. The charge-carrier concentration at any temperature is governed by the Fermi-Dirac distribution theory. Application of this theory to electrons would yield the following expression, known as the Boltzmann equation, for the electron-concentration n_e :

$$n_e = N e^{-E_g/2kT} \quad (2)$$

where N is the concentration in valence band, E_g is the energy gap between the conduction and valence band, k is the Boltzmann constant and T is the absolute temperature. A similar expression is valid for holes too. As mentioned in the previous section, the variation of μ with T can be ignored in semiconductors. The conductivity is thus directly proportional to the charge concentration and hence bears an exponential relation to temperature similar to Eq. (2). With such a relation inserted into the expression for the resistance R of the device, we would get

$$R = \frac{\ell}{a\sigma} = \frac{\ell}{a\sigma_\infty} \cdot e^{E_g/2kT} \quad (3)$$

In Eq. (3), ℓ and a are respectively the usual length and area of cross-section and σ_∞ is the conductivity at a very high temperature (ideally infinity), when all the valence electrons will have moved into the conduction band. Now, Eq. (3) can be rewritten in the form

$$R = R_\infty e^{B/T} \quad (4)$$

where R_∞ and B are constants associated with the thermistor made out of the semiconductor. R_∞ will be in ohms and

$B = (E_g/2k)$ has dimensions of temperature. With E_g around 0.6 eV and $k = 8.625 \times 10^{-5}$ eV/K, we would get a B of about 3500 K for a typical thermistor. R_∞ , which is theoretically the resistance at infinite temperature, can take values ranging from fractions of an ohm to several ohms, depending on the material and size of the thermistor. Equation (4) is normally written in the form

$$R = Ae^{B/T} \quad (5)$$

with A being equal to R_∞ .

In Eq. (5), let us consider two temperatures T_0 and T . If the thermistor resistances at these two temperatures are R_0 and R , we would get

$$\frac{R}{R_0} = \frac{Ae^{B/T}}{Ae^{B/T_0}} = e^{(B/T - B/T_0)}$$

This leads to a commonly used R - T relationship, namely,

$$R = R_0 e^{B(1/T - 1/T_0)} \quad (6)$$

R_0 here is usually the thermistor resistance at a room temperature of 298 K (25°C). R_0 and B for a few thermistors are given in Table 1 (6,7).

APPLICATIONS OF THERMISTORS

General

The features of a thermistor that favor its use as a temperature sensing element are:

- high sensitivity
- availability in small sizes (beads as small as 0.7 mm in diameter), which facilitates measurement at a point and with fast response.
- wide range of resistance values
- possibility of covering a large temperature range from 120 K to 470 K and higher.

Because of these advantages, thermistors are extensively used for a variety of applications involving nonelectrical and electrical variables. The most common applications are in the measurement and control of temperature in process industries. Thermal conductivity, fluid flow, and gas composition are some of the other nonelectrical quantities for the measurement of which thermistors can be employed (1,6,8,9). One of the earliest known uses of the thermistor has been in the measurement of power in RF (radio frequency) and microwave circuits and devices (10). A problem frequently faced in the design of high-performance electronic circuits is the sensitivity of their response to ambient temperature variations. The thermistor with its high negative temperature coefficient comes in handy to minimize or nullify the above-mentioned undesirable effect. Millivoltmeters, biasing circuits of bipolar transistors, and log-antilog amplifiers (11) are typical examples where this property is used. Thermistors also serve as vital components in feedback systems used for the automatic control of amplifier gain and stabilization of output amplitude in electronic circuits.

Figure 3. Thermistor converts temperature into an electrical output.

Methods of Deriving a Temperature-Dependent Output (5,12)

A thermistor is essentially a passive transducer and hence requires energization by an external power source for deriving a temperature-dependent electrical output. The various techniques employed for this purpose are illustrated in simple forms in Fig. 3(a) to (d). In Fig. 3(a), the thermistor is excited by a constant voltage V_S and the resulting current indicated by the ammeter is a function of temperature. In Fig. 3(b), a constant current I_S is passed through the thermistor across which a temperature-dependent voltage is developed. The thermistor is used as one of the arms of a Wheatstone bridge in the circuit of Fig. 3(c). The bridge is initially in a balanced condition at a temperature, say, T_0 . A change in temperature from this value causes an unbalanced voltage or current that can be detected by D and related to the change in temperature.

It is also possible to configure the thermistor in a circuit so that a temperature-dependent frequency or time-interval is obtained as an output. An output of this type is preferred, when temperature indication in digital form is desired or when the information is to be transmitted over long distances. An arrangement for realizing this is shown in the block-schematic of Fig. 3(d), where the thermistor (R_T) is used as a timing component of an oscillator or multivibrator.

Control of Temperature

It may often happen that the control of temperature in a process is also desired in addition to its measurement. In this case, a temperature-dependent signal is obtained using any one of the basic schemes described above. This signal, say X_T , is compared with a "set-point" (X_S) and the resulting error signal is used to control the heating or cooling of the process. The block diagram of Fig. 4 serves to explain the principle.

Measurement of Fluid Flow (1,8)

The use of the thermistor here is similar to that of the hot-wire anemometer with the thermistor taking the place of the Wollaston wire. The thermistor probe, energized electrically to attain

Figure 4. Thermistor in feedback path controls the temperature of a process.

a sufficiently high temperature, is placed in the fluid. Fluid flow causes a decrease in temperature of the probe, because of the heat transfer from the probe to the surrounding fluid. This decrease in temperature is accompanied by an increase in resistance of the thermistor. Additional heat input into the thermistor is needed to bring its resistance and temperature to the earlier value. To this end, the current through the thermistor is increased to a new level, which is then a measure of the fluid velocity. This mode of operation is called constant temperature or constant resistance mode. A bridge-configuration similar to Fig. 3(c) with the thermistor forming one of the arms is often preferred. The advantage of using a thermistor in place of a hot-wire lies in overall compactness, higher temperature sensitivity, and less risk of probe burn-out.

If, instead of a moving fluid, we have a static medium surrounding the thermistor, an arrangement similar to that already described can be used to measure any quantity of the medium which affects the heat transfer. In this manner, we can build thermistor-based instruments to measure variables such as thermal conductivity, gas composition, pressure of gas, and so on.

Measurement of Power in Radio Frequency Circuits

The earliest known application of a thermistor is in the measurement of RF and microwave power. The power-measuring instrument here is called *bolometer* (10), with the thermistor being known as the bolometer element. As is the case with most other applications, the thermistor is used as one arm of a simple bridge configuration shown in Fig. 5.

The thermistor suitably mounted in an RF/microwave system absorbs the high frequency power under measurement and is consequently heated. Simultaneously, it is energized by two other sources—a dc and a low-frequency ac [usually AF (audiofrequency)]. The dc current is adjustable and serves

Figure 5. Thermistor helps RF power measurement through AF.

to set the thermistor resistance to a value that would be required for impedance matching on the RF side. The bridge is initially balanced with the thermistor receiving power from all the three sources, the AF power being minimal. The RF/microwave power is then turned off and without disturbing the dc, the AF power is increased to restore the bridge balance. Since the bridge is once again in balance, the thermistor resistance and hence the total input power to the bolometer element is the same under both conditions. The increase in AF power should therefore be equal to the unknown RF power. The accuracy of measurement will be enhanced if the initial AF voltage fed to the bolometer is as near zero as possible. A recent method employing two self-balancing thermistor bridges for RF power measurement is given in section 1.4.6 of Ref. 13.

Compensation and Stabilization

We are aware that the thermistor basically possesses a negative temperature coefficient of resistance. It can therefore be used to counteract the effect of the positive temperature coefficient of some other element on the response of a device or a circuit, when ambient temperature changes. Take for example a moving coil millivoltmeter, where the coil is of copper having a temperature coefficient of about +0.4%. By choosing a thermistor or a thermistor-resistor combination for the series multiplier, it is possible to make the millivoltmeter reading insensitive to ambient temperature changes.

Another application of a thermistor as a compensating element is in logarithmic amplifiers (11). In this circuit (Fig. 6), the A_1 - R_1 - D_1 combination constitutes the basic logarithmic amplifier. Its output voltage is

$$v_1 = -V_T \ln \frac{v_i}{I_0 R_1} \quad (7)$$

where I_0 is the reverse saturation current of D_1 and $V_T = kT/q$ is the voltage equivalent of thermal energy. I_0 and V_T in Eq. (7) make v_1 highly dependent on ambient temperature. If diode D_2 matches with D_1 , it would, along with the current source I_S , compensate for changes in I_0 with temperature. The voltage at the noninverting pin of A_2 is

$$v_2 = -V_T \ln \frac{v_i}{I_S R_1}$$

The output voltage of the complete logarithmic amplifier circuit becomes

$$\begin{aligned} v_o &= (1 + R_T/R_2) \cdot v_2 \\ &= -(1 + R_T/R_2) \cdot V_T \ln \frac{v_i}{I_S R_1} \end{aligned} \quad (8)$$

A suitable thermistor can be chosen for R_T so that changes in the values of R_T and V_T due to variations in ambient temperature will have equal and opposite effects on the output voltage v_o .

Amplitude Stabilization in Oscillators (11)

We often use a thermistor as a nonlinear feedback element in amplifiers and oscillators to achieve an output of constant amplitude. Let us consider the Wien-bridge oscillator of Fig. 7, built using an op-amp. Here negative feedback is provided by

Figure 6. Thermistor R_T helps to reduce the temperature dependence of v_o .

the R_3 – R_4 potential divider connected across the output. R_4 is usually a thermistor. When there is a tendency for the amplitude of the output voltage v_o to increase, the current through the thermistor increases. This, in turn, causes a decrease in R_4 due to additional self-heating. The voltage across R_3 increases, resulting in more negative feedback, which tends to reduce the output and therefore maintain it at a constant value. We can also view the action of the thermistor here as an automatic control mechanism that alters the gain of an amplifier to achieve output amplitude stability. In principle, we can, with an appropriate arrangement, exploit the negative slope of the thermistor R – T characteristic to stabilize other electrical quantities as well.

LINEARIZATION OF THERMISTOR RESPONSE (14–19)

Whereas high sensitivity and fast response are the major plus points for a thermistor, the nonlinearity of its R – T characteristic stands as a stumbling block for its use in several applications in which we need an output varying linearly with temperature. The technique of achieving this is broadly known as “linearization.”

Shaping of R – T Characteristic

The simplest method for achieving linearization is to use a linear resistor in series or in parallel with the thermistor and obtain a terminal resistance that varies more linearly with temperature (14). Consider, for example, a typical circuit as in Fig. 8, where R_T is an Omega 44034 thermistor and R_p is a 2 k Ω resistor connected in parallel with it. The curves on the figure clearly show the effect of adding R_p to get an R – T characteristic with improved linearity over a temperature range of 30°–50°C. The sensitivity however falls considerably (from 107 Ω /K to nearly at 19.7 Ω /K, at 40°C). If we pass a constant current through the R_p – R_T combination, the resulting voltage would vary linearly with temperature. The temperature range over which this technique is applicable is quite narrow.

A Technique for Linear T -to- f Conversion

With thermistors that closely obey the two-constant law $R = A e^{B/T}$ over a specific temperature range, it is possible to obtain, using electronic circuits, an output in the form of a frequency which is proportional to temperature.

Refer to the schematic diagram of the T -to- f converter shown in Fig. 9. This circuit functions essentially as a relaxation oscillator (15). A reference voltage V_r energizes the network N containing the thermistor, and also a series R – C circuit. Let at $t = 0$, the output of the monostable multivibrator be low and the switch S open. The capacitor C starts to get charged

Figure 7. Thermistor (R_4) stabilizes oscillation amplitude.

Figure 8. R – T characteristic (a) before and (b) after the connection of a 2 k Ω resistor in parallel with Omega 44034 thermistor.

Figure 9. Linear T -to- f converter.

and its voltage rises according to the relation

$$v_c = V_r(1 - e^{-t/RC}) \quad (9)$$

The network N provides a temperature-dependent voltage

$$v_T = V_r \left(1 - \frac{k}{A} e^{-B/T} \right) \quad (10)$$

where k depends on the parameter values of certain elements in N. Let v_c reach the level v_T at $t = t_0$. From Eqs. (9) and (10), we then obtain

$$t_0 = \frac{BRC}{T} - RC \ln \frac{k}{A} \quad (11)$$

At this instant, the comparator output is lowered, triggering the monoshot. The output of the monostable increases; the switch S gets closed and discharges the capacitor. The monostable remains in the high state for its period τ at the end of which it returns to low state, initiating another cycle of operation. The period of the relaxation oscillator, namely, $t_0 + \tau$ will be BRC/T , if τ is adjusted to be equal to $RC \ln(k/A)$. We thus get a frequency of oscillation

$$f = \frac{1}{t_0 + \tau} = \frac{T}{BRC}$$

which varies linearly with the absolute temperature T . The circuit achieves perfect linearization if the two-constant law is strictly valid for the thermistor used. Any nonlinearity in the output is due mainly to the departure of the thermistor behavior from the assumed law.

There are available in the literature a large number of linearizing circuits, producing an output in the form of a voltage, frequency, or time interval linearly related to temperature. In most of these circuits, linearization is achieved by expressing the output as a function of temperature in Taylor-series form and adjusting the circuit elements, to nullify the second-order term (16,17,18). The range of temperature over which these techniques will be useful is generally limited.

Wide-Range Linearization

The linearization methods discussed in the previous sections are basically hardware techniques, which would exhibit larger error as the temperature range is increased. As mentioned earlier, the major reason for the errors is the deviation of the R - T characteristic from the $Ae^{B/T}$ -law. This is because some of the assumptions such as invariance of carrier mobility with temperature, used in the derivation of that law, are not valid over a wide temperature range. One approach to reducing the linearity error would be to add suitable resistors in series and/or parallel to the physical thermistor, so as to obtain a terminal resistance which closely obeys the $Ae^{B/T}$ -law over a wide range (19). Other methods use empirical relationships involving three constants, to approximate the actual R - T characteristic of the thermistor better than the two-constant law. Under this category (1,7) we have:

$R = AT^{-c}e^{B/T}$, called the Becker-Green-Pearson (BGP) law

$R = Ae^{B/(T+\theta)}$, Bosson's law

$1/T = A + B \ln R + C (\ln R)^3$, Steinhart-Hart equation

For an Omega 44034 thermistor (7), the above three approximations would respectively give rise to a maximum fit error of 0.065 K, 0.037 K, and 0.018 K over the temperature range 0 to 100°C. This value would be -0.533 K if the two-constant law is used. It is true that the three-constant laws fit better than the conventional $Ae^{B/T}$ -law, but they do not lend themselves to easy hardware linearization. The availability of computing power in the form of microprocessors and personal computers has made software-based linearization possible using these equations. A straightforward method would be to obtain an analog voltage proportional to the thermistor resistance, convert it to digital form using an analog-to-digital converter (ADC) and compute the temperature using the chosen three-constant equation.

CERTAIN PARAMETERS OF IMPORTANCE (1,4)

Self-Heating Error

In the applications which involve temperature measurement, we have tacitly assumed that the temperature of the thermistor is the same as that of the surroundings. This assumption is valid provided the thermistor has been long enough at the

location of measurement and is not electrically energized. Passage of current through the thermistor for obtaining an electrical output is bound to heat the thermistor to a temperature higher than the surroundings. Since the measurement schemes senses only the thermistor temperature, an error arises which is termed a self-heating error. To keep it small, the thermistor current must be sufficiently low, taking into account the environmental conditions and the heat dissipation capability of the thermistor.

Dissipation Constant

To help the user estimate the error due to self-heating, manufacturers often specify for each thermistor a parameter called the dissipation constant. This constant is defined as the power required to raise the temperature of the thermistor by 1 K above its ambient, and is usually expressed in mW/K. This parameter depends on the nature of the thermistor environment and also on how the sensor is mounted. For example, a commercial tiny bead type thermistor could have a dissipation constant much less than 1 mW/K in still air. Its value for a disk type device mounted on a chassis may be as high as 60 mW/K (3,7).

Response Time

Response time of a thermistor is of importance when monitoring of rapid changes in temperature is required. Since the dynamic behavior of a thermistor is that of a first order system, the response time is specified by the term time-constant. It is the time taken by the thermistor to undergo a resistance change equal to $(1 - e^{-1})$ times the total final change in resistance that would be caused by a given step temperature change. The time-constant and the response time depend on the thermal mass, specific heat, and dissipation constant of the thermistor. Very small-size bead thermistors having time-constants less than 0.5 s are commercially available.

Limitations

Along with their numerous advantages, thermistors have a few limitations too. A rather serious one is the problem of interchangeability. Even thermistors fabricated by the same technique with strict control of the manufacturing process exhibit a spread in their R - T characteristics. Another shortcoming is lack of stability, since the resistance of the thermistor drifts with aging and continued use. Bead type thermistors are generally more stable than their disk counterparts. At high temperatures, changes in composition might occur in the device and the sensor will then have to be recalibrated for further use. This places an upper limit (about 590 K) on the operating temperature of the thermistor. A lower limit for its use is imposed by the largest resistance value beyond which measurement becomes difficult. This lower limit lies around 120 K.

POSISTORS (5,6,7)

The thermistor sensors discussed in the preceding sections are basically ones having a negative temperature coefficient of resistance. Strictly speaking, they should be called NTC thermistors, since there is another class of thermally sensitive resistors which exhibit a large positive temperature coefficient over a small temperature range. These devices are known as PTC

Figure 10. Typical R - T characteristic of a PTC thermistor.

thermistors or posistors. The R - T characteristic of a typical posistor is shown in Fig. 10.

It is seen that, as the temperature is increased, the device exhibits an NTC characteristic with a gradually decreasing resistance-temperature coefficient up to a certain temperature. A transition now occurs and the resistance, instead of decreasing, steeply increases with temperature. This phenomenon is noticed in devices made of certain ferroelectric materials such as barium titanate doped with strontium or lead. The PTC is traceable to the sudden decrease in the dielectric constant above the Curie point, which results in an increase in the activation energy (E_g) and an associated increase in the resistivity of the material. The steep R - T characteristic in the transition phase of the posistor makes it ideally suited for applications such as low-cost self-regulating heaters, electronic switches, and overcurrent protectors (6,9).

THERMOCOUPLES

Thermocouples are relatively inexpensive devices used to measure temperatures for a wide variety of applications, ranging from furnace control to equipment calibration. They can be made to fit just about any application. Unlike many temperature-measuring devices, the thermocouple is not subject to self-heating problems. A thermocouple is based on the finding of Seebeck, who showed that a small electric current will flow in a circuit composed of two dissimilar conductors when their junctions are kept at different temperatures (1). When one junction is hotter than the other, an electromotive force (emf) is produced that is proportional to the difference in temperature between the measuring junction (hot junction) and the reference junction (cold junction). This condition is known as the Seebeck emf, and the output is measured in millivolts. The pair of conductors that constitute the thermoelectric circuit is called a thermocouple. Thermocouples are the most widely used method of measuring internal temperatures in solid bodies. There are many different types of thermocouples that measure temperature over a range as low as -190°C and as high as 2000°C (2).

The measurement of temperature is thought to be a simple process, but this is a popular misconception. There is a need for controlled, reliable, and reproducible temperature-sensing devices for science, engineering, and industry. There are seven types of instruments used to measure temperature: thermocouple thermometers, radiation pyrometers, resistance thermometers, liquid-in-gas thermometers, filled-system thermometers,

optical pyrometers, and bimetal thermometers, and they all have advantages and disadvantages (3). The thermocouple is by far the most widely used device for temperature measurement because of its favorable characteristics that include good accuracy, coverage of a wide range of temperatures, fast thermal response, durability, high reliability, low cost, and versatility. This article concentrates only on the history, theory, junctions, calibration, and applications of thermocouples.

HISTORY OF THERMOCOUPLES

One person did not establish the principles or theory underlying thermoelectric effects. It was established by several scientists working over a span of many years beginning with Alessandro Volta, who concluded in 1800 that the electricity which caused Galvani's frog to twitch was due to a contact of two dissimilar metals (3). This conclusion was the forerunner of the principle of the thermocouple. Others who built on this base were Thomas Johann Seebeck (1821), Jean Charles Althanase Peltier (1834), and William Thomson—later Lord Kelvin (1848–1854). During this same period, Jean Baptiste Joseph Fourier published his basic heat-conduction equation (1821), Georg Simon Ohm discovered his equation for electric conduction (1826), James Prescott Joule found the principle of the first law of thermodynamics and the important I^2R heating effect (1840–1848), and Rudolf Julius Emanuel Clausius announced the principle of the second law of thermodynamics and introduced the concept of entropy (1850) (4,5).

Seebeck Effect

Thomas Johann Seebeck discovered the existence of thermoelectric currents while observing electromagnetic effects associated with bismuth–copper and bismuth–antimony circuits (4,5). His experiments showed that when the junctions of two dissimilar metals forming a closed circuit are exposed to different temperatures, a net thermal emf is generated which induces a continuous current. Measurements of the Seebeck effect can be made in terms of either the closed-circuit current or the open-circuit current. The Seebeck effect concerns the net conversion of thermal energy into electric energy with the appearance of an electric current. The Seebeck voltage refers to the net thermal electromotive force set up in a thermocouple under zero-current conditions. The direction and magnitude of the Seebeck voltage E_S , where E represents the thermoelectric emf, depends upon the temperature of the junctions and upon the materials making up the thermocouple. For a particular combination of materials A and B and for a small temperature difference dT , we obtain

$$dE_S = \alpha_{A,B} dT \quad (1)$$

where $\alpha_{A,B}$ is a coefficient of proportionality called the Seebeck coefficient and is also commonly called the thermoelectric power (1). The Seebeck coefficient is obtained in one of two ways:

1. As an algebraic sum ($\alpha_{A,B}$) of relative Seebeck coefficients (α_{AR}) and (α_{BR}), where for a given temperature difference and at given temperature levels, emfs of each of the substances, A and B, making up the thermocouple are

obtained with respect to an arbitrary reference material, R .

2. By numerically differentiating tabulated values of E_S versus T for a given reference temperature, T_R , according to the relation

$$E_S = \int_{T_R}^T \alpha_{A,B} dT \quad (2)$$

In either case, the Seebeck coefficient represents the net change in thermal emf caused by a unit temperature difference as in

$$\alpha_{A,B} = \lim_{\Delta T \rightarrow 0} \frac{\Delta E_S}{\Delta T} = \frac{dE_S}{dT} \quad (3)$$

If $E = aT + 0.5bT^2$ is determined by calibration, then $\alpha = a + bT$.

The Seebeck coefficient is a function of temperature level only based on the validity of the experimental relation

$$E_S = \int_{T_2}^T \alpha dT = \int_{T_1}^T \alpha dT - \int_{T_2}^{T_1} \alpha dT \quad (4)$$

where $T_1 < T_2 < T$. It follows that α is entirely independent of the reference temperature employed.

Peltier Effect

Jean Charles Althanase Peltier (1834) discovered interesting thermal effects when he introduced a small, external electric current in Seebeck's bismuth-antimony thermocouple (3,6). His experiments showed that when a small electric current is passed across the junction of two dissimilar metals in one direction, the junction is cooled and thus absorbs heat from its surroundings. When the direction of the current is reversed, the junction is heated as well as its surroundings. The Peltier effect takes place whether the current is introduced externally or is induced by the thermocouple. There are certain thermoelectric neutral points where no Peltier effect is apparent for special combinations of metals at certain temperatures.

The Thomson Effect

William Thomson—later Lord Kelvin—came to the conclusion that an electric current produces different thermal effects, depending upon the direction of its passage from hot to cold or from cold to hot, in the same metal (3,6). Thomson reasoned that if an electric current produces only the reversible Peltier heating effect, then the net Peltier voltage will equal the Seebeck voltage and will be linearly proportional to the temperature difference at the junctions of the thermocouple. Thomson also concluded that the net Peltier voltage is not the only source of emf in a thermocouple circuit but that a single conductor itself must also be a seat of emf.

The Seebeck, Peltier, and Thomson effects, together with several other phenomena, form the basis of functional thermoelectric modules.

THEORY OF THERMOCOUPLES

Electromotive Force (emf)

The emf is the energy per unit charge that is converted reversibly from chemical, mechanical, or other forms of energy into electrical energy in a conversion device such as a thermocouple. The basic principle of thermoelectric thermometry is that a thermocouple develops an emf, which is a function of the difference in temperature of its measuring (hot) junction and reference (cold) junction. If the reference junction temperature is known, the measuring junction's temperature can be measured by measuring the emf generated in the circuit. Therefore, we need an instrument capable of measuring emf.

There are three types of emf-measuring instruments in use in industry: deflection meters (millivoltmeters), digital voltmeters, and potentiometers. However, only two of them—digital voltmeters and potentiometers—are used where precision and accuracy are required for measuring thermal emfs. Digital voltmeters are high-impedance devices, and the readings are essentially independent of external circuit resistance. Potentiometers are used when the greatest accuracy is required in measuring emfs because its readings are free from uncertainties arising from changing circuit resistance (3).

Two metals, A and B, form an electric circuit with junctions that have temperatures t_1 and t_2 . In general, if the junction temperatures t_1 and t_2 are not identical, an emf will exist in such a circuit (7). The magnitude of the emf will depend on the metal used, the amount of temperature difference between t_1 and t_2 , and the actual temperature values of t_1 and t_2 . By including a suitable device to indicate any emf or flow of current that may occur in the circuit, the temperature difference $t_1 - t_2$ can be measured. The term thermoelectric power (e) as applied to such a circuit for a given pair of metals and a specified average temperature is defined as the ratio of the magnitude of the thermoelectric emf (E) to the temperature difference, $t_1 - t_2$ between the junction (see Fig. 1).

There are several basic laws that define thermoelectric circuits. These laws have been established experimentally and are generally accepted despite the lack of theoretical development.

Law of Homogeneous Metals. A thermoelectric current cannot be sustained in a circuit of a single homogeneous material, however varying in cross section, by the application of heat alone (4).

This law requires two different materials for any thermoelectric circuit (i.e., a thermocouple). No voltage V_{ij} can appear if wires A and B are chemically and physically the same, regardless of the values of T_1 and T_2 . This law provides that the position of the voltmeter (Fig. 2) does not affect the emf V_{ij} as long as both wires attached to the voltmeter are homogeneous. The voltmeter could be placed anywhere along wire A or B or at either junction.

Experiments have been reported suggesting that a nonsymmetrical temperature gradient in a homogeneous wire gives rise to a measurable thermoelectric effect. However, there is evidence that indicates that any emf observed in such a circuit arises from the effects of local inhomogeneities, and any current detected in such a circuit when the wire is heated is taken as evidence that the wire is inhomogeneous.

Figure 1. Thermoelectric circuit.

Law of Intermediate Metals. The algebraic sum of the thermoelectromotive forces in a circuit composed of any number of dissimilar materials is zero if all of the circuit is at a uniform temperature (7).

This law implies that a third homogeneous material can always be added in a circuit with no effect on the net emf of the circuit as long as its extremities are at the same temperature. A junction whose temperature is uniform and which makes good electric contact does not affect the emf of the thermoelectric circuit regardless of the method used in forming the junction. This is significant in that it allows for cheaper materials to be used as extension wires.

This law also implies that if the thermal emfs of any two metals with respect to a reference metal are known, then the emf of the combination of the two metals is the algebraic sum of their emfs against the reference metal.

Law of Intermediate Temperatures. If a given two-junction circuit produces an emf V_1 when junction temperatures are T_1 and T_2 and produces an emf V_2 when its junction temperatures are T_2 and T_3 , then the same circuit will produce an emf equal to $V_1 + V_2$ when its junction temperatures are T_1 and T_3 (1).

Figure 2. Thermocouple thermometer circuit. Dissimilar wires A and B are joined at temperatures T_1 and T_2 . The original current-flow circuit of Seebeck has been modified by the insertion of a high-impedance potentiometer V to emphasize the present-day thermometry technique.

This law is very important in case an engineer wanted to use a specific thermocouple circuit with a different reference junction temperature than the one for which a set of emf-temperature values is known. The temperature-emf relationship for a specific thermocouple combination is a definite physical property and thus does not depend on details of the apparatus or method used for determining this relationship. Figure 3 lists the emf curves for ISA standard thermocouples.

THERMOCOUPLE JUNCTIONS

There are numerous variations on the construction for joining the two dissimilar wires that make up a thermocouple. Thermocouples are available in four main junction types: exposed or bare-wire junction, grounded junction, ungrounded or isolated junction, and reduced diameter junction.

Exposed- or Bare-Wire Junction

In this type of junction, the sheath and insulating material are removed to expose the thermocouple wires (3). These wires are

Figure 3. Thermal emf curves for ISA standard thermocouples. [Based on IPTS-68 (1974).]

Figure 4. Exposed- or bare-wire junction

Figure 5. Grounded junction.

Figure 6. Ungrounded junction.

Figure 7. Reduced diameter junction.

Figure 8. Thermocouple calibration system.

joined to form a measuring junction. While the thermocouple will have a fast response, the exposed ceramic is not pressure-tight, will pick up moisture, and will be subject to mechanical damage and expose the thermocouple to the environment (Fig. 4).

Grounded Junction

A closure is made by welding in an inert atmosphere so that two thermocouple wires become an integral part of the sheath weld closure (3). The wires are grounded to the sheath. This type of junction will give a slower response than an exposed wire, but the insulation is pressure-tight (Fig. 5).

Ungrounded or Isolated Junction

This type of junction is similar to the grounded junction except that the thermocouple wires are first made into a junction, which is then insulated from the sheath and the sheath enclosure (8). The closure is formed by welding without touching the thermocouple wires, and this results in an ungrounded thermocouple to the sheath material. This junction has a much slower response than the grounded junction but is still pressure-tight, protected from mechanical damage and the environment (Fig. 6).

Reduced Diameter Junction

This junction may be either grounded or insulated, and it is used where a fast response is required (3). It is more commonly used when a heavier sheath or wires are desired for strength, life, or lower resistance over the balance of the unit (Fig. 7).

CALIBRATION OF THERMOCOUPLES

Thermocouple wire is available commercially for measuring temperatures in the range of -190°C to 2000°C in matched pairs to conform to published standard tables. Each wire is calibrated separately, and then selected wires from two materials are paired such that the temperature-emf relationship for each pair does not deviate by more than the established standard tolerances. Common tolerances are usually $\pm 0.25\%$ to $\pm 0.75\%$.

The National Institute of Standards and Technology (NIST, formerly NBS) can provide temperature calibration when maximum authenticity is required for highly accurate temperature measurement applications. The temperatures covered by NIST are from -196°C to 1566°C , and a minimum length of 3 in. and a maximum of 24 in. wire is required.

The calibration of standard thermocouples consists of the determination of their emf values at a sufficient number of temperatures that they may be used to measure temperatures on a particular scale with a certain accuracy. This process may include annealing, test junction assembly, emf measurement, and construction of emf-temperature tables or equations. A diagram of a thermocouple calibration system is shown in Fig. 8 (9).

Annealing

Most base-metal thermocouples are annealed during manufacturing. Annealing is considered to be satisfactory for most thermometric purposes, so that the calibration process for base-metal thermocouples usually does not include an annealing step. For noble-metal thermocouples, annealing has been

demonstrated to be effective in promoting more uniform calibration results. NIST anneals all noble-metal thermocouples prior to calibration. The thermocouples are heated to about 1450°C in air by passage of electric current through their length while they are suspended loosely between supports. After approximately 45 min, they are annealed at 750°C for about 30 min and then cooled to room temperature.

Thermocouple Extension Wires

Thermocouple extension wires, also known as extension wires or lead wires, are electric conductors for connecting thermocouple wires to the temperature-measuring and temperature-control instrument. Extension wires are usually supplied in cable form, with positive to negative wires electrically insulated from each other. The chief reasons for using extension wires are economy and mechanical flexibility. Economy-base-metal thermoelements (\$10 per pound) are always used as extension wires for noble-metal thermocouple wires (\$700 per troy ounce). Mechanical-flexibility insulated solid or stranded wires in sizes from 14 to 20 gauge are used as extension wires. This lends mechanical sturdiness and flexibility to the thermocouple circuitry while permitting the use of larger-diameter base-metal thermocouples for improved oxidation resistance and service life, or smaller-diameter noble-metal thermocouple wire to save cost.

Test Junction Assembly

If a thermocouple is to be calibrated by comparison with a standard thermocouple, then the test wires are usually welded to the measuring junction of the reference thermocouple. By creating a single measuring-junction bead containing all of the thermocouples to be measured, an engineer can eliminate the temperature gradients between the pairs.

Cold Junction Compensation

As a differential output transducer, the voltage output of a thermocouple is dependent on the temperature at both the hot and cold junctions. The freezing point of water, 0°C (32°F), was selected as a convenient cold junction reference.

To construct an ice bath reference junction, both legs of the thermocouple are fused to copper wire to form a transition junction. The leads are then waterproofed and the transition junction is immersed in an ice bath (Fig. 9). The open-circuit voltage appears across the copper leads exiting from the ice bath.

The copper leads are used to connect to the emf readout device. This procedure avoids the generation of thermal emf at

Figure 9. Ice bath circuit.

the terminals of the readout instrument. Voltages measured in this way may be directly converted into temperature by using NBS millivolt-temperature reference tables (7).

THERMOCOUPLE APPLICATIONS

The Instrument Society of America (ISA) assigned a letter designation to each of several types of thermocouples (Table 1). This allows the specification of an emf-temperature relation for each type of thermocouple without specifying its position. By specifying the emf-temperature relations by the letter designation rather than by the compositions, the ISA could ensure that manufacturers could deviate from other compositions that may be trademarked and still meet the published table values. The ISA thermocouples are accepted by NIST in the consensus temperature standard ANSI MC 96 and the useful ranges for thermocouple thermometers as established by the ASTM Committee E-20.

Representative samples of wire of each thermocouple type were studied extensively at NIST in order to develop reference tables of emf versus temperature over the useful range for each type of thermocouple. The reference tables are published along with Seebeck coefficient data in the NIST Monograph 125 issued in 1974.

Base Metals for Thermocouples

Base metals are the metal that is in greatest abundance for a given metal (10,11). However, when discussing base metals in terms of thermocouples, corrosion properties are what is most important for the material used. Base metals used for thermocouples that readily oxidize and are highly corrosive are iron and constantan. The corrosion characteristics of thermocouples are listed in Table 2.

Table 1. ISA Standard Thermocouples

ISA Designation	Approximate Composition (Positive Leg Listed First)	Useful Temperature Range (°C)
Base metal types		
Type E	(Ni + 10% Cr) vs. (Cu + 43% Ni)	-270 to 1000
Type T	Cu vs. (Cu + 43% Ni)	-270 to 400
Type J	Fe vs. (Cu + 43% Ni)	-270 to 1200
Type K	(Ni + 10% Cr) vs. (Ni + 2% Al + 2% Mn + 1% Si)	-270 to 1372
Noble metal types		
Type S	(Pt + 10% Rh) vs. Pt	-50 to 1767
Type R	(Pt + 13% Rh) vs. Pt	-50 to 1767
Type B	(Pt + 30% Rh) vs. (Pt + 6% Rh)	0 to 1820

Table 2. Corrosion Characteristics of Common Thermocouples (12–13)

Type of Thermocouple	Influence of Temperature and Gas Atmospheres
Type S, R, and B Platinum vs. platinum–rhodium	1. Resistance to oxidizing atmosphere: very good. 2. Resistance to reducing atmosphere: poor. 3. Platinum corrodes easily above 100°C. Should be used in gas-tight ceraminc protecting tube.
Type K Chromel-P vs. alumei	1. Resistance to oxidizing atmosphere: good to very good. 2. Resistance to reducing atmosphere: poor. 3. Affected by sulfur, reducing, or sulfurous gas, SO₂ and H₂S.
Type J Iron vs. constantan	1. Oxidizing and reducing atmospheres have little effect on accuracy. Best used in dry atmospheres. 2. Resistance to oxidation: good up to 400°C but poor above 700°C. 3. Resistance to reducing atmosphere: good (up to 400°C).
Type T Copper vs. constantan	1. Subject to oxidation and alteration above 400°C, due to copper; above 600°C, due to constantan wire. Contamination of copper affects calibration greatly. 2. Resistance to oxidizing atmosphere: good. 3. Resistance to reducing atmosphere: good. 4. Requires protection from acid fumes.

Noble Metals for Thermocouples

Noble metals are metals whose potential is highly positive relative to the hydrogen electrode; they have high resistance to chemical reaction, particularly to oxidation and to solution by inorganic acids (10,11). These metals are sometimes referred to as precious metals and are relatively scarce and valuable such as gold, silver, and platinum and are listed in Table 2.

Type K Thermocouples (Chromel-P Versus Alumel)

This type of thermocouple is regarded as the most versatile thermocouple because of its combination of high sensitivity, stability, oxidation resistance, and price. Type K thermocouples are recommended for use in an oxidizing or completely inert atmosphere over the temperature range of –200°C to 1260°C (–330° to 2300°F). Type K thermocouples should not be used in atmospheres that are reducing, alternately oxidizing and reducing, or vacuum for long periods of time since vaporization of chromium from the positive element may alter calibration used in thermometry applications in the –270° to 1372°C temperature range.

Type E Thermocouple (Ni–Cr Versus Cu–Ni)

Type E thermocouples have proven to be most useful in terms of lower wire conductivity and higher Seebeck coefficient. They are recommended for use over the temperature range of –200°C to 900°C (–330° to 1600°F) in oxidizing or inert atmospheres. These thermocouples are suitable for subzero temperature measurements since they are not subject to corrosion in atmospheres with high moisture contents. Type E thermocouples develop the highest emf per degree of all the commonly used types of thermocouples.

Type T Thermocouple (Copper Versus Constantan)

Type T thermocouples are resistant to corrosion in moist atmospheres and are suitable for subzero temperature measurements. They can be used in a vacuum and in oxidizing, reducing, or inert atmospheres over the temperature range of –200° to 370°C (–330° to 700°F). This type of thermocouple, along with Type E and Type K, are widely used in cryogenics, and its temperature range of use is between –270° and 400°C.

Type J Thermocouple (Iron Versus Constantan)

These thermocouples are suitable for use in vacuum and in oxidizing, reducing, or inert atmospheres over the temperature range of 0° to 760°C (32° to 1400°F). This thermocouple is not recommended for use below the ice point because rusting and embrittlement of the iron make it less desirable.

Type R and S Thermocouples (Platinum Versus Platinum–Rhodium)

Type R and S thermocouples are recommended for continuous use in oxidizing or inert atmospheres over the temperature range of 0° to 1480°C (32° to 2700°F). The continued use of these thermocouples at high temperatures causes excessive grain growth, which can result in mechanical failure of the platinum element.

Type B Thermocouple (Platinum–Rhodium Versus Platinum–Rhodium)

These thermocouples are recommended for continuous use in oxidizing or inert atmospheres over the temperature range of 870° to 1700°C (1000° to 3100°F). There are also suitable for short-term use in a vacuum. They should not be used in reducing atmospheres nor in those containing metallic or nonmetallic vapors.

Special Problems with the Use of Thermocouples

The thermocouple possesses an apparent simplicity that often deceives its users (1). The sensor appears to be a tiny detector that evaluates the temperature exactly at the location of the measuring junction. In certain commercially available thermocouple systems, the reference junction is contained within a digital voltmeter so that there is no messy ice bath to manipulate. There are several problems that are unique to thermocouples. Each problem arises from the nature of thermocouple measurements and the fact that the thermometric quantity is measured in terms of a small steady voltage. Any spurious source of voltage in the thermocouple circuit directly contributes to the temperature measurement error.

Some of the primary sources of thermocouple error areas follows:

1. Deviations from specifications in wire manufacture.
2. Use of low-impedance measuring instrumentation, leading to "loop-current" errors that arise from the flow of substantial currents within the thermocouple circuit.
3. Presence of electromagnetic interference, whether at the measuring junction or along improperly shielded extension wires.
4. Use of switching apparatus that introduced spurious and sometime variable voltages.
5. Use of extension wires that do not match the emf-temperature relation of the thermocouple wires themselves or that introduce unwanted emf's in their connections to the circuit.

SUMMARY

The use of thermocouples for temperature measurement provides a reliable and reproducible measurement for a variety of applications in many different disciplines. This article discussed the history of thermocouples, theory of thermocouples, thermocouple junctions, calibration of thermocouples, and thermocouple applications. Since the materials used to make thermocouples are relatively inexpensive and readily available, their use is widespread for scientific and industrial applications. From as low as -190°C to as high as 2000°C , thermocouples are used for just about every low-cost temperature measurement application.

THERMOPILES

Thermopiles and thermocouples are transducers of thermal energy into electrical energy and vice versa. A thermocouple is the basic unit from which thermopiles are constructed and operates on the principles of thermoelectricity. In a closed electric circuit consisting of two dissimilar conductors joined together, electric current flows when the two junctions are maintained at different temperatures. The pair of conductors that make up the circuit are called thermoelements and the electric circuit is called a thermocouple. The open circuit voltage generated in this way is widely used for the accurate measurement of temperature and is schematically illustrated in Fig. 1. For a given pair of conductors, thermoelectric voltage is found to be a function of the temperature difference between the two junctions. In order to measure temperature using a thermocouple, one of the junctions, called the reference junction, is maintained at a fixed reference temperature. In this way, the thermoelectric voltage generated depends only on the temperature of the second junction which is known as the measurement junction. The temperature-voltage relationship for most commonly used thermocouple materials are available in the form of tables, curves, and mathematical equations. For most metals and alloys, thermoelectric voltages generated are very small—of the order of several tens of microvolts per degree Celsius.

If several thermocouples made of the same pair of conductors are connected in series with the alternate junctions at the hot and cold temperatures, respectively, the total output voltage increases by a factor, N , of the number of thermocouples in the circuit. Such a circuit consisting of several

Figure 1. Schematic diagram of a thermocouple circuit consisting of two dissimilar materials A and B with the two junctions at different temperatures T_0 and T_1 . The open circuit thermoemf is measured using a high impedance voltmeter.

Figure 2. Schematic diagram of a thermopile consisting of four thermocouples connected in series. The alternate junctions of the thermopile are connected to the measurement junction at a temperature T_1 and the reference junction at a temperature T_0 .

thermocouples connected in series is called a thermopile and is shown in Fig. 2. This is a simple way of increasing the output voltage for a given temperature difference and is often used in many practical applications. Thermopiles find widespread use in various applications that include the accurate measurement of temperature, cooling and heating applications, generation of electricity, and infrared radiation detection. Thermoelectric thermometry is widely employed in scientific and industrial temperature measurement and control. When used in direct thermal contact with the object of interest, thermocouples can measure temperature over a large range from as low as 1 K (-272°C) to as high as 2000°C . This temperature range is further extended when thermopiles are used as the transducer elements in radiation pyrometry. Thermoelectric power generation and thermoelectric cooling are used to a much lesser extent but still dominate some niche applications such as power generation in spacecraft. Recent advances in silicon micromachining technology and thin-film deposition techniques are finding new applications for thermopiles as infrared detectors, accelerometers, and flow sensors.

We begin with a very brief review of thermoelectricity based on a standard thermocouple circuit as shown in Fig. 1. The bulk of this article will, however, concentrate on the various practical applications of thermopiles. A detailed account of thermoelectricity can be found in several excellent books such as Barnard (1) and Pollock (2).

BASICS OF THERMOELECTRICITY

Seebeck Effect

The Seebeck effect can be qualitatively understood by assuming a conductor as being made up of a rigid lattice of atoms in which a gas of free electrons moves under the influence of applied force fields. In the presence of a thermal gradient in such a conductor, electrons at the hot end diffuse toward the cold end. Scattering of electrons by the lattice causes a transfer of some of their energy to the lattice, resulting in the process of thermal conduction. The diffusion of high energy electrons also leads to the build-up of excessive electrons toward the cold end of the conductor and therefore to a build-up of an electric potential which is opposed to the thermal gradient. In this way, a dynamic equilibrium is established between the high energy electrons, being driven toward the cold end by the thermal gradient,

and the low energy electrons, being driven toward the hot end by the potential gradient. This electric potential arises whenever there exists a thermal gradient in a conductor and is known as the thermoelectric emf, or electromotive force. It is important to understand that thermoelectric electromotive force (emf) is not a junction potential but instead arises from the interaction of electrons with the lattice within a material in the presence of a thermal gradient.

In order to measure the Seebeck potential, electrical connections to the two ends of the specimen under test are made using a material different from the specimen. Otherwise the symmetry in the circuit will cause no net emf to be detected. The necessary use of two different materials results in the well known configuration of a thermocouple—in which two different conductors are joined together to form the hot and the cold junctions and the open circuit voltage of the couple is measured using a voltmeter. For homogeneous conductors, the thermoelectric emf depends only upon the temperatures of the two junctions and not upon the detailed shapes of the samples or the detailed forms of the temperature distributions along them. The rate of change of thermoelectric emf $V(T)$ with temperature T is known as the absolute thermopower $S(T)$ of the conductor, that is,

$$\frac{\Delta V(T)}{\Delta T} = S(T) \quad (1)$$

For a thermocouple as shown in Fig. 1, the open circuit voltage $V_{AB}(T_0, T_1)$ between the free ends of the thermoelements at temperature T_0 is given by

$$V_{AB}(T_0, T_1) = V_A(T_0, T_1) - V_B(T_0, T_1) = \int_{T_0}^{T_1} [S_A(T) - S_B(T)] dT \quad (2)$$

If material B is chosen to be a superconductor and is in its superconducting state (i.e., below the transition temperature), it will make no contribution to V_{AB} and the absolute thermopower of material A , S_A , can be experimentally measured.

In addition to the Seebeck effect, thermoelectricity has a manifestation in two other forms, known as the Peltier and Thomson effects.

Peltier Effect

If an electric current flows across a junction between two dissimilar materials there is a net evolution or absorption of heat in the junction region depending upon the direction of the flow of current. A Peltier coefficient Π_{AB} may be defined as the rate of absorption or evolution of heat per unit current flowing from material A to material B . If dQ_{AB}/dt is the net rate of evolution or absorption of heat at the junction at temperature T , then

$$\frac{dQ_{AB}(T)}{dt} = \Pi_{AB} I \quad (3)$$

where I is the current flowing from A to B . Π_{AB} is a function of the junction temperature of the two conductors. For metals, direct measurement of the Peltier coefficient is difficult to perform because of the small amount of heat evolution/absorption associated with the Peltier effect, as well as the difficulty in decoupling the effect from the associated Joule heating and

Thomson effect. Instead, it is usually determined using the experimental values of S_{AB} and the Kelvin relations.

Thomson Effect

The Thomson effect relates to the evolution or absorption of heat on the passage of an electric current through a single conductor in the presence of a thermal gradient. Thomson heat is proportional to the product of the current and the thermal gradient. The constant of proportionality is called the Thomson coefficient μ which is defined as the heat generated per second per unit current flow per unit temperature gradient when current flows through a conductor in the presence of a temperature gradient. It is a reversible heat, in the sense that the conductor changes from a Thomson heat absorber to a heat generator when either the direction of the current or the thermal gradient is reversed but not both at the same time. Using arguments based upon equilibrium thermodynamics, Thomson, later called Lord Kelvin, derived the relationship between the Seebeck coefficient, the Peltier coefficient, and the Thomson coefficient. These relations are known as the Kelvin relations and for a material at a temperature T can be written as:

$$\frac{\Pi}{T} = S \quad (4)$$

$$\frac{\mu}{T} = \frac{dS}{dT} \quad (5)$$

These relations allow any two of the thermoelectric effects to be quantitatively calculated if one of either μ or S can be determined over a given range of temperature.

The term “thermoelectric effects” as commonly used refers to all the reversible phenomena which occur at the junctions of dissimilar materials and throughout regions of a material in which finite thermal gradients are present. This is important because passage of current is simultaneously associated with the irreversible phenomena of the evolution of heat (“Joule heating”) and the conduction of heat. From a thermodynamic perspective and from Eq. (4), the Seebeck coefficient, S , can be interpreted as the mean transport entropy per unit charge, while Thomson coefficient μ , defined as amount of heat evolved or absorbed within a material per unit current flowing in the presence of a temperature gradient in the material, can be interpreted as the specific heat per unit charge. Thermodynamic perspective of thermoelectric effects is extremely insightful and these arguments were instrumental in the derivation of the Kelvin relations above. However, Lord Kelvin derived these relationships based on the questionable assumptions of reversible thermodynamics, which apparently gave correct results but had to await the developments of irreversible thermodynamics by Onsager in 1931 before these relationships were finally validated. In order to quantitatively predict the thermopower of a material, a detailed understanding of the electronic behavior of the material is necessary. Nevertheless, the various contributions to thermopower can be understood by remembering that the Seebeck coefficient is related to the electrochemical potential Θ' as:

$$S \propto \frac{1}{e} \frac{\Delta\Theta'}{\Delta T} \quad (6)$$

where e is the charge of the carrier, and T is the temperature.

The electrochemical potential,

$$\Theta' = \Theta + e\phi \quad (7)$$

includes both the chemical potential (commonly known as Fermi level) Θ , and the electrical potential, ϕ . In a homogeneous material, the chemical potential depends only on the temperature, whereas the quantity $e\Delta\phi/\Delta T$ depends on the detailed environment at any given point inside the material. The nature of this electrical environment is determined by the detailed way in which the electrons are scattered by the lattice vibrations, impurities, and other imperfections. In metals and alloys

$$\frac{\partial\Theta}{\partial T} \ll \left| e \frac{\Delta\phi}{\Delta T} \right| \quad (8)$$

and the thermopower is primarily determined by the scattering effects. On the other hand, in insulators, the opposite is true and the thermopower is dominated by chemical potential. The magnitude of the electronic thermopower for bulk metals and alloys at high temperatures (above Debye temperature ≈ 300 K for most metals and alloys), as given by the free-electron model, Barnard (1), is

$$S = \frac{-\pi^2 k^2 T}{3e} \left[\frac{1}{\Omega} \frac{\partial\Omega}{\partial E} + \frac{1}{l} \frac{\partial l}{\partial E} \right]_{E=E_F} \quad (9)$$

where k is the Boltzmann constant, e the electronic charge, Ω is the area of the Fermi surface, l is the electron mean-free-path, and E_F is the Fermi energy. Equation (9) implies that thermopower is very sensitive to changes in the electron scattering mechanisms, presence of impurities, strain, and even pressure. It must be emphasized that, although solid state physics gives a broad understanding of the phenomena of thermoelectricity, it has been very difficult to accurately predict the magnitude and occasionally even the sign of the thermopower of metals and alloys. Therefore, for most of the practical thermocouple systems, the dependence of thermoelectric emf on temperature is an empirical relationship.

LAWS OF THERMOCOUPLE CIRCUITS

Based on the thermoelectric effects discussed and using the simple thermocouple circuit shown in Fig. 1, a number of empirical statements can be deduced. These laws are simple restatements of the detailed principles of thermoelectricity and form the basis for the practical construction and applications of thermocouple circuits.

Law of Homogeneous Materials

No thermoelectric voltage can be measured in a thermocouple circuit consisting of chemically and physically identical homogeneous materials no matter what the shape or cross-section of the conductor or the temperature difference between the two junctions. In reality though one must remember that, in the presence of a thermal gradient, thermoelectric voltages might be observed in single material circuits which are very likely to include inhomogeneities such as stressed or oxidized sections of the same material. Thermoelectrically speaking, these sections can be considered as different materials.

Figure 3. Schematic illustration of the law of different materials at different temperatures. This law is useful in generating the thermocouple calibration chart, the thermoelements of which have been calibrated against a common reference material.

Law of Different Materials at a Single Temperature

No thermoelectric voltage can be measured in a thermoelectric circuit consisting of many dissimilar materials and junctions if it is maintained throughout at a constant temperature. This law simply affirms the fact that in the absence of thermal gradients no thermoelectric phenomena can be observed.

Law of Different Materials at Different Temperatures

For the same junction temperatures, the algebraic sum of the thermoelectric voltages in two circuits composed respectively of materials A–B and B–C is the same as the thermoelectric emf of a single circuit composed of materials A–C. This law is schematically shown in Fig. 3. The main application of this law is in the generation of the temperature–thermoemf relationship for a given thermocouple combination if the temperature–thermoemf relationship of the constituent materials are available with respect to a common reference material such as platinum.

Law of Intermediate Temperatures

For a given two junction thermocouple, if the thermoelectric emf measured is V_1 when the two junctions are at temperatures T_0 and T_1 and V_2 when the two junctions are at temperatures T_1 and T_2 , then the thermoelectric emf V_3 produced by the same thermocouple when its junctions are at temperatures T_0 and T_2 is equal to $V_1 + V_2$. This law is particularly important if a thermocouple is intended for use at a different reference junction temperature than that used in its original calibration. This law is schematically illustrated in Fig. 4.

THERMOPILES AND TEMPERATURE SENSORS

As we have already discussed, a thermocouple essentially transforms thermal energy into electrical energy and vice versa. As temperature sensors, thermocouples have the advantages of not requiring any power supply for their operation and can be used over a very large temperature range. However, they have the disadvantages of small output voltages, susceptibility to noise pickup by the thermocouple wires,

and relatively high drift. For homogeneous, macroscopic metals and alloys at high temperatures, the laws of thermoelectricity are essentially independent of the physical dimensions of the thermocouple. This means that most thermocouples are constructed from wires as small as is practical or most cost effective. However, small thermocouples are more readily suited for spot measurements of temperature and therefore provide a small physical cross-section to interact with the sensing stimulus.

A thermopile consisting of several thermocouples connected in series not only offers a simple way of increasing the sensing cross-section of the thermocouple but as discussed earlier also offers the possibility of obtaining a larger electrical signal for a given temperature difference. As transducers of thermal energy into electrical energy the two main, Seebeck effect based, applications of thermopiles are as temperature and radiant flux sensors and as generators of electrical power. As transducers of electrical energy into thermal energy using Peltier effect, the main application of thermopiles is as cooling devices or refrigerators. The use of several thermocouples connected in series results in higher sensitivity in sensor applications and higher power in electricity generation applications. In cooling and heating applications, the many thermocouple junctions of thermopiles not only result in more power but can also be set-up into practical configurations for uniform heating and cooling of large surface areas.

The arrangement of connecting several thermocouples in series such that the alternate junctions are at two different temperatures amplifies the thermoelectric voltage of a single thermocouple by the number of thermocouples, N , connected in series.

$$V_{\text{Thermopile}} = N \cdot V_{\text{Thermocouple}} \quad (10)$$

However, this also results in an increase in the noise due to the N -fold increase in the resistance of the device. In an open circuit voltage measurement configuration, the primary source of internal noise in a thermocouple is from the random fluctuation of the charge carriers in the material and is called the Johnson noise. The root mean square (rms) open circuit Johnson noise voltage, V_n , in a 1 Hz bandwidth for a material of resistance R

Figure 4. Schematic illustration of the law of intermediate temperatures. This law is mainly used for operating thermocouples at reference temperatures which are different from the standard reference temperature.

Table 1. Seven Standard Types of Thermocouples Used in the Measurement of Temperature

Thermocouple Type	Nominal Composition (% weight)	Useful Temperature Range (°C)	Comments
Type B	(Pt + 30% Rh) vs. (Pt + 6% Rh)	0–1704	Recommended for continuous use in oxidizing and inert atmospheres. Limited vacuum use is possible.
Type E	(Ni + 10% Cr) vs. (Cu + 43% Ni)	–250–871	Primarily for oxidizing atmospheres. Does not corrode at sub-zero temperatures
Type J	Fe vs. (Cu + 43% Ni)	–210–1200	Suitable for vacuum use or where free oxygen is deficient since iron rapidly oxidizes above 538°C (1000°F).
Type K	(Ni + 10% Cr) vs. (Ni + 2% Al)	–250–1260	Suitable for continuous use above 538°C in oxidizing atmospheres.
Type R	(Pt + 13% Rh) vs. Pt	–50–1482	Not suitable for reducing atmospheres and for continuous high temperature applications.
Type S	(Pt + 10% Rh) vs. Pt	–50–1482	Not suitable for reducing atmospheres and for continuous high temperature applications.
Type T	Cu vs. (Cu + 43% Ni)	–250–400	High resistance to corrosion from atmospheric moisture or moisture condensation. Can be used in either vacuum, oxidizing, or reducing atmosphere.

which is at a temperature T is given by

$$V_n = \sqrt{4kRT} \quad (11)$$

where k is the Boltzmann constant. It can be seen that, while the signal from a thermopile increases by a factor of N , the open circuit noise voltage in a thermopile increases by a factor of $\sqrt{N}$, therefore resulting in an effective signal to noise ratio increase of $\sqrt{N}$.

Choice of Materials

Based on the material of construction, thermopiles can be broadly classified into two major groups as: (1) metal-alloy thermopiles and (2) semiconductor thermopiles. Metal-alloy thermopiles are mainly used in temperature measurement applications whereas semiconductor thermoelements find applications in power generation, refrigeration, and radiant flux measurements. This is due to the fact that although metals and alloys have a small Seebeck coefficient, typically of the order of a few tens of microvolts per kelvin, they can be very reliably and inexpensively reproduced. Semiconductors on the other hand exhibit superior properties for thermoelectric energy conversion applications with larger Seebeck coefficients, typically of the order of hundreds of microvolts per kelvin. Semiconductor thermoelements are more expensive and can be less easily formed into various convenient forms for temperature measurement applications.

Most commercially available thermocouples and thermopiles used for temperature measurement are made up of metals and alloys. As stated above metals and alloys exhibit very reproducible thermoelectric properties and can be very easily and inexpensively formed into convenient forms such as thin wires suitable for temperature measurements. Additionally, modern potentiometers can measure very low voltages very accurately and reliably. These developments have made it possible to routinely measure temperatures accurately to a fraction of a degree Celsius using standard metallic thermocouples. Although it is possible to measure temperature using any combinations of metals and alloys, only seven combinations of different alloys are commonly used for temperature measurement in the range of 20 K to 2000 K. For each of the seven

thermocouple combinations there exist internationally agreed reference tables for thermal emf versus temperature as well as a letter designation. Table 1 lists the type designation of the alloy compositions, their useful temperature range, and the typical application environment for each of the thermocouple types. For a more detailed discussion on the use of thermocouples for temperature measurement refer to the American Society for Testing and Materials (ASTM) manual (3).

Thermoelectric Figure of Merit

The efficiency of energy conversion of thermoelectric devices is not only related to the absolute thermopower of the materials but also to their thermal and electrical conductivity. This can be qualitatively understood, for example, by considering a thermocouple as an electricity generator. In order to achieve high energy conversion efficiencies, the conductive heat losses from the transducing junction through the thermocouple legs need to be minimized (i.e., low thermal conductivity materials are required) and the electrical power output Z , for a given material is given by (V^2R) needs to be maximized (i.e., large thermopower and low electrical resistivity materials are required). In fact, thermoelectric figure of merit, Z , for a given material is given by

$$Z = \frac{S^2\sigma}{\kappa} \quad (12)$$

where S is the absolute thermopower of the material, and σ and κ are its electrical conductivity and thermal conductivity, respectively. The thermoelectric figure of merit has the dimensions of inverse of temperature. A more detailed derivation of the thermoelectric figure of merit is based on the maximization of the coefficient of performance of a thermoelectric power generator/refrigerator or the normalized detectivity D of an infrared detector. For a more comprehensive treatment of the figure of merit of thermoelectric materials, see references by Rowe and Bhandari (4), Kaye and Welsh (5), or Baltes et al. (6).

Materials with a large value of Z over a large temperature range are required in order to achieve a high energy conversion efficiency. For a thermocouple, the figure of merit can be extended to take into consideration the different

material properties of the two materials and is given by

$$Z_{AB} = \frac{S_{AB}^2}{\left(\sqrt{\frac{\kappa_A}{\sigma_A}} + \sqrt{\frac{\kappa_B}{\sigma_B}} \right)^2} \quad (13)$$

where the subscripts *A* and *B* refer to the properties of the two materials constituting the thermocouple respectively. Table 2 lists the thermopower and the figure of merit for some of the commonly used bulk and thin film thermocouple materials respectively.

Standard Construction

The main application of thermocouples and thermopiles is as temperature sensors. As has been discussed earlier, in their most popular use a thermopile is constructed of several thermocouples connected in series. Thermopiles are used for the direct measurement of temperature by placing the measurement junction in intimate thermal contact with the object of interest and the reference junction at a fixed known temperature. The detailed construction of a thermopile depends on the specific application for which it is being used. For most temperature measurement applications, the thermopile configuration that is most practically implemented is a modified form of the thermopile shown in Fig. 2. The measurement junction of the thermopile made of metals A and B, is located at the temperature, T_1 , to be measured. The input and output wires of the reference junction are connected to an extension wire C and is maintained at a temperature T_0 . The extension wires C finally connect the thermopile to a high impedance voltmeter at room temperature T_R . This configuration occurs invariably in all situations where the temperature to be measured is located remotely as compared to the voltmeter. Summing the various thermoelectric voltages for the circuit we get

$$V = V_C(T_0, T_R) + N\{V_A(T_0, T_1) - V_B(T_0, T_1)\} - V_C(T_0, T_R) \quad (14)$$

If the two wires made of material C are homogeneous and have

the same thermoelectric properties, then the total thermoelectric emf measured is the same as obtained using the thermopile made only of materials A–B. Developments in electronic circuits have led to accurate tracking of the variations in reference junction temperature using thermistors. This is often used to compensate for any errors in the measured temperature caused due to drifts in the temperature of the reference junction.

Thermocouples can also be connected in parallel as shown in Fig. 5. In such a case the parallel thermopile configuration provides a temperature averaging effect. However, extreme care must be taken to prevent the possibility of closed loop currents within the thermocouple pairs which can arise easily due to the variations in the calibration curves of the individual thermocouples, differences in the individual resistance of the thermocouples, and variations in the Seebeck coefficient of the individual thermoelements in the temperature range of measurements. Therefore, in spite of the possibility of temperature averaging, the parallel arrangement of thermocouples is not commonly used.

Figure 5. Schematic drawing of a thermopile consisting of four thermocouples connected in electrical parallel configuration. Used with a certain amount of caution, this configuration can be used for temperature averaging.

Reference Junction

As we have already discussed, a thermopile essentially measures the difference in temperature between the two junctions across which it spans. To measure temperature using a thermopile; one of its junctions is maintained at a fixed reference temperature and the temperature of the measurement junction is deduced using the calibration chart of the thermocouple constituting the thermopile. Reference junction serves two functions, namely, (1) as a junction at a standard reference temperature of 0°C for producing the thermocouple voltage-temperature calibration chart or (2) as a junction at a known temperature, other than the reference temperature of 0°C, which is either fixed or variable. The standard reference temperature used in thermocouple calibration is the ice point, or 0°C—the equilibrium temperature between ice and water at 1 atmosphere pressure. Historically, this reference temperature has evolved from the ease of availability of ice and water in the laboratory and its uniqueness in the phase diagram. For a detailed treatment of reference junctions for thermocouple calibration refer to Quinn (7).

The fixed reference temperature of 0°C is good for calibrating thermocouples and thermopiles but is very cumbersome and most often impractical to implement in typical industrial situations. In order to maintain the reference junctions at a constant temperature of 0°C, Peltier coolers, discussed later, are sometimes used. However, it is very difficult to maintain the temperature of the actual cold junctions at this temperature due to the variability in thermal contact and the difficulty of surrounding the reference junction sufficiently to ensure the temperature to the desired accuracy. Therefore, it is desirable to use temperatures other than 0°C for the reference junction. In its most widespread use, the reference junction is normally kept at ambient conditions and its temperature is continuously monitored using a thermistor. In this way, any variations in the temperature of the reference junction are known and electronically compensated.

In using thermopiles to measure temperature, in addition to the errors associated with reference junction, and deviations from standard thermoemf due to thermocouple materials and extension wires, users should also be aware of the possible error sources associated with measurement junctions. These errors can be especially significant when thermopiles are used in the measurement of surface temperatures, since their very presence perturbs the heat transfer characteristics of the surface and changes the temperature distribution. The thermopile wires provide additional heat transfer paths and can effectively lower the actual temperature of the measurement surface. Another major source of error arises from the thermal contact resistance between the surface and the thermopile junction. This thermal contact resistance causes a temperature gradient to be set up between the surface and the thermopile junction and therefore prevents the junction from attaining the surface temperature. The relationship between the measured and true temperature can be expressed as:

$$\zeta = \frac{T_m - T_t}{T_m - T_a} \quad (15)$$

where ζ is called the installation factor, T_m is the measured temperature, T_t is true surface temperature, and T_a is the temperature of the ambient. In addition, errors can also arise in

surfaces where temperature gradients exist due to the errors associated with the exact positions of the thermopile junctions relative to the surface. The response time of the thermopiles can also cause errors in the measurement of transient temperature signals.

OTHER APPLICATIONS OF THERMOPILES

Thermopiles are extensively used as the basic transduction elements in many thermal sensors (8). Thermal sensors operate by first converting the input signals (the measurand) into a temperature signal in the sensor element which is subsequently transduced into an electrical signal. The most well-known application of thermopiles as thermal sensors has been for detecting infrared radiation. When used as radiation sensors, the measurement junction of the thermopile is placed in intimate contact with a radiation absorbing structure while the reference junction is attached to a heat sink. Absorption of incident radiation causes a preferential rise in the temperature of the measurement junction and therefore in a thermoemf. Recent advances in silicon micromachining technology have made possible several novel thermopile-based thermal sensors which include accelerometers, calorimeters, and mass flow sensors. A comprehensive review of silicon micromachined sensors is presented by Middelhoek (9), and for an excellent review of thermoelectric microsensors and systems refer to Baltes et al. (6). In addition, thermopiles are also used in heating and cooling applications and in some niche power generation applications. These applications of thermopiles are discussed in detail in the following sections.

Radiation Detectors

The most commonly known physical manifestation of energy is as electromagnetic radiation. Electromagnetic radiation spans a very large spectrum from gamma rays at the high energy end to radio waves at the low energy end. Lying between the visible and microwave parts of the electromagnetic spectrum, infrared radiation is widely used for: noncontact temperature measurements, intrusion alarm systems, remote sensing, astronomy, and heat emission based target detection and tracking. These applications are all possible because heated objects provide an excellent source for infrared radiation which is emitted by virtue of their temperature. The quantity of importance, most often, is the radiant power being emitted by a blackbody or monochromatic source. Excellent reviews on infrared radiation and infrared detectors are available in Smith, Jones, and Chasmar (10) and Keyes (11).

The sensing element of a thermopile infrared detector consists of a very small heat capacity radiation absorbing structure which is thermally isolated from the main sensor body which acts as a heat sink. The measurement junction of the thermopile is thermally attached to the sensing element while, the reference junction is attached to the main body of the sensor. Upon absorption of the incident radiant flux, the sensing element heats up relative to the main body of the sensor and the thermopile generates an open circuit voltage which is calibrated to read the power density. Traditionally, thermopiles were fabricated as bulk material devices by welding together fine wires and thin black radiation absorbers. However, developments in micromachining technology have made it possible to fabricate thermally isolated structures with small heat

Figure 6. Schematic representation of a sensing element of thermal mass (H), connected to the heat sink at temperature (T_0) via a thermal conductance (G). Absorption of the incident radiation of power (P) causes the temperature of the sensing element to rise to $T + \Delta T$.

capacity while advances in microfabrication techniques have made it possible to fabricate very high density thermopile structures using thin films. These developments have led to the design and construction of a variety of thin-film thermopile radiation detectors covering a wide range of impedance, sensitivity, and time constants (12,13,14,15).

A simple model of a thin-film thermopile is shown in Fig. 6. The detector element of thermal mass H is coupled to the heat sink at a constant temperature T_0 via a thermal conductance G . When a radiant power P is incident on the sensor element, its temperature T is found by solving the equation:

$$\epsilon P = H \frac{\partial T}{\partial t} + G(T - T_0) \quad (16)$$

where ϵ is the emissivity of the sensor element and t is time. For a sinusoidal power input, $P = P_0 \exp(i\omega t)$, the steady state solution of Eq. (16) is

$$\Delta T = T - T_0 = \frac{AP_0}{\sqrt{G^2 + \omega^2 H^2}} \quad (17)$$

A characteristic thermal time constant, τ , for the detector can be defined as

$$\tau = H/G \quad (18)$$

From Eq. (17) it can be seen that a high sensitivity, which corresponds to a large ΔT , can be achieved by making G as small as possible and $\omega H \ll G$. In other words, both the heat capacity of the detector element and its thermal coupling to the surroundings should be as small as possible. A small heat capacity for the detector element implies a detector element of as small and light weight a construction as is practically possible whereas the smallest value for G is achieved when the thermal coupling of the sensing element to the heat sink is only through radiative exchange. The design challenge of a thermopile radiation detector, therefore, is the optimization of the interaction of the sensing element (measurement junction) with incident radiation while simultaneously reducing its thermal mass and all other thermal contacts to the surroundings.

Silicon micromachining technology, by the use of precise lithographic patterning and crystallographic etching techniques, has made it possible to fabricate free-standing membranes and structures with very low heat capacity and good thermal isolation (16,17). The measurement junction of such

Figure 7. Schematic diagram of a micromachined thermopile infrared detector. The hot junctions of the thermopile (the sensing element) are fabricated on a free-standing cantilever while the cold junctions are thermally attached to the silicon rim which acts as the heat sink. These devices are fabricated using silicon microfabrication techniques along with anisotropic etching of silicon.

a thermopile is located along the contours of the highest temperatures on the free-standing structure whereas the reference junction is located along the thick rim of the substrate. Figure 7 schematically illustrates a typical micromachined cantilever structure based thermopile. This technology is naturally oriented toward the use of semiconductors and metal thin films as the thermoelements. Fortunately, semiconductors, as we have discussed earlier, are found to have a high thermoelectric figure of merit and make an excellent choice for this technology. To further improve the responsivity and spectral response, these infrared detectors are often coated with absorber materials such as gold black or with infrared absorbing thin films (18,19). Thin-film thermopiles with a responsivity of several tens of volts per watts and a time constant of tens of milliseconds are commercially available. Figure 8 shows a commercial thin film Bi/Sb thermopile infrared detector from Dexter Research Center and

Figure 8. Optical micrograph of a commercial thin film Bi/Sb thermopile infrared detector from Dexter Research Center. The device consists of a 2 mm $\times$ 2 mm active area and 40 thermocouple junctions connected in series. The detector has a responsivity of 19.2 V/W and a time constant of 40 ms. Figure 9. SEM (scanning electron microscope) micrograph of a cantilever beam infrared sensor array. The length of the oxide/nitride cantilever beam is $300\text{ }\mu\text{m}$, the width is $200\text{ }\mu\text{m}$ and the depth of the etch groove is about $120\text{ }\mu\text{m}$. The thermopile is made up of *n*-polysilicon/*p*-polysilicon as the thermoelements. (Courtesy Physical Electronics Laboratory, ETH, Zurich, Ref. 14)

Figure 9 shows a typical CMOS (complementary metal-oxide-semiconductor) based polysilicon thermopile. Further reduction in the thermal mass of such sensors has been achieved by completely removing the supporting membranes under the thermoelements. These modifications have reduced the time constants of the infrared detectors to a few microseconds. Such a free-standing copper-constantan microthermopile is shown in Fig. 10. Current efforts in this field are focused on the further optimization of the thermo-mechanical design of the sensing elements (20), utilizing thin film semi-metals and semiconductors as thermoelements and the integration of the sensor with on-chip antenna structures (21). Efforts are also focused on fabricating these devices as planar imaging arrays with integrated CMOS circuitry for signal conditioning and readout (22).

Integrated Thermopiles

The demand for intelligent sensor systems, which has included an increasing number of sensors as well as an increasingly complex analog and digital circuitry, has been the motivation behind the development of integrated microsensors. In particular, thermal sensors are at the heart of several such microsystems. Thermal sensors first convert the measurement signals into a thermal signal, which is then transduced into an electrical signal primarily using thermoelectric or thermoresistive techniques. Thermoresistive elements (thermistors) compete in nearly every application along with thermopiles and are also widely used in sensor applications. This section will limit the discussion only to the use of integrated thermopiles in various microsensor applications. Integrated thermopiles offer the possibility of batch fabricating microsensors and systems at large volumes and low cost with high reliability and thus form a subject of great current interest. Integrated thermopiles fabricated using micromachining technology are used, as the transduction elements, in several thermal microsensors ap-

Figure 10. SEM micrograph of a copper-constantan free-standing microthermopile. The free-standing wires are $1\text{ }\mu\text{m}$ wide and the length of the free-standing wires is $35\text{ }\mu\text{m}$. The cold junctions (large pads) are thermally attached to the substrate. The small thermal mass of the sensing element results in a fast response time of $\sim 20\text{ }\mu\text{s}$.

plications which can be broadly classified as: (1) thermomechanical sensors (mass flow sensors, pressure sensors, and accelerometers), (2) thermal converters (electrical power sensors), and (3) thermochemical sensors (calorimeters and reaction enthalpy sensors).

Mass Flow Sensors, Pressure Sensors, and Accelerometers

In a mass flow sensor, a thermally isolated resistor is heated using a constant power. Thermopile sensors are placed along the upstream and downstream of the flow with the resistor heater in between them. The heat transfer coefficient, which is the ratio of the heat flow (from the heater surface to the flowing fluid) and the temperature difference (between the heater surface and the flowing fluid), among other parameters, is a function of the flow velocity. It is larger for the upstream flow than for the downstream flow and therefore induces a temperature difference between the upstream and the downstream thermopiles which is used to detect the flow velocity as well as the flow direction along the line of the sensors (23,24). The heat transfer coefficient is a very sensitive function of the heater and sensor geometry, the nature of fluid flow (laminar, turbulent, and so on), the heat capacity and thermal conductivity of the fluid itself. A simpler way of detecting flow is to measure the increase in power required to maintain the temperature of a heated resistor at a constant value in the presence of fluid flow. This is the principle on which hot wire anemometer work and the power, P , dissipated in the wire is related to the flow velocity, v , as

$$P/\Delta T \propto v^{1/2} \quad (19)$$

where ΔT is the temperature difference between the wire and

Figure 11. SEM picture of a bridge type flow sensor fabricated using bipolar technology. the fluid. Figure 11 shows a CMOS thermopile based flow sensor.

Thermal conductance of a gas is a function of the gas pressure (i.e., the dissipation of thermal energy from a heater to a heat sink across a small gap filled with the gas depends on the gas pressure). For a constant power dissipation in the heater, this pressure-dependent thermal conductance of the gas causes a variation in the heater temperature and provides an accurate way of measuring the gas pressure. The temperature of the resistor heater is measured using an integrated silicon-based thermopile. For the typical micromachined sensor geometries, these pressure sensors are best suited for vacuum measurements in the range of 10 mPa to 10 kPa. Such integrated thermopile-based vacuum sensors have been fabricated using both bulk and surface micromachining techniques, see (Refs. 6) and (25).

A silicon accelerometer is based on the detection of movement of a suspended mass under the influence of acceleration. A thermopile based accelerometer detects the change in heat flow between the suspended mass and a heat source under the influence of acceleration. A typical sensor consists of a thermally isolated bridge with thermopiles on top of a heat source and a proof mass etched out of bulk silicon suspended in close proximity over the bridge (26).

Thermal Converters and Thermal Conductivity Sensors

In a thermal converter, electric power is dissipated into an ohmic resistor and converted into thermal power which is then measured using a thermopile-based temperature sensor. The operation of these sensors is based on the square-law relationship between the voltage and power. These devices have been used in wide-frequency-band ac power measurements and in particular for the measurement of microwave ac power

(true root mean square voltage value) (6,25). In addition to ac power measurements, integrated thermopiles have also been used for the measurement of thermal conductivity of thin films and materials. Such sensors are based on the fabrication of micromachined freestanding structures of appropriate geometries in which the contribution to thermal effects of specific layers can be effectively isolated and quantified. These freestanding structures are heated by dissipating known quantities of electrical power and integrated thermopiles are used for the accurate temperature measurement in such structures (6,25)

Integrated Thermopile-Based Calorimeters

In microcalorimetry applications, the measurement junction of a thermopile is placed on a thermally isolated bridge or membrane structure and is coated with a catalytic layer for the desired chemical reaction. Under the influence of the surface catalyst, the chemical reaction takes place on the membrane surface and the heat of the reaction is detected by the change in temperature of the measurement junction of the thermopile with respect to the reference junction (27). This is an example of a chemical sensor based on microcalorimetry. If instead of a catalyst, a coating that converts absorbed microwaves into heat is used, the microcalorimeter can be used as a microwave sensor. Another example would be to coat the thermally isolated structure with a ferromagnetic coating with high hysteresis. Ac magnetic fields would cause heat generation in such a sensor structure, which can be measured using an integrated thermopile (8).

Thermoelectric Refrigeration

The passage of an electric current through a thermoelectric circuit can be used to cool one of its junctions by selectively pumping away heat to the other junction using Peltier effect. Since thermoelectric refrigerators contain no moving parts, they operate quietly, require very low maintenance and have a long life. In addition, the coefficient of performance of thermoelectric refrigerators is independent of the size of the system to be cooled which makes them ideally suited for low capacity cooling applications. However, the widespread use of thermoelectric refrigerators has been hindered by the higher costs and lower cooling efficiency as compared with the more commonly used compression-cycle refrigerators. Consequently, thermoelectric refrigerators are employed in certain niche application such as in spacecraft, artificial satellites, scientific equipment, cooled stages for laboratory applications where compactness, quiet performance, operation in vacuum environments, and high reliability are of major concern. Small cooling systems with powers of less than 10 W are commonly used as cold traps in vacuum systems, cooled stages inside vacuum chambers, as cooling jackets for cooled infrared detectors, as active heat sinks for cooling of main processor chips in personal computers, and for controlling the temperature of thermocouple reference junctions. Reviews on thermoelectric refrigeration can be found in Rowe and Bhandari (4) and Ioffe (28).

A thermoelectric refrigerator module is normally constructed such that all the cold junctions of the thermopile are on one face and the hot junctions on another face. Heat is pumped to the hot junction at a rate proportional to the current in the circuit and to the number of thermocouples, *N*, constituting

Figure 12. Schematic diagram illustrating the use of different thermocouples in a temperature sandwich arrangement. Each thermocouple operates at the best average Z value and the overall figure of merit is given by the envelope as shown on the right hand side.

the thermopile. The most widely used materials in the construction of thermoelectric refrigerators are alloys of bismuth, antimony, selenium, and tellurium. Single layer module sizes range from 2.5 mm to 50 mm square and from 2.5 mm to 7.5 mm thick, with cooling capacities ranging from a few watts to about 100 W. The maximum temperature difference that a single thermoelectric module can produce for a cooling power, $P_c = 0$ W, is around 65°C .

Thermoelectric materials have a different value for the thermoelectric figure of merit, Z , at different temperatures. If several thermocouple pairs are connected in series in a cascade arrangement at different temperatures as shown in Fig. 12, such that each thermopile operates at its best Z value, the overall coefficient of performance of the refrigerator can be increased. Since the lower stages remove heat dissipated by the stages above them and from the load, multistage modules are constructed in a pyramidal shape as shown in Fig. 13. Multistage modules of up to six layers can generate several hundreds of watts of cooling capability and provide temperatures as low as -100°C with the heat sink at 27°C . In most small refrigeration systems with cooling powers in the range of up to 50 W, the

pumped heat is dissipated into the surroundings by natural air convection or by using cooling liquids. In general, thermoelectric refrigeration systems are most economical cooling solutions for small cooling powers up to 50 W. In the 50 W and above cooling power range, thermoelectric systems are often more expensive and always less efficient than compression cycle systems. For these cooling powers, a thermoelectric system is only used if some other characteristic is of greater importance. Review of industrial thermoelectric cooling applications are presented in (Refs. 29) and (30).

Thermoelectric Generators

Thermopiles can also be employed to generate electrical power if a temperature difference is maintained across its two faces. These thermoelectric generators are primarily used as remote, maintenance free, unattended power supplies in space stations and space vehicles, unmanned light houses, navigational buoys, remote mines, and drilling platforms. Another area where thermoelectric generators find application is in medical applications, especially as miniature batteries delivering under $300 \mu\text{W}$ of energy in cardiac pacemakers and other stimulator applications (4).

The main components of a thermoelectric generator are: (1) a heat source, (2) a thermopile, (3) a heat sink, and (4) an output control system. Most often, the physical arrangement of a thermopile generator is determined by the nature of its heat source. Thermoelectric generators are normally classified by the kind of fuel source they use as isotopic or nonisotopic. Nonisotopic generators are mainly powered by fossil fuels and to a limited extent by solar radiation. In isotopic generators, radioactive isotopes are used as the fuel sources. Radioactive isotopes emit high energy density over long periods of time. For example, plutonium (P-238) has a half life of 87 years and so the thermal output from the fuel capsule only decreases by 4% in 10 years. Thus, radioactive sources are very attractive fuel sources for thermoelectric generators. Currently all radioactive thermoelectric generators (RTGs) use either plutonium-238 or strontium-90 as the fuels (4,5). Depending on the kind of

Figure 13. A three-stage schematic of the cascade arrangement of thermopiles. This arrangement affords flexibility in the geometrical requirements of each stage for optimal performance.

radiation emitted by each of these sources, elaborate care has to be taken to shield and confine the emission while maintaining the compactness and light weight of the entire system. In general, plutonium-238 requires minimal shielding and is best suited for space and medical applications where cost considerations are not important, while strontium-90 at one fortieth the cost of plutonium is employed in terrestrial applications where bulkiness of shielding is not an issue. However, due to safety and security reasons, RTGs have not been used for medical applications since the late 1980s. On the positive side, though, the development of these generators has had a significant impact on the development of high Z thin film materials.

Aside from the heat source, production of power using thermoelectric generators apparently seems very straightforward. The practical implementation, however, involves a very complex arrangement of coupling the heat source to the thermopile junctions while electrically isolating the junctions at the hot face of the generator module at the high operating temperatures. In addition, problems associated with material degradation and poisoning when continuously operated at high temperatures reduce the conversion efficiencies and performance over time. In general, the overall conversion of a thermoelectric device depends upon the temperature of its operation and the proportion of available heat which passes through the thermoelements.

Conventionally, thermoelectric power is generated at relatively high values of current and low voltage, with the load voltage from the thermoelectric module being about half the open circuit voltage of the thermopile. Solar powered thermoelectric generators using selective absorber coatings and with thermoelements fabricated from fine grained Si-Ge alloys have been predicted to operate with an efficiency of better than 12% between room temperature and 1000 K. A portable flame-powered generator, weighing about 5 kg, using leaded petrol as fuel, has been developed with a power output of 45 W at 6 Vdc and an overall efficiency of 2%. On the other hand, batteries powered by plutonium-238 and a bismuth-telluride thermopile module can supply several tenths of a volt for more than 10 years.

ACCELEROMETERS

Acceleration is an important parameter for general-purpose absolute motion measurements and vibration and shock sensing. Accelerometers are commercially available in a wide variety of ranges and types to meet diverse application requirements. They are manufactured to be small in size, light in weight, and rugged and robust to operate in harsh environments. They can be configured as active or passive sensors. An active accelerometer (e.g., piezoelectric) gives an output without the need for an external power supply, while a passive accelerometer only changes its electric properties (e.g., capacitance) and requires an external electrical power. In applications, the choice of active- or passive-type accelerometers is important, since active sensors cannot measure static or dc mode operations. For true static measurements, passive sensors must be selected.

Accelerometers can be classified in a number of ways, such as deflection or null-balance types, mechanical or electrical types, and dynamic or kinematic types. The majority of industrial accelerometers can be classified as either deflection type or null-balance type. Those used in vibration and shock measurements are usually the deflection types, whereas those used for measurements of motions of vehicles, aircraft, and so on for navigation purposes may be either type. In general, null-balance types are used when extreme accuracy is needed.

A large number of practical accelerometers are the deflection types; the general configuration is shown in Fig. 1. There are many different deflection-type accelerometers. Although principles of operation are similar, they differ in minor details, such as the spring elements used, types of damping provided, and types of relative motion transducers employed. These types of accelerometers behave as second-order systems; the detailed mathematical analysis will be given in the following sections.

Dynamic accelerometers have an operation that is based on measuring the force required to constrain a seismic mass to track the motion of the accelerated base, such as a spring-constrained-slug accelerometer. Although applicable to all, the mathematical treatment of the dynamic response of an accelerometer as a second-order system is given in detail in

the section dedicated to seismic accelerometers. Another type is the kinematic accelerometer, which is based on timing the passage of an unconstrained proof mass from spaced points marked on the accelerated base, and is used for highly specific applications such as interspace spacecraft and gravimetry-type measurements.

For practical purposes, accelerometers can also be classified as mechanical or electrical types, depending on whether the restoring force or other measuring mechanism is based on mechanical properties (for example, the law of motion, distortion of a spring, or fluid dynamics) or on electrical or magnetic forces.

TYPES OF ACCELEROMETERS

Seismic Accelerometers

These accelerometers make use of a seismic mass that is suspended by a spring or a lever inside a rigid frame. The schematic diagram of a typical seismic accelerometer is shown in Fig. 1. The frame carrying the seismic mass is connected firmly to the vibrating source whose characteristics are to be measured. As the system vibrates, the mass tends to remain fixed in its position so that the motion can be registered as a relative displacement between the mass and the frame. This displacement is sensed by an appropriate transducer and the output signal is processed further. Nevertheless, the seismic mass does not remain absolutely steady, but for selected frequencies it can satisfactorily act as a reference position.

By proper selection of mass, spring, and damper combinations, the seismic instruments may be used for either acceleration or displacement measurements. In general, a large mass and soft spring are suitable for vibration and displacement measurements, while relatively small mass and a stiff spring are used in accelerometers. However, the term *seismic* is commonly applied to instruments that sense very low levels of vibration in the ground or in structures. They tend to have low natural frequencies.

The following equation may be written by using Newton's second law of motion to describe the response of seismic arrangements similar to shown in Fig. 1:

$$m d^2 x_2 / dt^2 + c dx_2 / dt + k x_2 = c dx_1 / dt + k x_1 + m g \cos(\theta) \quad (1)$$

where x_1 is the displacement of the vibration frame, x_2 is the displacement of the seismic mass, c is the velocity constant, θ is the angle between the sense axis and gravity, and k is the spring constant.

Subtracting $m d^2 x_1 / dt^2$ from both sides of the equation and rearranging gives

$$m d^2 z / dt^2 + c dz / dt + k z = m g \cos(\theta) - m d^2 x_1 / dt^2 \quad (2)$$

where $z = x_2 - x_1$ is the relative motion between the mass and the base.

In Eq. (1), it is assumed that the damping force on the seismic mass is proportional to velocity only. If a harmonic vibratory motion is impressed on the instrument such that

$$x_1 = x_0 \sin \omega_1 t \quad (3)$$

Figure 1. A typical deflection-type seismic accelerometer. In this basic accelerometer, the seismic mass is suspended by a spring or cantilever inside a rigid frame. The frame is connected to the vibrating structure; as vibrations take place the mass tends to remain fixed so that relative displacements can be picked up. They are manufactured in many different types and sizes with diverse characteristics.

where ω_1 is the frequency of vibration (rad/s). Writing

$$m d^2 x_1 / dt^2 = m x_0 \omega_1^2 \sin \omega_1 t$$

modifies Eq. (2) as

$$-m d^2 z / dt^2 + c dz / dt + kz = mg \cos(\theta) + m a_1 \sin \omega_1 t \quad (4)$$

where $a_1 = m x_0 \omega_1^2$.

Equation (4) will have transient and steady-state solutions. The steady-state solution of the differential equation (4) may be determined as

$$z = [mg \cos(\theta) / k] + [m a_1 \sin \omega_1 t / (k - m \omega_1^2 + j c \omega_1)] \quad (5)$$

Rearranging Eq. (5) results in

$$z = [mg \cos(\theta) / \omega_n] + \{a_1 \sin(\omega_1 - \phi) / [\omega_n^2 (1 - r^2)^2 + (2\zeta r)^2]^{1/2}\} \quad (6)$$

where $\omega_n = \sqrt{k/m}$ is the natural frequency of the seismic mass, $\zeta = (c/2) \sqrt{k/m}$ is the damping ratio, which also can be written in terms of critical damping ratio as $\zeta = c/c_c$, where $c_c = 2\sqrt{km}$, $\phi = \tan^{-1}[c\omega_1/(k - m\omega_1^2)]$ is the phase angle, and $r = \omega_1/\omega_n$ is the frequency ratio.

A plot of Eq. (6), $(x_1 - x_2)_0/x_0$ against frequency ratio ω_1/ω_n is illustrated in Fig. 2. This figure shows that the output amplitude is equal to the input amplitude when $c/c_c = 0.7$ and $\omega_1/\omega_n > 2$. The output becomes essentially a linear function of the input at high frequency ratios. For satisfactory system performance, the instrument constant c/c_c and ω_n should carefully be calculated or obtained from calibrations. In this way the anticipated accuracy of measurement may be predicted for frequencies of interest. A comprehensive treatment of the analysis is by McConnell (1); interested readers should refer to this text for further details.

Figure 2. A typical displacement of a seismic instrument. The amplitude becomes large at low damping ratios. The instrument constants should be selected such that in measurements the frequency of vibration is to be much higher than the natural frequency, for example, greater than 2. Optimum results may be obtained when the value of the instrument constant c/c_c is about 0.7.

If the seismic instrument has a low natural frequency and a displacement sensor is used to measure the relative motion z , then the output is proportional to the displacement of the transducer case. If the velocity sensor is used to measure the relative motion, the signal is proportional to the velocity of the transducer. This is valid for frequencies significantly above the natural frequency of the transducer. Velocity coil output produces a device commonly known as a geophone. It is not an accelerometer in the strict sense but it is similarly used. It excels at measuring low to medium frequency vibrations, as it offers exceptionally low self-generated noise output and very low output impedance. However, if the instrument has a high natural frequency and the displacement sensor is used, the measured output is proportional to the acceleration

$$kz = m d^2 x_1 / dt^2 \quad (7)$$

This equation is true since displacement x_2 becomes negligible in comparison with x_1 .

In these instruments the input acceleration a_0 can be calculated simply by measuring $(x_1 - x_2)_0$, the static deflection relative to the case. Generally, in acceleration measurements, unsatisfactory performance is observed at frequency ratios above 0.4. Thus, in such applications, the frequency of acceleration must be kept well below the natural frequency of the instrument. This can be done by constructing the instrument to have a low natural frequency by selecting soft springs and large masses.

Seismic instruments are constructed in a variety of ways. Figure 3 illustrates the use of a voltage divider potentiometer for sensing of the relative displacement between the frame and the seismic mass. In the majority of potentiometric instruments, the device is filled with a viscous liquid that interacts continuously with the frame and the seismic mass to provide damping. These accelerometers have a low frequency of operation (less than 100 Hz) and are mainly intended for slowly varying acceleration and low-frequency vibrations. A typical family of such instruments offers many different models, covering the range of $\pm 1 g$ to $\pm 50 g$ full scale. The natural frequency ranges from 12 Hz to 89 Hz, and the damping ratio ζ can be kept between 0.5 to 0.8 by using a temperature-compensated liquid-damping arrangement. Potentiometer resistance may be

Figure 3. A potentiometer accelerometer. The relative displacement of the seismic mass is sensed by a potentiometer arrangement. The potentiometer adds extra weight, making these accelerometers relatively heavier. Suitable liquids filling the frame may be used as damping elements. These accelerometers are used in low-frequency applications.

Figure 4. A strain-gauge seismic instrument. The displacement of the proof mass is sensed by piezoresistive strain gauges. The natural frequency of the system is low due to need of a long level beam to accommodate strain gauges. The signal is processed by bridge circuits.

selected in the range of $1,000 \Omega$ to $10,000 \Omega$, with a corresponding resolution of 0.45% to 0.25% of full scale. The cross-axis sensitivity is less than $\pm 1\%$. The overall accuracy is $\pm 1\%$ of full scale or less at room temperatures.

Linear variable differential transformers (LVDTs) offer another convenient means of measurement of the relative displacement between the seismic mass and the accelerometer housing. These devices have higher natural frequencies than potentiometer devices, up to 300 Hz. Since the LVDT has lower resistance to motion, it offers much better resolution. A typical family of liquid-damped differential-transformer accelerometers exhibits the following characteristics. The full scale ranges from $\pm 2 g$ to $\pm 700 g$, the natural frequency from 35 Hz to 620 Hz, the nonlinearity 1% of full scale, the full-scale output is about 1 V with an LVDT excitation of 10 V at 2,000 Hz, the damping ratio ranges from 0.6 to 0.7, the residual voltage at the null position is less than 1%, and the hysteresis is less than 1% full scale. The size is 50 mm^3 , with a mass of about 120 g.

Electrical resistance strain gauges are also used for displacement sensing of the seismic mass as shown in Fig. 4. In this case, the seismic mass is mounted on a cantilever beam rather than on springs. Resistance strain gauges are bonded on each side of the beam to sense the strain in the beam resulting from the vibrational displacement of the mass. Damping for the system is provided by a viscous liquid that entirely fills the housing. The output of the strain gauges is connected to an appropriate bridge circuit. The natural frequency of such a system is about 300 Hz. The low natural frequency is due to the need for a sufficiently large cantilever beam to accommodate the mounting of the strain gauges. Other types of seismic instruments with piezoelectric transducers using seismic masses are discussed in detail in the section dedicated to piezoelectric-type accelerometers.

Seismic vibration instruments are affected seriously by temperature changes. Devices employing variable resistance displacement sensors will require correction factors to account for resistance change due to temperature. The damping of the instrument may also be affected by changes in the viscosity of the fluid due to temperature. For instance, the viscosity of silicone oil, often used in these instruments, is strongly

Figure 5. A compression-type piezoelectric accelerometer. The crystals are under compression at all times either by a mass or mass and spring arrangement. Acceleration causes a deformation of the crystal, thus producing a proportional electrical signal. They are small in size and widely used. They demonstrate poor performance at low frequencies.

dependent on temperature. One way of eliminating the temperature effect is to use an electrical resistance heater in the fluid to maintain the temperature at a constant value regardless of surrounding temperatures.

Piezoelectric Accelerometers

Piezoelectric accelerometers are used commonly for general-purpose acceleration, shock, and vibration measurements. They are basically motion transducers with large output signals and comparatively small size. They are available with very high natural frequencies and are therefore suitable for high-frequency applications and shock measurements.

These devices utilize a mass in direct contact with the piezoelectric component or crystal as shown in Fig. 5. When a varying motion is applied to the accelerometer, the crystal experiences a varying force excitation ($F = ma$), causing a proportional electric charge q to be developed across it.

$$q = d_{ij}F = d_{ij}ma \quad (8)$$

where q is the charge developed and d_{ij} is the material's piezoelectric coefficient.

As this equation shows, the output from the piezoelectric material is dependent on its mechanical properties, d_{ij} . Two commonly used piezoelectric crystals are lead-zirconate titanate ceramic (PZT) and crystalline quartz. They are both self-generating materials and produce a large electric charge for their size. The piezoelectric strain constant of PZT is about 150 times that of quartz. As a result, PZTs are much more sensitive and smaller in size than quartz counterparts. In the accelerometers, the mechanical spring constants for the piezoelectric components are high, and the inertial masses attached to them are small. Therefore, these accelerometers are useful for high-frequency applications. Figure 6 illustrates a typical frequency response of a PZT device. Typically, the roll-off starts near 100 Hz. These active devices have no dc response. Since

Figure 6. The frequency response of a typical piezoelectric accelerometer. Measurements are normally confined to the linear portion of the response curve. The upper frequency of the accelerometer is limited by the resonance of the PZT crystal. The phase angle is constant up to the resonance frequency.

piezoelectric accelerometers have comparatively low mechanical impedances, their effects on the motion of most structures is negligible. They are also manufactured to be rugged and have outputs that are stable with respect to time and environment.

Mathematically, their transfer function approximates to a third-order system as

$$e_o(s)/a(s) = (K_q/C\omega_n^2) \tau s / [(\tau s + 1)(s^2/\omega_n^2 + 2\zeta s/\omega_n + 1)] \quad (9)$$

where K_q is the piezoelectric constant related to charge (C·cm), τ is the time constant of the crystal, and s is the Laplace variable. It is worth noting that the crystal itself does not have a time constant τ , but the time constant is observed when the accelerometer is connected into an electric circuit, for example, and RC circuit.

The low-frequency response is limited by the piezoelectric characteristic $\tau s/(\tau s + 1)$, while the high-frequency response is related to mechanical response. The damping factor ζ is very small, usually less than 0.01 or near zero. Accurate low-frequency response requires large τ , which is usually achieved by use of high-impedance voltage amplifiers. At very low frequencies thermal effects can have severe influences on the operation characteristics.

In piezoelectric accelerometers, two basic design configurations are used: compression types and shear-stress types. In compression-type accelerometers, the crystal is held in compression by a preload element; therefore the vibration varies the stress in compressed mode. In a shear-stress accelerometer, vibration simply deforms the crystal in shear mode. The compression accelerometer has a relatively good mass-to-sensitivity ratio and hence exhibits better performance. But, since the housing acts as an integral part of the spring-mass system, it may produce spurious interfaces in the accelerometer output if excited around its proper natural frequency.

Microelectronic circuits have allowed the design of piezoelectric accelerometers with charge amplifiers and other signal-conditioning circuits built into the instrument housing. This arrangement allows greater sensitivity and high-frequency

response and smaller size accelerometers, thus lowering the initial and implementation costs.

Piezoelectric accelerometers are available in a very wide range of specifications and are offered by a large number of manufacturers. For example, the specifications of a shock accelerometer may have 0.004 pC/g in sensitivity and a natural frequency of up to 250,000 Hz, while a unit designed for low-level seismic measurements might have 1,000 pC/g in sensitivity and only 7,000 Hz natural frequency. They are manufactured as small as 3×3 mm² in dimension with about 0.5 g in mass, including cables. They have excellent temperature ranges and some of them are designed to survive the intensive radiation environment of nuclear reactors. However, piezoelectric accelerometers tend to have larger cross-axis sensitivity than other types, about 2% to 4%. In some cases, large cross-axis sensitivity may be minimized during installations by the correct orientation of the device. These accelerometers may be mounted with threaded studs, with cement or wax adhesives, or with magnetic holders.

Electromechanical Force-Balance (Servo) Accelerometers

Electromechanical accelerometers, essentially servo or null-balance types, rely on the principle of feedback. In these instruments, an acceleration-sensitive mass is kept very close to a neutral position or zero displacement point by sensing the displacement and feeding back the effect of this displacement. A proportional magnetic force is generated to oppose the motion of the mass displaced from the neutral position, thus restoring this position just as a mechanical spring in a conventional accelerometer would do. The advantages of this approach are better linearity and elimination of hysteresis effects as compared with the mechanical springs. Also, in some cases, electrical damping can be provided, which is much less sensitive to temperature variations.

In high-vibration environments, force balance accelerometers benefit from two unique capabilities: velocity storage allows them to operate at saturation a small percentage of the time without actually losing information, and dynamic range change permits the useful range to be greater at high frequencies than near dc.

One very important feature of null-balance type instruments is the capability of testing the static and dynamic performances of the devices by introducing electrically excited test forces into the system. This remote self-checking feature can be quite convenient in complex and expensive tests in which it is extremely critical that the system operates correctly before the test commences. These instruments are also useful in acceleration control systems, since the reference value of acceleration can be introduced by means of a proportional current from an external source. They are usually used for general-purpose motion measurements and monitoring low-frequency vibrations. They are specifically applied in measurements requiring better accuracy than that achieved by those accelerometers based on mechanical springs such as the force-to-displacement transducer.

There are a number of different electromechanical accelerometers: coil-and-magnetic types, induction types, etc.

Coil-and-Magnetic Accelerometers. These accelerometers are based on Ampere's law, that is, "a current-carrying conductor disposed within a magnetic field experiences a force proportional to the current, the length of the conductor within the

Figure 7. A basic coil and permanent magnet accelerometer. The coil is supported by an arm with minimum friction bearings to form a proof mass in a magnetic field. Displacement of the coil due to acceleration induces an electric potential in the coil to be sensed and processed. A servo system maintains the coil in a null position.

field, the magnetic field density, and the sine of the angle between the conductor and the field."

Figure 7 illustrates one form of accelerometer making use of this principle. The coil is located within the cylindrical gap defined by a permanent magnet and a cylindrical soft iron flux return path. It is mounted by means of an arm situated on a minimum friction bearing or flexure so as to constitute an acceleration-sensitive seismic mass. A pickoff mechanism senses the displacement of the coil under acceleration and causes the coil to be supplied with a direct current via a suitable servo controller to restore or maintain a null condition.

Assuming a downward acceleration with the field being radial (90°), by using Ampere's law the force experienced by the coil may be written as

$$F = ma = i l B \quad (10)$$

or the current

$$i = ma / l B \quad (11)$$

where B is the effective flux density and l is the total effective length of the conductor in the magnetic field.

Current in the restoring circuit is linearly proportional to acceleration, provided (1) armature reaction effects are negligible and fully neutralized by a compensating coil in opposition to the moving coil, and (2) the gain of the servo system is large enough to prevent displacement of the coil from the region in which the magnetic field is constant.

In these accelerometers, the magnetic structure must be shielded adequately to make the system insensitive to external disturbances or the earth's magnetic field. Also, in the presence of acceleration there will be a temperature rise due to $i^2 R$ losses. The effect of these $i^2 R$ losses on the performance are determined by the thermal design and heat-transfer properties of the accelerometers. In many applications, special care must be

exercised in choosing the appropriate accelerometer such that the temperature rises caused by unexpected accelerations cannot affect the scale factors or the bias conditions excessively. In others, digital signal conditioning can be used to produce a constant temperature rise after an initial transient at the turn on.

A simplified version of another servo accelerometer is given in Fig. 8. The acceleration a of the instrument case causes an inertial force f on the sensitive mass m , tending to make it pivot in its bearings or flexure mount. The rotation θ from the neutral position is sensed by an inductive pickup coil and amplified, demodulated, and filtered to produce a current i_a directly proportional to the motion from the null position. This current is passed through a precision stable resistor R to produce the output voltage signal and is applied to a coil suspended in a magnetic field. The current through the coil produces magnetic torque on the coil, which takes action to return the mass to the neutral position. The current required to produce magnetic torque that just balances the inertial torque due to acceleration is directly proportional to the acceleration a . Therefore the output voltage e_o becomes a measure of acceleration a . Since a nonzero displacement θ is necessary to produce the current i_a , the mass is not exactly returned the null position but becomes very close to zero because of the high-gain amplifier. Analysis of the block diagram reveals that

$$e_o / R = (m r a - e_o K_c / R) (K_p K_a / K_s) / (s^2 / \omega_{nl}^2 + 2 \zeta_1 s / \omega_{nl} + 1) \quad (12)$$

where K_c , K_p , K_a , and K_s are constants. Rearranging this expression gives

$$m r R K_p K_a a / K_s = (s^2 / \omega_{nl}^2 + 2 \zeta_1 s / \omega_{nl} + 1 + K_c K_p K_a a / K_s) e_o \quad (13)$$

By designing the amplifier gain K_a to be large enough so that $K_c K_p K_a a / K_s \gg 1.0$, then

$$e_o / a(s) = K / (s^2 / \omega_{nl}^2 + 2 \zeta_1 s / \omega_{nl} + 1 + K_c K_p K_a a / K_s) e_o \quad (14)$$

where

$$K \cong m r R / K_c \quad \text{V/(m/s}^2\text{)} \quad (15)$$

$$\omega_n \cong \omega_{nl} \sqrt{K_c K_p K_a / K_s} \quad \text{rad/s} \quad (16)$$

$$\zeta \cong \zeta_1 / \sqrt{K_c K_p K_a / K_s} \quad (17)$$

Equation (15) shows that the sensitivity depends on the values of m , r , R , and K_c , all of which can be made constant. In this case, a high-gain feedback is useful in shifting the requirements for accuracy and stability from mechanical components to a selected few parameters for which the requirements can be met easily. As in all feedback systems, the gain cannot be made arbitrarily high because of dynamic instability; however, a sufficiently high gain can be achieved to obtain good performances. At very low frequencies, less than a few hertz, high gain can be used with no loss of stability, and modern integrated circuit (IC) amplifiers have static gains over one million. An excellent comprehensive treatment of this topic is given by Doebelin (2).

Induction Accelerometers. The cross-product relationship of current, magnetic field, and force gives the basis for induction-type electromagnetic accelerometers, which are essentially

Figure 8. A simplified version of a rotational-type servo accelerometer. Acceleration of the instrument case causes an inertial force on the sensitive mass, tending to make it pivot in its bearings or flexure mount. The rotation from neutral is sensed by an inductive sensing apparatus and amplified and demodulated, and then filtered to produce a current directly proportional to the motion from the null position. The block diagram representation is useful in analysis.

generators rather than motors. One type of instrument, the cup-and-magnet design, includes a pendulous element with a pickoff mechanism and a servo controller driving a tachometer coupling. A permanent magnet and a flux return ring, closely spaced with respect to an electrically conductive cylinder, are attached to the pendulus element. A rate-proportional drag force is obtained by electromagnetic induction effects between the magnet and conductor. The pickoff mechanism senses pendulum deflection under acceleration and causes the servo controller to turn the rotor in a sense to drag the pendulus element toward the null position. Under steady-state conditions motor speed is a measure of the acceleration acting on the instrument. Stable servo operation is achieved by employing a time-lead network to compensate the inertial time lag of the motor and magnet combination. The accuracy of the servo-type accelerometers is ultimately limited by consistency and stability of scale factors of coupling and cup-and-magnet devices as a function of time and temperature. Since the angular rate is proportional to acceleration, angular position represents a change in velocity. This is a useful feature, particularly in navigation applications.

Another accelerometer based on induction design uses the eddy-current induction torque generation. The force-generating mechanism of an induction accelerometer consists of a stable magnetic field, usually supplied by a permanent magnet, which penetrates orthogonally through a uniform conduction sheet. The movement of the conducting sheet relative to the magnetic field in response to an acceleration results in

a generated electromotive potential in each circuit in the conductor. This action is in accordance with the law of Faraday's principle. In induction-type accelerometers, the induced eddy currents are confined to the conductor sheet, making the system essentially a drag coupling.

A typical commercial instrument based on the servo-accelerometer principle might have a micromachined quartz flexure suspension, differential capacitance angle pickoff, air squeeze film plus servo lead compensation for system damping. Of the various available models, a 30 *g* range unit has a threshold and resolution of 1 μ *g*, a frequency response that is flat to within 0.05% at 10 Hz and 2% at 100 Hz, a natural frequency of 1,500 Hz, a damping ratio from 0.3 to 0.8, and transverse or cross-axis sensitivity of 0.1%. If, for example, the output current is about 1.3 mA/*g*, a 250 Ω readout resistor would give about ± 10 V full scale at 30 *g*. These accelerometers are good for precision work and used in many applications such as aircraft and missile control systems, measurement of tilt angles for borehole navigation, and axle angular bending in aircraft weight and balance systems.

Piezoresistive Accelerometers

Piezoresistive accelerometers are essentially semiconductor strain gauges with large gauge factors. High gauge factors are obtained since the material resistivity is dependent primarily on the stress, not only on dimensions. This effect can

Figure 9. Bonding of piezoelectric and piezoresistive elements on to inertial system. As the inertial member vibrates, deformation of the tension and compression gauges causes resistance to change. The change in resistance is picked up and processed further. Accelerometers based on PZTs are particularly useful in medium- to high-frequency applications.

be greatly enhanced by appropriate doping of semiconductors such as silicon. The increased sensitivity is critical for vibration measurements since it allows miniaturization of the accelerometer. Most piezoresistive accelerometers use two or four active gauges arranged in a Wheatstone bridge. Extra precision resistors are used, as part of the circuit, in series with the input to control the sensitivity, balancing and offsetting temperature effects. The mechanical construction of a piezoresistive accelerometer is shown in Fig. 9.

In some applications, overload stops are necessary to protect the gauges from high-amplitude inputs. These instruments are useful for acquiring vibration information at low frequencies, for example, below 1 Hz. In fact, the piezoresistive sensors are inherently true static acceleration measurement devices. Typical characteristics of piezoresistive accelerometers may be 100 mV/g as the sensitivity, 0 Hz to 750 Hz as the frequency range, 2,500 Hz as the resonance frequency, 25 g as the amplitude range, 2,000 g as the shock rating, and 0°C to 95°C as the temperature range, with a total mass of about 25 g.

Differential-Capacitance Accelerometers

Differential-capacitance accelerometers are based on the principle of the change of capacitance in proportion to applied acceleration. They come in different shapes and sizes. In one type, the seismic mass of the accelerometer is made as the movable element of an electrical oscillator as shown in Fig. 10. The seismic mass is supported by a resilient parallel-motion beam arrangement from the base. The system is set to have a certain defined nominal frequency when undisturbed. If the instrument is accelerated the frequency varies about and below the nominal value depending on the direction of acceleration.

The seismic mass carries an electrode located in opposition to a number of base-fixed electrodes that defined variable capacitors. The base-fixed electrodes are resistance coupled in the feedback path of a wideband, phase-inverting amplifier. The gain of the amplifier is predetermined to ensure maintenance of oscillations over the range of variation of the capacitance

Figure 10. A typical differential-capacitance accelerometer. The proof mass is constrained in its null position by a spring. Under acceleration, variable frequencies are obtained in the electrical circuit. In a slightly different version the proof mass may be constrained by an electrostatic feedback force, thus resulting in a convenient mechanical simplicity.

determined by the applied acceleration. The value of the capacitance C for each of the variable capacitors is given by

$$C = \epsilon k S / h \quad (18)$$

where k is the dielectric constant, ϵ is the capacitivity of free space, S is the area of electrode, and h is the variable gap.

Denoting the magnitude of the gap for zero acceleration as h_0 , the value of h in the presence of acceleration a may be written

$$h = h_0 + ma/K \quad (19)$$

where m is the value of the proof mass and K is the spring constant. Thus,

$$C = \epsilon k S / (h_0 + ma/K) \quad (20)$$

For example, the frequency of oscillation of the resistance-capacitance type circuit is given by the expression

$$f = \sqrt{6}/2\pi RC \quad (21)$$

Substituting this value of C in Eq. (20) gives

$$f = (h_0 + ma/K) \sqrt{6}/2\pi R \epsilon k S \quad (22)$$

Denoting the constant quantity $\sqrt{6}/2\pi R \epsilon k S$ as B and rewriting Eq. (22) gives

$$f = B h_0 + B m a / K \quad (23)$$

The first term on the right-hand side expresses the fixed bias frequency f_0 and the second term denotes the change in frequency resulting from acceleration, so that the expression may

Figure 11. A diaphragm-type capacitive accelerometer. The seismic element is cushioned between the electrodes. Motion of the mass between the electrodes causes air movement passing through the holes, which provides a squeeze film damping. In some cases oil may be used as the damping element.

be written as

$$f = f_0 + f_a \quad (24)$$

If the output frequency is compared with an independent source of a constant frequency of f_0 whereby f_a may be determined.

A commonly used example of a capacitive-type accelerometer is based on a thin diaphragm with spiral flexures that provide the spring, proof mass, and moving plate necessary for the differential capacitor, as shown in Fig. 11. Plate motion between the electrodes pumps air parallel to the plate surface and through holes in the plate to provide squeeze film damping. Since air viscosity is less temperature sensitive than oil, the desired damping ratio of 0.7 hardly changes more than 15%. A family of such instruments are easily available with full-scale ranges from ± 0.2 g (4 Hz flat response) to $\pm 1,000$ g (3,000 Hz), a cross-axis sensitivity less than 1%, and a full-scale output of ± 1.5 V. The size of a typical device is about 25 mm^3 with a mass of 50 g.

Strain-Gauge Accelerometers

Strain-gauge accelerometers are based on resistance properties of electrical conductors. If a conductor is stretched or compressed, its resistance alters because of dimensional changes and the changes in the fundamental property of material called piezoresistance. This indicates that the resistivity ρ of the conductor depends on the mechanical strain applied onto it. The dependence is expressed as the gauge factor

$$(dR/R)/(dL/L) = 1 + 2\nu + (d\rho/\rho)/(dL/L) \quad (25)$$

where 1 indicates the resistance change due to length, 2ν in-

dicates resistance change due to area, and $(d\rho/\rho)/(dL/L)$ indicates the resistance change due to piezoresistivity.

In acceleration measurements, the resistance strain gauges can be selected from different types, such as unbonded metal-wire gauges, bonded metal-wire gauges, bonded metal-foil gauges, vacuum-deposited thin-metal-film gauges, bonded semiconductor gauges, and diffused semiconductor gauges. However, bonded and unbonded metal-wire gauges usually find wider applications in accelerometers. Occasionally, bonded semiconductor gauges, known as piezoresistive transducers, are used, but they suffer from high temperature sensitivities, nonlinearities, and some mounting difficulties. Nevertheless, in recent years, they have found new applications with the development of micromachine transducer technology, which is discussed in detail in the microaccelerometer section.

Unbonded-strain-gauge accelerometers use the strain wires as the spring element and as the motion transducer, using similar arrangements as in Fig. 9. They are useful for general-purpose motion and vibration measurements from low to medium frequencies. They are available in wide ranges and characteristics: typically ± 5 g to ± 200 g full scale, a natural frequency of 17 Hz to 800 Hz, 10 V excitation voltage ac or dc, full-scale output ± 20 mV to ± 50 mV, a resolution less than 0.1%, an inaccuracy less than 1% full scale, and a cross-axis sensitivity less than 2%. The damping ratio (using silicone oil damping) is 0.6 to 0.8 at room temperature. These instruments are small and light, usually with a mass less than 25 g.

Bonded-strain-gauge accelerometers generally use a mass supported by a thin flexure beam. The strain gauges are cemented onto the beam to achieve maximum sensitivity, temperature compensation, and sensitivity to both cross-axis and angular accelerations. Their characteristics are similar to unbonded-strain-gauge accelerometers but have greater sizes and weights. Often silicone oil is used for damping. Semiconductor strain gauges are widely used as strain sensors in cantilever-beam and mass types of accelerometers. They allow high outputs (0.2 V to 0.5 V full scale). Typically, a ± 25 g acceleration unit has a flat response from 0 Hz to 750 Hz, a damping ratio of 0.7, a mass of 28 g, and an operational temperature of -18°C to $\pm 93^\circ\text{C}$. A triaxial $\pm 20,000$ g model has a flat response from 0 kHz to 15 kHz, a damping ratio of 0.01, and a compensation temperature range of 0°C to 45°C and is $13 \times 10 \times 13 \text{ mm}^3$ in size and 10 g in mass.

Inertial Types: Cantilever and Suspended-Mass Accelerometers

There are a number of different inertial-type accelerometers, most of which are in development stages or used under very special circumstances, such as gyropendulum, reaction-rotor, vibrating-string, and centrifugal-force-balance designs. In many types, the force required to constrain the mass in the presence of the acceleration is supplied by an inertial system.

The vibrating-string instrument, Fig. 12, makes use of a proof mass supported longitudinally by a pair of tensioned, transversely vibrating strings with uniform cross section and equal lengths and masses. The frequency of vibration of the strings is set to several thousand cycles per second. The proof mass is supported radially in such a way that the acceleration normal to the strings does not affect the string tension. In the presence of acceleration along the sensing axis, a differential tension exists on the two strings, thus altering the frequency of vibration. From the second law of motion the frequencies may

Figure 12. A vibrating-string accelerometer. A proof mass is attached to two strings of equal mass and length and it is supported radially by suitable bearings. The vibration frequencies of strings are dependent on the tension imposed by the acceleration of the system in the direction of the sensing axis.

be written as

$$f_1^2 = T_1/4m_s l, \quad f_2^2 = T_2/4m_s l \quad (26)$$

where T is the tension and m_s and l are the masses and lengths of strings, respectively.

The quantity $T_1 - T_2$ is proportional to ma where a is the acceleration along the axis of the strings. An expression for the difference of the frequency-squared terms may be written as

$$f_1^2 - f_2^2 = (T_1 - T_2)/4m_s l = ma/4m_s l \quad (27)$$

hence

$$f_1 - f_2 = ma/[(f_1 + f_2)4m_s l] \quad (28)$$

The sum of frequencies ($f_1 + f_2$) can be held constant by servoing the tension in the strings with reference to the frequency of a standard oscillator. Then, the difference between the frequencies becomes linearly proportional to acceleration. In some versions, the beamlike property of the vibratory elements is used by gripping them at nodal points corresponding to the fundamental mode of the vibration of the beam and at the respective centers of percussion of the common proof mass. The output frequency is proportional to acceleration, and the velocity is proportional to phase, thus offering an important advantage. The velocity change can be measured by something almost as simple as counting zero crossings. Improved versions of these devices lead to cantilever-type accelerometers, discussed next.

In this accelerometer, a small cantilever beam mounted on the block is placed against the vibrating surface, and an appropriate mechanism is provided for varying the beam length. The beam length is adjusted such that its natural frequency is equal to the frequency of the vibrating surface, and hence the resonance condition is obtained. Recently, slight variations of cantilever-beam arrangements are finding new applications in microaccelerometers.

In a different type of suspended-mass configuration, a pendulum is used that is pivoted to a shaft rotating about a vertical axis. Pickoff mechanisms are provided for the pendulum and the shaft speed. The system is servo controlled to maintain it at null position. Gravitational acceleration is balanced by the centrifugal acceleration. The shaft speed is proportional to the square root of the local value of the acceleration.

All inertial force accelerometers just described are absolute measure instruments. That is, their scale factors are predetermined solely by establishing mass, length, and time quantities, as distinguished from voltage and spring stiffness.

Electrostatic-Force-Feedback Accelerometers

Electrostatic accelerometers are based on Coulomb's law between two charged electrodes. They measure the voltage in terms of force required to sustain a movable electrode of a known area, mass, and separation from an affixed electrode. The field between the electrodes is given by

$$E = Q/\epsilon k S \quad (29)$$

where E is the intensity or potential gradient (dV/dx); Q is the charge, S is the area of the conductor, and k is the dielectric constant of the space outside the conductor.

By using this expression it can be shown that the force per unit area of the charged conductor (in N/m^2) is given by

$$F/S = Q^2/2\epsilon k S^2 = \epsilon k E^2/2 \quad (30)$$

In an electrostatic-force-feedback accelerometer (similar in structure as in Fig. 9) an electrode of mass m and area S is mounted on a light pivoted arm for moving relative to the fixed electrodes. The nominal gap h between the pivoted and fixed electrodes is maintained by means of a force-balancing servo system capable of varying in the electrode potential in response to signals from a pickoff mechanism that senses relative changes in the gaps.

Considering one movable electrode and one stationary electrode and assuming that the movable electrode is maintained at a bias potential V_1 and the stationary one at a potential V_2 . The electrical intensity E in the gap can be expressed as

$$E_1 = (V_1 - V_2)/h \quad (31)$$

so that the force of attraction may be found as

$$F_1 = \epsilon k E^2 S/2h^2 = \epsilon k (V_1 - V_2)^2 S/2h^2 \quad (32)$$

In the presence of acceleration, if V_2 is adjusted to restrain the movable electrode to the null position, the expression relating acceleration and electrical potential may be given by

$$a = F_1/m = \epsilon k (V_1 - V_2)^2 S/2h^2 m \quad (33)$$

The device so far described can measure acceleration in one direction only, and the output is quadratic, that is,

$$(V_1 - V_2) = D\sqrt{a} \quad (34)$$

where D is the constant of proportionality.

The output may be linearized in a number of ways, one of them being the quarter-square method. If the servo controller applies a potential $-V_2$ to the other fixed electrode, the force of attraction between this electrode and the movable electrode becomes

$$a = F_1/m = \epsilon k(V_1 + V_2)^2 S/2h^2 m \quad (35)$$

and the force-balance equation of the movable electrode when the instrument experiences a downward acceleration a now is

$$ma = F_1 - F_2 = [(V_1 + V_2)^2 - (V_1 - V_2)^2] \epsilon k S/2h^2 m$$

or

$$ma = \epsilon k S(4V_1 V_2)/2h^2 m \quad (36)$$

Hence, if the bias potential V_1 is held constant and the gain of the control loop is high so that variations in the gap are negligible, the acceleration becomes a linear function of the controller output voltage V_2 as

$$a = V_2[(\epsilon k S 2V_1)/h^2 m] \quad (37)$$

The principal difficulty in mechanizing the electrostatic force accelerometer is the relatively high electric field intensity required to obtain an adequate force. Also, extremely good bearings are necessary. Damping can be provided electrically or by viscosity of the gaseous atmosphere in the interelectrode space if the gap h is sufficiently small. The scheme works best in micromachined instruments. Nonlinearity in the voltage breakdown phenomenon permits larger gradients in very small gaps.

The main advantages of electrostatic accelerometers are extreme mechanical simplicity, low power requirements, absence of inherent sources of hysteresis errors, zero temperature coefficients, and ease of shielding from stray fields.

Microaccelerometers

By the end of the 1970s it became apparent that the essentially planar integrated-circuit (IC) technology processing could be modified to fabricate three-dimensional electromechanical structures, called micromachining. Accelerometers and pressure sensors were among the first IC sensors. The first accelerometer was developed in 1979. Since then the technology has been progressing steadily, and now an extremely diverse range of accelerometers is readily available. Most sensors use bulk micromachining rather than surface micromachining techniques. In bulk micromachining the flexures, resonant beams, and all other critical components of the accelerometer are made from bulk silicon in order to exploit the full mechanical properties of a single silicon crystal. With proper design and film process, bulk micromachining yields an extremely stable and robust accelerometer.

The selective etching of multiple layers of deposited thin films, or surface micromachining, allows movable microstructures to be fabricated on silicon wafers. With surface micromachining, layers of structure material are disposed and patterned

Figure 13. Steps of surface micromachining. The acceleration-sensitive three-dimensional structure is formed on a substrate and a sacrificial element. The sacrificial element is etched to leave a free-standing structure. The spacing between the structure and substrate is about $2 \mu\text{m}$.

as shown in Fig. 13. These structures are formed by polysilicon and a sacrificial material such as silicon dioxide. The sacrificial material acts as an intermediate spacer layer and is etched away to produce a freestanding structure. Surface machining technology also allows smaller and more complex structures to be built in multiple layers on a single substrate.

The operational principles of microaccelerometers are very similar to capacitive force-balance or vibrating-beam accelerometers, discussed earlier. Manufacturing techniques may change from one manufacturer to another. However, in general, vibrating-beam accelerometers are preferred because of better air-gap properties and improved bias performance characteristics.

Vibrating-beam accelerometers, also termed resonant beam force transducers, are made in such a way that an acceleration along a positive input axis places the vibrating beam in tension. Thus the resonant frequency of the vibrating beam increases or decreases with the applied acceleration. A common structure, mechanically coupled beam also known as a double-ended tuning fork (DETF) is shown in Fig. 14.

Figure 14. A double-ended tuning fork (DETF) acceleration transducer. Two beams are vibrated 180° out of phase to eliminate reaction forces at the beam ends. The resonant frequency of the beam is altered by acceleration. The signal-processing circuits are also integrated in the same chip.

In DETF, an electronic oscillator capacitively couples energy into two vibrating beams to keep them oscillating at their resonant frequency. The beams vibrate 180° out of phase to cancel reaction forces at the ends. The dynamic cancellation effect of the DETF design prevents energy from being lost through the ends of the beam. Hence, the dynamically balanced DETF resonator has a high Q factor, which leads to a stable oscillator circuit. The acceleration signal is output from the oscillator as a frequency-modulated square wave that can be used for a digital interface.

The vibrating beam accelerometer is similar in philosophy to the vibrating string accelerometer. Frequency output provides an easy interface with digital systems, and measurement of phase provides an easy integration to velocity. Static stiffness eliminates the tension and makes the device much smaller. A recent trend is to manufacture vibrating beam accelerometers as micromachined devices. With differential frequency arrangements, many common mode errors can be eliminated, including clock errors.

The frequency of resonance of the system must be much higher than any input acceleration, and this limits the measurable range. In one military micromachined accelerometer the following characteristics are given: a range of $\pm 1200\text{ g}$, a sensitivity of 1.11 Hz/g , a bandwidth of $2,500\text{ Hz}$, and unloaded DETF frequency of $9,952\text{ Hz}$, the frequency at $+1,200\text{ g}$ is $11,221\text{ Hz}$, the frequency at $-1,200\text{ g}$ is $8,544\text{ Hz}$, and the temperature sensitivity is $5\text{ mg/}^\circ\text{C}$. The accelerometer size is 6 mm diameter by 4.3 mm length, with a mass of about 9 g , and it has a turn-on time less than 60 s . The accelerometer is powered with $+9$ to $+16\text{ V dc}$ and the nominal output is $9,000\text{ Hz}$, square wave.

Surface micromachining has also been used to manufacture application-specific accelerometers, such as for air-bag applications in the automotive industry. In one type, a three-layer differential capacitor is created by alternate layers of polysilicon and phosphosilicate glass (PSG) on a 0.38 mm thick, 100 mm long wafer. A silicon wafer serves as the substrate for the mechanical structure. The trampoline-shaped middle layer is suspended by four supporting arms. This movable structure is the seismic mass for the accelerometer. The upper and lower polysilicon layers are fixed plates for the differential capacitors. The glass is sacrificially etched by hydrofluoric acid (HF).

CALIBRATIONS AND SENSITIVITY

Calibrations of accelerometers are necessary in acceleration, vibration, and shock sensing. The calibration methods can broadly be classified to be *static* or *dynamic* calibrations. The static calibration is conducted at one or several levels of constant accelerations. For example, if a tilting table calibration method is selected, the vertical component of the free fall is made use of without a choice of magnitude, but with the advantage of being readily available, and accurate to a few parts in 10^7 . On the other hand, if a centrifuge is selected, it produces a constant acceleration as a function of speed of rotation, and the magnitudes can be chosen in a wide range from 0 g to well over $50,000\text{ g}$, but with typical uncertainty of 1% in measuring the actual radius from the axis of rotation to the effective center of mass. The dynamic calibration is usually done by using an electrodynamic shaker.

The electrodynamic shaker is designed to oscillate in a sinusoidal motion with variable frequencies and amplitudes. They are stabilized at selected levels of calibration. This is an absolute method that consists of measuring the displacement with laser interferometry and a precise frequency meter for accurate frequency measurements. The shaker must be driven by a power amplifier thus giving a sinusoidal output with minimal distortion. The National Institute of Science and Technology uses this method as a reference standard. Precision accelerometers, mostly of the piezoelectric types, are calibrated by the absolute method and then used as the working standards. A preferred method is the back-to-back calibration, where the test specimen is directly mounted on the working standard, which in turn is mounted on an electrodynamic shaker.

Sensitivity

A vibrational structure may have been subjected to different forms of vibrations, such as compressional, torsional, or transverse. A combination of all these vibrations may also take place simultaneously, which makes analysis and measurement difficult and complex. It was discussed earlier that the differential equations governing the vibrational motion of a structure depends on the number of degrees of freedom, which are described as a function of space coordinates $f(x, y, z, t)$. For example, the transverse vibrations of structures may be a fourth-order equation differential equation.

Fortunately, most common acceleration and vibration measurements are simple in nature, being either compressional or torsional. They can easily be expressed as second-order differential equations, as explained in the frequency response section. However, during measurements, most accelerometers are affected by transverse vibrations and their sensitivity can play a major role in the accuracy of the measurements.

The transverse, also known as cross-axis, sensitivity of an accelerometer is its response to acceleration in a plane perpendicular to the main accelerometer axis as shown in Fig. 15.

Figure 15. A vectorial illustration of cross-axis sensitivity. Accelerometers may sense vibrations not only in the direction of the main axis but also perpendicular to the main axis. These cross-axis responses are minimized in many accelerometers to a value less than 1% . Sometimes this sensitivity may be used to determine the correct orientation of the device.

The cross-axis sensitivity is normally expressed as a percentage of the main-axis sensitivity and should be as low as possible. There is no single value of cross-axis sensitivity, but it varies depending on the direction. The direction of minimum sensitivity is usually supplied by the manufacturers.

The measurement of the maximum cross-axis sensitivity is part of the individual calibration procedure and should always be less than 3% to 4%. If high levels of transverse vibration are present, this may result in erroneous overall results. In this case, separate arrangements should be made to establish the level and frequency contents of the cross-axis vibrations. The cross-axis sensitivity of typical accelerometers mentioned in the relevant sections were (2% to 3% for piezoelectric types and less than 1% for most others). In force-feedback accelerometers the transverse sensitivity is proportional to the input axis misalignment; therefore, it may be calibrated as a function of the temperature to within several microradians.

APPLICATIONS

This section is concerned with applications of accelerometers to measure physical properties such as acceleration, vibration and shock, and motions associated with inertial navigation. A full understanding of accelerometer dynamics is necessary in relation to characteristics of acceleration, vibration, and shock. The vibrations can be periodic, stationary random, nonstationary random, or transient.

Periodic Vibrations. In periodic vibrations, the motion of an object repeats itself in an oscillatory manner. This can be represented by a sinusoidal waveform

$$x(t) = X_{\text{peak}} \sin(\omega t) \quad (38)$$

where $x(t)$ is the time-dependent displacement, $\omega = 2\pi ft$ is the angular frequency, and X_{peak} is the maximum displacement from a reference point.

The velocity of the object is the time rate of change of displacement

$$u(t) = dx/dt = \omega X_{\text{peak}} \cos(\omega t) = U_{\text{peak}} \sin(\omega t + \pi/2) \quad (39)$$

where $u(t)$ is the time-dependent velocity, and $U_{\text{peak}} = \omega X_{\text{peak}}$ is the maximum velocity.

The acceleration of the object is the time rate change of velocity

$$a(t) = du/dt = d^2u/dt^2 = -\omega^2 X_{\text{peak}} \sin(\omega t) = A_{\text{peak}} \sin(\omega t + \pi) \quad (40)$$

where $a(t)$ is the time-dependent acceleration, and $A_{\text{peak}} = \omega^2 X_{\text{peak}} = \omega U_{\text{peak}}$ is the maximum acceleration.

From the preceding equations it can be seen that the basic form and the period of vibration remains the same in acceleration, velocity, and displacement. But velocity leads displacement by a phase angle of 90° and acceleration leads velocity by another 90° . The amplitudes of the three quantities are related as a function of frequency, shown in Fig. 16.

In nature, vibrations can be periodic but not necessarily sinusoidal. If they are periodic but nonsinusoidal, they can be

Figure 16. The logarithmic relationship between acceleration, velocity, and displacement. Velocity at a particular frequency can be obtained by dividing acceleration by a factor proportional to frequency. For displacement acceleration must be divided by a factor proportional to square of the frequency. Phase angles need to be determined separately, but they can be neglected in time-average measurements.

expressed as a combination of a number of pure sinusoidal curves, describes by Fourier analysis as

$$x(t) = X_0 + X_1 \sin(\omega_1 t + \phi_1) + X_2 \sin(\omega_2 t + \phi_2) + \dots + X_n \sin(\omega_n t + \phi_n) \quad (41)$$

where $\omega_1, \omega_2, \dots, \omega_n$ are frequencies (rad/s), $X_0, X_1, \dots, X_n$ are maximum amplitudes of respective frequencies, and $\phi_1, \phi_2, \dots, \phi_n$ are phase angles.

The number of terms may be infinite, and the higher the number of elements better the approximation. These elements constitute the *frequency spectrum*. The vibrations can be represented in the time domain or frequency domain, both of which are extremely useful in the analysis. As an example, in Fig. 17, the time response of the seismic mass of an accelerometer is given against a rectangular pattern of excitation of the base.

Figure 17. The time response of a shock excitation of a single-degree-of-freedom system. As the duration of the shock pulse increases sustained oscillations get shorter in time but larger in amplitude. The maximum system response may be as high as twice the magnitude of the shock pulse.

Stationary Random Vibrations. Random vibrations occur often in nature, where they constitute irregular cycles of motion that never repeat themselves exactly. Theoretically, an infinitely long time record is necessary to obtain a complete description of these vibrations. However, statistical methods and probability theory can be used for the analysis by taking representative samples. Mathematical tools such as probability distributions, probability densities, frequency spectra, cross-correlations, auto correlations, digital Fourier transforms (DFTs), fast Fourier transforms (FFTs), auto-spectral-analysis, rms values, and digital filter analysis are some of the techniques that can be employed. Interested readers should refer to references for further information.

Transients and Shocks. Often, short duration and sudden occurrence vibrations need to be measured. Shock and transient vibrations may be described in terms of force, acceleration, velocity, or displacement. As in the case of random transients and shocks, statistical methods and Fourier transforms are used in the analysis.

Nonstationary Random Vibrations. In this case, the statistical properties of vibrations vary in time. Methods such as time averaging and other statistical techniques can be employed.

The majority of accelerometers described here can be viewed and analyzed as seismic instruments consisting of a mass, a spring, and a damper arrangement as shown in Fig. 1. Taking only the mass-spring system, if the system behaves linearly in a time invariant manner, the basic second-order differential equation for the motion of the mass alone under the influence of a force can be written as

$$f(t) = m d^2 x / dt^2 + c dx / dt + kx \quad (42)$$

where $f(t)$ is the force, m the mass, c the velocity constant, and k the spring constant.

Nevertheless, in seismic accelerometers the base of the arrangement is in motion too. Therefore, Eq. (42) may be generalized by taking the effect motion of the base into account. Then this equation may be modified as

$$m d^2 z / dt^2 + c dz / dt + kz = mg \cos(\theta) - m d^2 x_1 / dt^2 \quad (43)$$

where $z = x_2 - x_1$ is the relative motion between the mass and the base, x_1 the displacement of the base, x_2 the displacement of the mass, and θ the angle between the sense axis and gravity.

In order to lay a background for further analysis, taking the simple case, the complete solution to Eq. (42) can be obtained by applying the superposition principle. The superposition principle states that if there are simultaneously superimposed actions on a body, the total effect can be obtained by summing the effects of each individual action.

Equation (42) describes essentially a second-order system that can be expressed through Laplace transform as

$$X(s)/F(s) = 1/ms^2 + cs + k \quad (44)$$

or

$$X(s)/F(s) = K/(s^2/\omega_n^2 + 2\zeta s/\omega_n + 1) \quad (45)$$

Figure 18. Unit-step-time responses of a second-order system with various damping ratios. The maximum overshoot, delay, rise, settling times, and frequency of oscillations depend on the damping ratio. A smaller damping ratio gives a faster response but larger overshoot. In many applications a damping ratio of 0.707 is preferred.

where s is the Laplace operator, $K = l/k$ is the static sensitivity, $\omega_n = \sqrt{k/m}$ is the undamped critical frequency (rad/s), and $\zeta = (c/2)\sqrt{k/m}$ is the damping ratio.

As can be seen in the performance of accelerometers, the important parameters are the static sensitivity, the natural frequency, and the damping ratio, which are functions of mass, velocity, and spring constants, respectively. Accelerometers are designed to have different characteristics by suitable selection of these parameters.

Once the response is expressed in the form of Eqs. (44) and (45), analysis can be taken further either in the time domain or in the frequency domain. The time response of a typical second-order system for a unit-step input is given in Fig. 18. The Bode plot gain phase responses are depicted in Fig. 19. Detailed discussions about frequency response, damping, damping ratio, and linearity are made in relevant sections, and further information can be obtained in the references.

Systems in which a single structure moves in more than one direction are termed multi-degree-of-freedom systems. In this case, the accelerations become functions of dimensions as d^2x/dt^2 , d^2y/dt^2 , and d^2z/dt^2 . Hence, in multichannel vibration tests multiple transducers must be used to create uniaxial, biaxial, or triaxial sensing points for measurements. Mathematically, a linear multi-degree-of-freedom system can be described by a set of coupled second-order linear differential equations, and when the frequency response is plotted it normally shows one resonance peak per degree of freedom.

Frequently, acceleration and vibration measurements of thin plates or small masses are required. Attaching an accelerometer with a comparable mass onto a thin plate or a small test piece can cause *mass loading*. Since acceleration is dependent on the mass, the vibration characteristics of the loaded test piece may be altered, thus yielding wrong measurements.

Figure 19. Bode plot of the gain and phase angle of the transfer function $G(j\omega)$ of a second-order system against frequency. Curves are functions of frequencies as well as damping ratios. These plots can be obtained theoretically or by practical tests conducted in frequency range.

In such cases, a correct interpretation of the results of the measuring instruments must be made. Some experimental techniques are also available for the correction of the test results in the form performing repetitive tests conducted by sequentially adding small known masses and by observing the differences.

In general, accelerometers are preferred over other displacement and velocity sensors due to the following reasons:

1. They have a wide frequency range from zero to very high values. Steady accelerations can easily be measured.
2. Acceleration is more frequently needed since destructive forces are often related to acceleration rather than to velocity or displacement.
3. Measurement of transients and shocks can readily be made, which is much easier than displacement of velocity sensing.
4. Displacement and velocity can be obtained by simple integration of acceleration by electronic circuitry. Integration is preferred over differentiation.

Selection, Full-Scale Range, and Overload Capability

Ultimate care must be exercised for the selection of correct accelerometer to meet the requirements of a particular application. At first glance there may seem to be a confusingly large selection of accelerometers available. But they can be classified in two main groups. The first group is the general-purpose accelerometers offered in various sensitivities, frequencies, and full scale and overload ranges, with different mechanical and

electrical connection options. The second group of accelerometers have characteristics targeted toward a particular application. A list of manufacturers of accelerometers is supplied in Table 1.

In deciding about the application type, for example, general purpose or special, and the accelerometer to be employed, the following characteristics need to be considered: the transient response or cross-axis sensitivity; frequency range, sensitivity, mass and dynamic range; cross-axis response; and environmental conditions, temperature, cable noise, stability of bias, scale factor, and misalignment. Some useful hints about these characteristics will be given below.

The Frequency Range. Acceleration measurements are normally confined to using the linear portion of the response curve. The response is limited at low frequencies as well as at high frequencies by the natural resonances. As a rule of thumb the upper-frequency limit for the measurement can be set to one-third of the accelerometer's resonance frequency such that the vibrations measured will be less than 1 dB in linearity. It should be noted that an accelerometer's useful frequency range is significantly higher, that is, to one-half or two-thirds of its resonant frequency. The measurement frequencies may be set to higher values in applications in which lower linearity (say 3 dB) may be acceptable as in the case of monitoring of internal conditions of machines since the repeatability is more important than the linearity. The lower measuring frequency limit is determined by two factors. The first is the low-frequency cutoff of the associated preamplifiers. The second is the effect of ambient temperature fluctuations to which the accelerometer may be sensitive.

The Sensitivity, Mass, and Dynamic Range. Ideally, a higher transducer sensitivity is better, but compromises may have to be made for sensitivity versus frequency, range, overload capacity, size, and so on.

Accelerometer mass becomes important when using small and light test objects. The accelerometer should not load the structural member, since additional mass can significantly change the levels and frequency presence at measuring points and invalidate the results. As a general rule, the accelerometer mass should not be greater than one-tenth the effective mass of the part or the structure that it is mounted onto for measurements.

The dynamic range of the accelerometer should match the high or low acceleration levels of the measured objects. General-purpose accelerometers can be linear up to 5,000 g to 10,000 g , which is well into the range of most mechanical shocks. Special accelerometers can measure up to 100,000 g .

An important point in the practical application of accelerometers is that if mechanical damping is a problem, air damping is preferable to oil damping, since oil damping is extremely sensitive to viscosity changes. If the elements are stable against temperature, electronic damping may be sufficient.

The Transient Response. Shocks are characterized as sudden releases of energy in the form of short-duration pulses exhibiting various shapes and rise times. They have high magnitudes and wide frequency contents. In the applications where transient and shock measurements are involved, the overall linearity of the measuring system may be limited to high and low frequencies by phenomena known as zero shift and ringing,

respectively. The zero shift is caused by both the phase nonlinearity in the preamplifiers and the accelerometer not returning to steady-state operation conditions after being subjected to high shocks. Ringing is caused by high-frequency components of the excitation near-resonance frequency preventing the accelerometer to return back to its steady-state operation condition. To avoid measuring errors due to these effects the operational frequency of the measuring system should be limited to the linear range.

Full-Scale Range and Overload Capability. Most accelerometers are able to measure acceleration in both positive and negative directions. They are also designed to be able to accommodate overload capacity. Appropriate discussions are made on full scale range and overload capacity of accelerometers in the appropriate sections. Manufacturers also supply information on these two characteristics.

Environmental Conditions. In selection and implementation of accelerometers, environmental conditions such as temperature ranges, temperature transients, cable noise, magnetic field effects, humidity, and acoustic noise need to be considered.

Manufacturers supply information on environmental conditions of use.

SIGNAL CONDITIONING

Common signal conditioners are appropriate for interfacing accelerometers to computers or other instruments for further signal processing. Caution needs to be exercised to provide the appropriate electric load to self-generating accelerometers. Generally, the generated raw signals are amplified and filtered suitably by the circuits within the accelerometer casing supplied by manufacturers. Nevertheless, piezoelectric and piezoresistive transducers require special signal conditioners with certain characteristics, which is discussed in the following section. Examples of signal conditioning circuits will also be given for the microaccelerometers.

Signal Conditioning Piezoelectric Accelerometers. The piezoelectric accelerometer supplies a very small energy to the signal conditioner. It has a high capacitive source impedance. The equivalent circuit of a piezoelectric accelerometer can be

Figure 20. A typical charge amplifier. The transducer charge, which is proportional to acceleration, is first converted to voltage form to be amplified. The output voltage is a function of the input charge. The response of the amplifier can be approximated by a first-order system. In the PZT transducer the preamplifier is usually integrated within the same casing.

regarded as an active capacitor that charges itself when loaded mechanically. The configuration of external signal conditioning elements are dependent on the equivalent circuit selected. The charge amplifier design of the conditioning circuit is the most common approach, since the system gain and low-frequency responses are well defined. The performance of the circuit is independent of cable length and capacitance of the accelerometer.

The charge amplifier consists of a charge converter output voltage, which occurs as a result of the charge input signal returning through the feedback capacitor to maintain the input voltage at the input level close to zero, as shown in Fig. 20. An important point about charge amplifiers is that their sensitivities can be standardized. They basically convert the input charge to voltage first and then amplify this voltage. With the help of basic operational-type feedback, the amplifier input is maintained at essentially 0 V; therefore it looks like a short circuit to the input. The charge converter output voltage that occurs as a result of a charge input signal is returned through the feedback capacitor to maintain the voltage at the input level near zero. Thus, the charge input is stored in the feedback capacitor, producing a voltage across it that is equal to the value of the charge input divided by the capacitance of the feedback capacitor. The complete transfer function of the circuit describing the relationship between the output voltage and the input acceleration magnitude may be determined by the following complex transform:

$$E_o/a_0 = S_a j R_f C_f \omega \{1 + j R_f C_f [1 + (C_a + C_c)/(1 + G) + C_f] \omega\} \quad (46)$$

where E_o is the charge converter output (V), a_0 the magnitude of acceleration (m/s^2), S_a the accelerometer sensitivity (mV/g), C_a the accelerometer capacitance (F), C_c the cable capacitance (F), C_f the feedback capacitance (F), R_f the feedback loop resistance, and G the amplifier open-loop gain.

In most applications, since C_f is selected to be large compared with $(C_a + C_c)/(1 + G)$, the system gain becomes independent of the cable length. In this case the denominator of

the equation can be simplified to give a first-order system with roll-off at

$$f_{-3\text{db}} = \frac{1}{2} \pi R_f C_f \quad (47)$$

with a slope of 10 dB per decade. For practical purposes, the low-frequency response of this system is a function of well-defined electronic components and does not vary by cable length. This is an important feature when measuring low-frequency vibrations.

Many accelerometers are manufactured with preamplifiers and other signal-conditioning circuits integrated with the transducer enclosed in the same casing. Some accelerometer preamplifiers include integrators to convert the acceleration proportional outputs to either velocity or displacement proportional signals. To attenuate noise and vibration signals that lie outside the frequency range of interest most preamplifiers are equipped with a range of high-pass and low-pass filters. This avoids interference from electrical noise or signals inside the linear portion of the accelerometer frequency range. Nevertheless, it is worth mentioning that these devices usually have two time constants, external and internal. The mixture of these two time constants can lead to problems particularly at low frequencies. The internal time constant is usually fixed by the manufacturer through design and construction. Special care must be observed to account for the effect of external time constants in many applications by mainly observing impedance matching.

Signal Conditioning of Piezoresistive Transducers. Piezoresistive transducers generally have high-amplitude outputs, low-output impedances, and low intrinsic noise. Most of these transducers are designed for constant-voltage excitations. They are usually calibrated for constant-current excitations to make them independent of external influences. Many piezoresistive transducers are configured as full-bridge devices. Some have four active piezoresistive arms, together with two fixed precision resistors to permit shunt calibration in the signal conditioner as shown in Fig. 21.

Microaccelerometers. In microaccelerometers signal-conditioning circuitry is integrated within the same chip with the sensor as shown in Fig. 22. A typical example of the signal-conditioning circuitry is given in Fig. 23 in block diagram

Figure 21. A bridge circuit for piezoresistive and strain gauge accelerometers. The strain gauges form the four arms of the bridge. The two extra resistors are used for balancing and for fine-adjustment purposes. This type of arrangement reduces temperature effects.

Figure 22. A block diagram of an accelerometer combined with microcontroller unit (MCU). The signal-conditioning, switching, and power-supply circuits are integrated to form a microaccelerometer. The device can directly be interfaced with a digital signal processor or a computer by using the data out D_{out} , data in D_{in} , chip select CS, and clock synchronization SCLK pins. In some cases analog-to-digital converters and memory are also integrated.

form. In this type of accelerometer, the electronic system is essentially a crystal-controlled oscillator circuit and the output signal of the oscillator is a frequency-modulated acceleration signal. Some circuits provide a buffered square-wave output that can directly be interfaced digitally. In this case the need for analog-to-digital conversion is eliminated, thus removing one of the major sources of errors. In other types of accelerometers signal conditioning circuits such as analog-to-digital converters are retained within the chip.

Force Feedback Accelerometers. These often must be digitized for use in digital systems. If they are used in inertial navigation systems there may be specific problems introduced by the accuracy requirements. The dynamic range may exceed

24 bits, and the system must operate in real time. Accurate integration may be required to get velocity changes as an output. A common solution is to use voltage-to-frequency or current-to-frequency converters to convert the analog signals to a train of velocity-weighted pulses. These converters cost as much and add as much to the error budget as the accelerometer.

Here, it is worth mentioning that global positioning systems (GPSs) are becoming add-ons to many position-sensing mechanisms. Because of antenna dynamics, shadowing, multipath effects, and the need for redundancy in critical systems such as aircraft, many of these systems will require inertial aiding tied in with accelerometers and gyros. With the development of micromachining, small and cost-effective GPS-assisted inertial systems will be available in the near future. These developments will require extensive signal processing with a high degree of accuracy. Dynamic ranges of the order of one million to one (e.g., 30 to 32 bits) need to be dealt with. A challenge awaits the signal-processing practitioner in achieving these accuracy requirements.

TACHOMETERS

Tachometers are devices for measuring the rotation speed of machine shafts, relative to a referential, which is generally the machine's stator. Tachometers get their name from the Greek words *takhys*, meaning "quick," and *metron*, meaning "measure." Therefore, etymologically, a tachometer is a device capable of measuring a speed. However, in the technical context, linear velocity meters generally are not referred to as tachometers, and the word is reserved for shaft rotation speed meters.

Moving vehicles can have translation movements and rotation movements relative to a referential. When guidance and navigation problems are considered, these movements must be sensed and their speed measured. The devices for measuring these rotational movement speeds of the vehicle relative to a fixed referential of inertia are generally called rotation rate meters or gyrometers and are not referred to as tachometers.

A rotation speed can be obtained from an angular position sensor by means of a time derivation. However, derivation

increases measurement errors and noise that may exist in the position measurement. The speed can also be obtained from an angular acceleration sensor by means of a time integration. However, integration has an initial value undetermination and may also cause the integrator to wind up due to any offset that may exist in the acceleration measurement. Therefore, even when a mechanical system has angular position or acceleration sensors, the speed of rotation is generally measured independently with some kind of tachometer.

Tachometers may be classified in several ways. One possible classification is based on the type of the tachometer's output quantity, which may be

1. A voltage value (amplitude or rms [root mean square] value): tachogenerators
2. A visual indication by a pointer mechanical position: drag-cup and fly-ball tachometers
3. A frequency value (or time value): inductive, Hall effect, optical pulse, strain gauge, variable capacitance, and switch tachometers; or stroboscopes

In this article, the description of the several types of tachometers follows an order suggested by this classification. Note that some tachometers may fit into more than one class, depending on the way their output is used. For instance, tachogenerators and inductive pulse tachometers may fit into class 1 or 3; stroboscopes may be classified as class 2 or 3.

Another classification is based on the principle of physics that underlies its operation. From this viewpoint there are

1. Electrodynamic tachometers: tachogenerators, drag cup, inductive pulse
2. Mechanical tachometers: the fly-ball
3. Magnetic tachometers: the Hall effect
4. Optical tachometers: the optical pulse and the stroboscope

Tachometers may be permanently installed and fixed on the machine group for constant monitoring of speed. For this purpose, any kind of tachometer but a stroboscope will do. Or they may be intermittently used to check the speed, without the need for permanent mechanical setting. For this purpose, the stroboscope and the optical reflected pulse tachometers are suitable, as they do not need moving pieces and only need an appropriate light source to be pointed at the machine to get a speed reading. Although not so well adapted, other types of tachometers with rotating internal parts may be found in portable tachometers. In these portables, the axle of the rotating parts protrudes from the apparatus box and has a rubber wheel on the end of it. To use the meter, the operator must put this wheel in contact with the rotating shaft, which then transmits the motion to the inner mechanisms of the device. The output then appears on the tachometer display. Care must be taken to avoid getting grease and dirt on the rubber wheel, which would cause it to slip on the shaft.

A vehicle's rotational speed is generally much slower than a machine shaft rotation. This vehicle motion speed can be measured with two kinds of sensors: the rate gyroscope, based on the mechanical conservation of angular momentum; and optical gyros, based on the interference of two optical beams whose wavelengths are modified differently by the motion. Although

these are not considered to be tachometers, they do measure a rotation speed and therefore will be described later in this article.

TACHOGENERATORS

Tachogenerators are small auxiliary machines acting as generators, driven by the shaft of the group whose rotation speed is to be measured. They provide an output voltage that has certain characteristics (constant value, rms value, frequency, etc.) proportional to that speed. There are several types of tachogenerators.

Dc Tachogenerators

Direct current (dc) tachometers are essentially dc generators (dynamos). Driven by a rotating axle, they provide an output dc voltage proportional to the rotation speed. A dynamo (Fig. 1) is composed of an iron rotor (armature), where a number of copper coils are wound, rotating inside a stator (inductor), which creates a magnetic induction flux ϕ that is stationary in space and constant in time. This induction flux can be generated by extra coils in the stator, which act as electromagnets being fed by direct currents; or it can be created by permanent magnets in the stator poles.

According to Faraday's law of induction, in each rotating coil an alternative emf (electromotive force) $e(t)$ is induced whose maximum is $E = kN\phi$, where k is a constant dependent on the way the device is constructed and N is the rotating speed in rpm.

The coils of the rotor have their terminals connected to different insulated copper segments of a cylinder, coaxial with

Figure 1. Dc tachogenerator (dynamo). (a) Internal constitution. (b) Voltages.

the rotor, called the commutator [Fig. 1(a)]. A pair of stationary carbon brushes slips over the segments, with little friction. The brushes are in contact with only one pair of segments at a time and, therefore, they establish electric contact between an outside stationary circuit and the two terminals of only one coil each time.

The brushes are positioned so that the two segments come in contact with the two terminals of a coil exactly when that coil's emf goes through its maximum value. As the rotor's rotation tends to decrease that emf, it also moves those segments away from the brushes, making way for new segments, which establish contact with the next coil where the emf is now at a maximum. In this way, the commutator acts like a mechanical rectifier, picking up only the maximum value of emf [Fig. 1(b)]. So the output voltage of the dynamo, measured between the stationary brushes at no load condition, is $V = E = kN\phi$.

Keeping the flux ϕ constant, the voltage is proportional to the rotation speed N . As can be seen by Faraday's law, inversion of the rotation direction (correspondent to a switch of algebraic sign of N) causes an inversion of the output voltage polarity. So the voltage is a measure of both direction and magnitude of the rotational speed.

As the number of armature coils is finite, the brushes are in contact with them not only at the moments when their emf is at a maximum, but also a little before and a little after that. Therefore, the voltage at the brushes is not exactly constant but has a ripple, which decreases as the number of coils built into the rotor increases. In practice, other sources of ripple exist, such as eccentricities, asymmetries, and irregularities of the brushes contacts. The ratio of the amplitude of that ripple (difference between maximum and minimum) to the mean voltage value is called undulation and is an index of performance of the tachometer. This undulation value can reach as high as 2%.

Typical sensitivities of the dc tachometer generators are about 5 V to 10 V per 1000 rpm, with ranges of typically 0–5000 rpm up to 0–10,000 rpm.

To behave as a tachometer, the dynamo must be kept at constant flux condition. So the flux is usually generated by permanent magnets made of appropriate alloys or sintered materials; and no load current must be allowed, so the tachometer must only be connected to high-impedance voltmeter devices.

To minimize the mechanical load of the tachometer on the group, the rotor is built with as little a moment of inertia as possible. One typical construction solution is to wind the armature coils over a hollow plastic rotor while the magnetic circuit is completed by an iron stationary cylinder inside the rotor.

Dc tachometers have the advantage of furnishing a dc signal proportional to the speed, with nonlinearity usually less than 1% of full scale and with a polarity that shows the direction of movement. Therefore, they are appropriate for control purposes. However, they have the disadvantage of having a voltage ripple, which may demand electric filtering, causing a time delay that may be inconvenient. Another disadvantage is that the construction of the windings and of the commutator is difficult, making the devices expensive. For these reasons, these devices tend to be replaced by digital, pulsed types.

Ac Tachogenerators

Alternating current (ac) tachometers are ac generators coupled with the group, producing an ac voltage that is a measure of the speed. Ac machines of two types, synchronous and induction,

can be used to build two corresponding types of ac tachogenerators.

Ac Synchronous Tachogenerators. The ac synchronous generator, also called an alternator, generates an ac voltage that is synchronized with the rotation speed of the rotor. Generally it is built with the inductor in its rotor and the induced coils in the stator. By means of dc rotor currents or permanent magnets at the poles, the rotor creates an induction field B in the airgap, which is constant in time and is fixed with respect to the rotor. The revolution movement of the rotor inside the stator causes a similar rotation of the magnetic field. This field is expected to have sinusoidal spatial distribution.

The induction flux ψ linked to a coil in the stator with n turns is $\psi = n\phi \cos \alpha$, where ϕ is the simple flux produced by a rotor pair of poles and α is the electric angle between the coil and the pole magnetic axes. With the rotor rotating at an angular speed ω , the angle is $\alpha = \omega t$. However, if the rotor has p pairs of poles, the magnetic north-south sequence passing through the coil in the stator occurs p times in each mechanical revolution. Then its electric frequency is $p\omega$, and then $\alpha = p\omega t$. According to Faraday's law of induction, the emf induced in the coil is then

$$e(t) = (p\omega)n\phi \cos(p\omega t\pi/2)$$

If no current is drawn from that coil, its no load voltage equals this emf. So in the static coil, an alternative voltage is produced, with both its magnitude and its frequency proportional to the rotating speed, provided the flux ϕ is kept constant. To keep a constant flux ϕ , the ac synchronous tachogenerators have permanent magnets on the rotor, built with the same technologies referred to in the section on dc tachometers; and their stator coils must be connected to high-impedance voltmeter devices. To increase the induced voltages, they generally have more than one pair of poles, typically four. Their sensitivities and ranges are similar to those of the dc tachometers.

Ac synchronous tachogenerators are less expensive than the dc tachometers because they do not need the costly commutator. The speed information is obtained by measuring the tachogenerator voltage amplitude with an ac voltmeter (sensitive to rms values, or a dc voltmeter provided the voltage is electronically rectified). For control purposes, the alternative voltage must be conditioned by means of an ac/dc converter and filtering circuit, which may cause undesirable delays.

Alternatively, the rotating speed may be obtained by measuring the voltage frequency, which is necessarily p times the speed in rps. This is a more accurate means of measurement, if a digital frequency meter is used, and is appropriate for use in digital measuring and control systems.

Neither the voltage nor the frequency measures give any information about the direction of the rotation. This is a disadvantage of the ac synchronous tachogenerators when compared with the dc ones. To overcome this limitation, synchronous tachogenerators with two stator coils are used. Voltages induced in both coils are equal in amplitude and frequency but have different phases (typically they differ by 90°). A circuit sensing which one is leading and which one is lagging provides the information about the direction of rotation.

Ac Induction Tachogenerators. Ac induction tachogenerator tachometers have the structure of a two-phase induction motor: The stator has two different coils whose magnetic axes are

perpendicular in space; the rotor has no salient poles and also has a two-phase winding, which is kept short circuited. Indeed, as all the rotor conductors are short circuited at their terminals, there is no need to individualize the coils. These can be replaced by a uniform distribution of rotor conductors, forming the so-called squirrel cage rotor. The currents induced in the cage, regardless of the number of its conductors, have the same magnetic effect as a two-phase winding. The same effect is obtained with an even smoother current distribution, like the one obtained in a continuous conducting sleeve over the rotor, the so-called drag-cup rotor.

One of the stator coils is fed with a sinusoidal voltage $u_1 = U \cos(\omega t)$ while the other is kept in open circuit. Because the two coils are orthogonal, the voltage induced in the second coil will be null if the rotor is stopped. However, if the rotor is moving with angular velocity Ω , the currents induced in it will cause a magnetic link with the second coil. If resistive voltages can be neglected compared with inductive ones, then a voltage will be induced in the second coil that is $u_2 = \Omega k U \cos(\omega t + \pi/2)$, where k is a constant that depends on the construction of the device. That is, a voltage is obtained that has the same frequency as the feeding voltage and whose amplitude is proportional to the speed to be measured. The direction of the rotation is obtained by comparing the phases of u_1 and u_2 . Indeed, reversing the direction of the movement is equivalent to changing the algebraic sign of Ω , which is the same as switching the phase of u_2 by 180° .

The preceding expressions assume that the second coil is kept without current, so a high-impedance voltmeter device must be used. A constant rotating speed Ω is also assumed; this means that if Ω changes, the frequency of the changes of Ω must not approach the frequency ω of the input voltage. This is generally the case. For the most common cases, power line frequency is used to feed the tachometer, as the main machine mechanical speed cannot have rapid oscillations on the order of tens of hertz.

This type of tachometer may be built with a squirrel cage rotor, thus providing an inexpensive instrument. However, the drag-cup rotor is more common because it provides better results with the advantage of having a lesser inertia than the former. The drag-cup rotor consists of a hollow sleeve of aluminum providing the rotor electric circuit. The cup rotates around a stationary iron core that completes the magnetic circuit.

With drag-cup rotors, ac induction tachometers can have an accuracy up to 0.1% of full-scale deflection, with ranges typically between 0 rpm and 5000 rpm and sensitivities of up to 10 V per 1000 rpm.

THE DRAG-CUP TACHOMETERS

The drag-cup tachometer (Fig. 2), also called eddy-current tachometer, is not a tachogenerator. It does not furnish an electric signal proportional to the speed. Instead, its response is a visual indication of speed by means of the position of a needle over a scale. It can be used in addition to any position transducer if an electric signal is needed, but this is not a common solution. The drag-cup tachometer is a very common device and is generally used as a speed and engine rpm indicator in automobiles, airplanes, and other vehicles.

The instrument consists of a rotating cylindrical permanent magnet driven by the rotating shaft. The magnet rotates inside

Figure 2. The drag-cup tachometer (exploded view).

a hollow conductive sleeve (a cup, usually made of aluminum), coaxial with the shaft. This cup can also rotate, but its movement is restrained by a spring. Surrounding the conductive cup, a fixed hollow iron cylinder closes the magnetic circuit of the magnet's induction field lines.

When the magnet rotates, its revolving magnetic field induces eddy currents in the conductive cup. The amplitude of these currents is proportional to the time derivative of the induction flux (that is, proportional to the rotation speed). These currents interact with the magnetic field and generate an electrodynamic torque proportional to the field amplitude (which is constant) and to the currents' amplitude. Therefore, the torque generated is proportional to the rotating speed. This electrodynamic torque causes a displacement of the cup to a position where the spring resisting torque balances the first one. The cup is attached to a pointer, whose position on a scale is an image of the equilibrium position of the cup, thus furnishing a reading of the speed.

This mechanism is similar to an induction motor: The rotating field of the permanent magnet is similar to the rotating field generated by a current-fed polyphase stator winding, with currents of a frequency similar to the rotating speed of the magnet. The cup behaves as a short-circuited rotor at standstill, experiencing the starting torque. Under these conditions, induction motor equations show that the torque is approximately proportional to the stator frequency (in this case, to the speed of the magnet), provided the currents induced in the cup do not have magnetic effects comparable with the field of the permanent magnet.

The permanent magnet used in drag-cup tachometers generally is made of Al-Ni, or other appropriate alloys, and has up to five pairs of poles. The dependence of its magnetic properties on the temperature is corrected by means of a thermoperm compensating disk. This is a disk made of a material whose magnetic conductivity depends on the temperature, placed close to the cylindrical magnet and partially shunting it to a degree that also depends on the temperature. The dependencies practically cancel each other.

Drag-cup tachometers are used in speed ranges up to 10,000 rpm and have a measuring accuracy on the order of 1%.

FLY-BALL TACHOMETERS

The fly-ball tachometer is a mechanical device that has been in use for a long time as a speed-governing device for thermic

engines (watt regulator). Used as a tachometer, it gives a visual information of the speed, positioning a pointer on a scale. Position sensors can be added to convert the pointer position into an electrical signal if this is needed.

The fly-ball tachometer consists of two massive spheres, connected through a system of levers to the shaft. The shaft rotation causes the spheres to rotate around it. The centrifugal force drives the spheres away from the shaft, but their radial displacement is restrained by the levers acting against a restitution spring. At equilibrium, the spheres rotate at a distance where the spring force and the centrifugal force are equal. This distance is shown by the position of a pointer driven by the lever-spring system.

Normal springs exercise a restitution force proportional to their deformation x , $F_s = K_s x$. Centrifugal force acting on constant masses is proportional to the rotation radius, R , and to the square of the rotation speed, Ω : $F_c = K_c R \Omega^2$. Note that the spring deformation and the rotation radii of the spheres R are related in a way depending on the mechanical design of the gearing, $R = R(x)$. At equilibrium $F_s = F_c$, which leads to a nonlinear equation $x = (K_c/K_s)R(x)\Omega^2$. Therefore, these tachometers have a nonlinear velocity scale. In some models, the nonlinearity is compensated for, to a certain extent, by using a nonlinear spring.

INDUCTIVE PULSES TACHOMETERS

The inductive pulses tachometer is a type of tachometer in which there is no mechanical contact between the moving shaft and the stationary sensor (Fig. 3). The output of the tachometer consists of a train of pulses, which can be processed either by analog or digital means. It consists of an iron-toothed wheel mounted in the shaft and rotating with it. Placed near it is a permanent magnet, around which a sensing coil is wound [Fig. 3(a)]. The magnet may be placed, as suggested by the figure, at a distance of about a millimeter from the outer face of the teeth. Alternatively, the magnet may be U shaped, with the wheel's teeth passing between the two poles.

As the wheel rotates, the teeth and gaps pass successively in front of the magnet, causing a periodic variation of the magnetic reluctance of the flux lines' path. Therefore, the induction flux through the coil wound around the magnet varies, thus causing periodic pulses of voltage to be induced at its terminals [Fig. 3(b)]. Both the amplitude and the frequency of the voltage impulses are proportional to the rotation speed and to the number of teeth in the wheel.

The rotation speed can then be obtained by means of any ordinary method of measuring the voltage peak value, time-average value, or rms value. However, this is not the most

common way, as the pulse amplitudes depend on circumstantial factors, like the temperature or variations of the sensor position relative to the toothed wheel. Another drawback of this method is the difficulty of measuring very low speeds when the pulse amplitudes are not high enough to be measured accurately.

Alternatively, the speed can be obtained, and usually with better accuracy, by measuring the pulse frequency, f , which is equal to the shaft's number of rotations per second times the number of teeth n of the toothed wheel. Expressing the rotation speed N in rpm, the following is obtained:

$$f = nN/60$$

When using the frequency measurement method, generally the pulses are first processed through some sort of electronic comparing circuit, like the Schmitt trigger or equivalent, in order to produce a train of sharper impulses, whose amplitude is now independent of the speed. The frequency of the pulses is then measured, either analogically or digitally. The ways of implementing these measures will be described later. The difficulty of measuring very low speeds persists, however, because the amplitude of the pulses from the pick-up coil may be too low to switch the electronic trigger. (This can be overcome if the field variations are sensed, not by means of the inductive process just described, but with a Hall effect sensor. The pulses produced by the Hall effect sensor have a constant amplitude, independent of speed, so only their frequency varies with the rotation velocity.)

To increase the sensitivity of the sensor at low speeds, wheels with more teeth are used. However, this procedure has time and space limitations. If there are too many teeth, the distance between them may become too small compared with the size of the polar piece. The polar piece would then face more than one tooth at a time, causing a space integration and averaging effect. The device would not be able to distinguish the teeth from the gaps and thus would become insensitive to the rotation. For this reason, the polar piece generally has a sharp tip, of a conical or other similar shape. A similar averaging effect occurs because of a time limitation. The pulses have nonzero duration. A wheel with a number of teeth, few enough to avoid the space integration but numerous enough to measure low speeds, will cause pulses of increasing frequency when the shaft speeds up. At high velocity, the pulses can become too rapid and start to overlap, and then the sensing circuit is no longer able to distinguish the too frequent pulses. For these reasons, a wheel with an appropriate number of teeth must be chosen for the range of rotation speeds to be measured.

The shape of the wheel's teeth is also designed according to the needs of the electronic circuitry to be used: Smoother teeth may cause an almost sinusoidal voltage to be induced, and teeth with sudden geometrical changes induce sharper pulses.

Some inductive pulse tachometers are provided with a second pick-up coil, generally placed in such a way as to induce pulses in quadrature with those of the first coil. The phases of both signals may be compared in some electronic circuitry to find if the second leads or lags behind the first one, thereby obtaining information about the direction of the rotation.

As there is no mechanical contact between moving and fixed parts, this kind of tachometer is suitable for use in low-torque mechanisms. If low inertia is also required, a plastic wheel is used, in which ferromagnetic pieces are regularly inserted in radial positions near the periphery. These pieces have the same

Figure 3. Inductive pulses tachometer. (a) Schematic constitution. (b) Flux and voltage at pick-up coil.

effect of regularly modifying the magnetic reluctance of the flux path, thereby causing a periodic variation of the flux through the pick-up coil with the consequent induction of a voltage train of pulses. This kind of wheel is more expensive than an iron one, but, in addition to the lower inertia it offers, it has the advantage of producing sharper voltage pulses.

Inductive pulse tachometers are widely used because they need almost no maintenance, they need no power feeding circuits, and the sensor device is not expensive. Having no electric contact between moving and stationary parts, they produce no sparks and therefore can be used in potentially explosive environments. The magnet and pick-up coil are usually assembled in a sealed case, which is mounted near the wheel, without touching it and with no magnetic barrier between the wheel and the magnet.

HALL EFFECT PULSE TACHOMETERS

The Hall effect pulse tachometer is similar to the inductive pulse tachometer, except that the magnetic induction field variations are sensed by means of a Hall effect sensor (Fig. 4) instead of a pick-up coil.

The Hall effect consists of the appearance of a voltage v_H through a material when an electric current I flows through it in the presence of an external magnetic induction field B . The electric carriers that constitute the current, because they are moving with a velocity v inside the field B , sense a Lorentz force. This is equivalent to an electric field $E = v \times B$, perpendicular to both the induction field and the current direction and that generates the external voltage that is felt.

The Hall effect can be better sensed in semiconductor than in conductor materials. The charge carriers will feel a force $F = qE$, which deflects their movement to one side of the material. If the material is p type [Fig. 4(a)], the carriers will be positive and the direction of velocity is the same as that of the current. Suppose that the B field is from the upper side; the positive traveling charges will be deflected to their left. The left side will then become positive with respect to the right side.

If the material is n type [Fig. 4(b)], the carriers will be negative; the direction of velocity is opposite to the current. The Lorentz electric field will be opposite to that of the previous case. As a consequence, the external voltage produced will also be reversed.

The voltage is directly proportional to the current I and to the field B . If a sensor based on the Hall effect device is fed with a constant current I , then the output voltage will be a measure of the induction B . Note that with inductive sensors,

it is the time derivative dB/dt that is sensed, while with Hall sensors it is the field itself that is sensed, regardless of its rate of variation. Typical sensors are supplied with currents on the order of 10 mA and have an output sensitivity on the order of 10 V/T.

The construction of Hall effect pulse tachometers is similar to inductive pulse tachometers. Like them, a toothed ferromagnetic wheel rotates in front of a permanent magnet. Instead of the pick-up coil used in inductive pulse tachometers, a Hall sensor is placed between the permanent magnet and the rotating toothed wheel. The airgap variation of the magnetic flux path, caused by the succession of teeth and gaps of the wheel, causes a variation in the intensity of the B field over the magnet's pole. The output voltage of the sensor, being proportional to the B intensity, follows its variations. Another option is to use a wheel with magnetic poles in its periphery and avoid the stationary magnet. The Hall sensor will sense the magnetic field from the wheel's poles.

The output of the Hall effect tachometers is a train of voltage pulses with a frequency f that is equal to the shaft's speed (in rps), times the number of pole pairs n of the magnetized wheel, or times the number n of teeth of the toothed wheel. Or, using the speed N in rpm,

$$f = nN/60$$

This frequency then is measured by one of the methods described later in this article. The pulses all have the same intensity regardless of the shaft's speed and, therefore, the device is sensitive to low as well as high speeds.

The sensor output is a measure of the rotation speed but gives no information about rotation direction. This is obtained with a second sensor placed in a position so that its signals are in quadrature with the first sensor's output. Electronic processing may distinguish which one is leading and which one is lagging, thus determining the direction of movement.

Hall effect tachometers have the same advantages of contactless sensing as inductive tachometers, but they have the additional advantage of sensing all speeds equally. However, they have the disadvantage of needing a power supply. When compared to optical-based tachometers, they have the advantage of being less sensitive to environmental conditions, like humidity, dust, or vibrations, and of having characteristics that vary less over time than the optical tachometers.

OPTICAL PULSE TACHOMETERS

Optical pulse tachometers (OPT) (Fig. 5), like the Hall effect tachometers, generate a train of constant amplitude pulses

Figure 4. Hall effect sensor. (a) With p -type semiconductor material. (b) With n -type semiconductor material.

Figure 5. Optical pulse tachometers. (a) Incident light method. (b) Reflected light method. (c) Portable reflected light OPT.

whose frequency is proportional to the rotating speed to be measured. The frequency of the pulses is measured either by analog or digital means, to be described later.

The pulses may be generated by two alternative ways: the incident light method or the reflected light method (also known as the transmittance and the reflectance methods).

The incident light type of optical tachometers uses the repetitive interception of a light beam to generate the pulses. A disk [Fig. 5(a)], which has at its periphery a sequence of transparent radial windows and opaque sectors, is mounted to the shaft and rotates with it. The entire disk may be made of transparent acrylic plastic, with black radial masks painted on it. Or the disk may be made of an opaque material, plastic or metallic, with slots cut in it; sometimes a toothed wheel is used. At one side of the disk, a light source emits a light beam parallel to the shaft. The light beam falls on a light sensing device. As the disk rotates, the transparent slots and the opaque zones alternatively cross the beam, alternatively transmitting and interrupting it, which causes a pulsing response of the light detector.

The reflected light solution uses the light source and detector on the same side of the disk [Fig. 5(b)]. The disk now has no slots, but its face has alternate light-absorbent zones and light-reflecting ones. The rotation of the disk causes the light sensor to detect alternate pulses of reflected light. Marks alternatively painted black and white usually create the desired effect. If increased reflection is needed, strips of reflective tape may be glued over the disk. The surface of this tape is covered with small spherical lenses, and these lenses reflect the incident light back in the same direction, even if that direction is not perpendicular to the tape surface. The reflected beam solution may be implemented without the disk. The shaft itself may be painted with light-absorbent and -reflecting strips, or have reflecting tape strips fixed to it.

As in inductive and Hall effect pulse tachometers, the frequency f of the optical tachometer's output is equal to the shaft's rotations per second times the number n of transparent slots in the disk (for the incident light method) or of reflecting marks (for the reflected light method). Using the rotation speed N in rpm,

$$f = nN/60$$

For use in mechanical settings where access is difficult or where inflammable atmospheres proscribe the presence of electric devices, the two light beams, one from the source and the other for the sensor, may be carried by optical fibers between the shaft proximity and the remote electronic setting.

The incident light method demands the disk to be mounted on the shaft and the light source and sensor to be installed carefully, in a fixed and correct position. Therefore, it requires more mechanical care than the reflected beam method, which may be used with an improvised mechanical setting, specially if the reflection is made on the shaft itself, without the use of the disk. However, the incident method device, once correctly installed, is more reliable because it provides steadier pulses than the reflected beam setting, which is more prone to errors due to vibration, misalignment, dust on the reflecting surfaces, and so on.

The ease of use of the reflected light method allows for the construction of stand-alone, battery-operated portable tachometers [Fig. 5(c)]. They include a light source, the reflected

light sensor, the signal processor, the frequency meter, and a digital or analog display where the speed can be directly read, normally in rpm. Usually these tachometers are furnished with a set of reflecting tape strips. The operation consists only of pointing the instrument at the shaft, where the tape has been previously attached, pressing a switch to emit the light, and reading the desired rotating speed.

A number of construction solutions are available for these tachometers. Any light source may be used. Generally an electric bulb has been used, but an increasing number of models use light emitting diodes (LEDs). The sensor used to be a photoelectric cell, but photosensitive semiconductor devices are now most common.

Photoelectronic devices having both a photodiode and phototransistor are available on the market and are also used in the construction of tachometers. Some of these devices are made in a U shape, with the diode at one extreme and the transistor at the other, and are suitable for the construction of incident beam tachometers, the slotted wheel passing between the two extremities of the U. Other devices are made with the diode and the transistor side by side and are appropriate for reflected beam tachometers. There are also reflected beam tachometers that use a laser beam, generally from a laser diode, when increased distance range is desired.

Like other pulse tachometers, optical tachometers measure the speed of rotation but not its direction. Another light source and sensor placed in quadrature is needed for phase detection and direction determination.

Optical tachometers have an advantage over the magnetic ones of easier installation and operation, but they have the disadvantages of being susceptible to environmental pollution, dust, and grease and of experiencing accelerated aging as the light source properties generally decay in time.

OTHER PULSE TACHOMETERS

Strain Gage Tachometers

A strain gage is a dc-fed Wheatstone bridge whose resistors vary their resistance when stretched or compressed. The resistors are fixed to a mechanical piece, which is to be deformed, and are mechanically installed in such a way that the deformation of the piece does not equally deform the four bridge arms. In so doing, a strain in the piece unbalances the bridge and causes a voltage output proportional to the deformation.

If the rotation of a shaft can be transformed into a periodic deformation of a stationary piece, then this deformation can be detected with a strain gage, causing an output signal that is synchronized with the rotation. The frequency of the signal is, therefore, equal to the rotation speed, but nothing can be said about its amplitude (this is preferably constant, but mechanical resonance may cause it to vary with the speed). This can be an appropriate way of sensing the rotation speed when the mechanical installation, by its own design characteristics, naturally causes a vibration or deformation of one of its stationary components. Then no further mechanical settings are necessary, except for the setting of a strain gage. If that mechanical deformation does not naturally occur, the method can still be implemented by introducing an extra piece and forcing it to suffer a deformation. The strain gage then is fixed to a cantilever-mounted beam, which is in contact with the periphery of an eccentric wheel or cam, driven by the shaft. The

rotation of the eccentric wheel or cam causes a sinusoidal vibration of the beam, synchronized with the rotation.

The output characteristics of these tachometers depend on the sensitivity of the strain gage, and on the mechanical properties of the mechanical setting. The amplitude of the signal is not a measure of the speed, but its frequency is, and it should be read by one of the methods described later. However, transient mechanical vibrations or resonance with harmonics may introduce spurious frequencies and thus cause a false speed reading.

Variable Capacitance Tachometers

The usual design of variable capacitors consists of a set of fixed conductive parallel plates, among which another set of parallel plates can rotate. These are parallel to the fixed plates, and their rotation axle is perpendicular to both sets of plates. The capacitance of the capacitor is proportional to the total juxtaposing area of fixed and movable plates, and this area depends on the angular position of the rotating plates.

If the movable plates are driven by a rotating shaft, then the capacitor will have a periodically changing capacitance, varying synchronously with the shaft rotation. This capacity variation may be sensed and translated into a measure of speed, in two different ways. One way is to feed the capacitor with a constant voltage U . Then its current i_C will be

$$i_C = \frac{dq}{dt} = \frac{d(CU)}{dt} = U \frac{dC}{dt} = U \frac{dC(\alpha)}{dt} \cdot \frac{d\alpha}{dt} = U \cdot \omega \cdot \frac{dC(\alpha)}{dt}$$

that is, proportional to the rotation speed ω , and will depend on the way the capacitance varies with the position.

If a smooth varying current is desired, the geometric design of the plates is such that a sinusoidal dependence $C(\alpha)$ is obtained, which causes a sinusoidal current to flow in the tachometer, with both amplitude and frequency proportional to the speed. The measure of any of these values indicates the desired speed.

For low speeds, these sinusoidal change derivatives may be too low to cause an easily measurable current. For this reason, the plates' design may include a smooth capacitance variation (for instance, a linear one, followed by a sudden change). The resulting current will be a smooth, low current during most of the period, followed by a sudden and sharp spike. The frequency of these pulses is proportional to the rotation speed and is fed to any frequency meter device to obtain the speed value. In general, the current must be first converted into a voltage, for measurement purposes.

An optional method of implementing a variable capacitance tachometer is to connect the capacitor to a Wien, Maxwell, or other ac capacitance measuring bridge. The bridge is fed with a ac voltage of a frequency higher than the rotation rhythm (more than 10 times the rotation pace) and is balanced for an intermediate capacitance value of the variable capacitor. The rotation of the shaft and the consequent variation of the sensor capacity periodically unbalance the bridge and cause it to output an ac voltage with the frequency of the power source and with an amplitude that periodically changes at the pace of the rotation. This is an amplitude modulation, with the feeding frequency acting as a carrier and the rotation speed acting as a modulator. This output signal is then demodulated to extract the modulator. The frequency of the modulator is then read by

any of the usual processes, and that frequency is the desired speed value.

Switch Tachometers

The switch tachometer is a device that, when it is driven by the rotating shaft, alternatively makes and breaks electrical contacts in a circuit, causing current pulses, whose frequency is measured by any usual method. Generally the switch is connected to an RC circuit, and the current provoked is the periodic charge and discharge of the capacitor.

One type of switch tachometer has a pair of rotating contacts, driven by the shaft and connected to a capacitor pair of terminals. A dc voltage is fed through a resistor into a stationary pair of terminals. The rotating capacitor terminals contact the fixed ones, and the rotation causes their periodical inversion. This causes the capacitor to be alternately charged and discharged through the resistor, with the resulting pulsed current.

Another type of switch tachometer uses a fixed circuit, with commuting switches driven by the shaft. A common way is to use reed switches. The reed can oscillate between two positions, each one making contact with a different circuit topology. The reed can be mechanically driven by a cam or yoke. A popular design is to make the reed magnetically actuated by a magnet fixed to the shaft. Being very flexible, the reed is attracted by the magnet and then released, which makes it alternatively touch two contacts.

The switch tachometer is referred to later in this article, in the section on frequency measurement.

STROBOSCOPES

The stroboscopic method of speed measurement is based on the inertia of the human eye. Therefore, it demands the presence of a human operator in the measurement loop. If a rotating or vibrating object is illuminated by a pulsing light whose flashing rhythm coincides with the rotation or vibration speed, the object will be illuminated whenever it is in the same position. Hence, it will always be seen in that position. The human eye, being incapable of distinguishing successive flashes if they are too rapid, will give the sensation of seeing an object standing still.

Stroboscope tachometers are made of a flashing lamp, a device to control its rhythm, and a frequency meter. Most stroboscopes have all the components integrated in the same portable box. The operation consists of pointing the light at the rotating shaft, regulating the flash frequency until the shaft appears stationary, and reading the frequency. For easier detection of the apparent immobility, the shaft must have some distinguishable feature on its outer surface. Normally, a white mark is painted or a reflective tape is fixed to the shaft. Old stroboscopes used a slotted rotating wheel to mask periodically the vision of the shaft or to interrupt periodically an illuminating light beam. Modern stroboscopes use a gas-filled flash lamp, which has a grid between its cathode and anode.

A high voltage, from a capacitor that is periodically charged, is applied between the cathode and the anode. Voltage pulses from a pulse generator are applied to the grid, each pulse permitting an electrical discharge from the capacitor through the bulb gas, with the resulting emission of an intense and short (about 10 μ s) strobe of light. Before the next voltage pulse is applied to the grid, the capacitor is again charged.

The frequency of the triggering pulses may be read directly on a dial mounted on the adjustment knob of the flashing rhythm, or the stroboscope may include an extra frequency meter, either analog or digital. Generally this frequency may be directly read in impulses per minute, to coincide with the usual way of expression rotation speeds.

Sometimes it is difficult to determine what the speed is, because the shaft may look like it is standing still for different flash frequencies. This may happen when different harmonics of the rotation rhythm are used as flash frequencies (in this case, the image of the mark in the shaft may be repeated in more than one position). Then a frequency f_1 for apparent immobilization must be found, and then the next and closest stationing frequency f_2 must be located. These two frequencies, because they are as close as possible, are two consecutive harmonics of the rotation rhythm N ; that is, $f_1 = KN$ and $f_2 = (k + 1)N$; therefore, the speed is $N = f_2 - f_1$ (assuming all the quantities are in the same units, that is, minute^{-1} or second^{-1}).

Inversely, if the flashing rate is a subharmonic of the rotation speed, $N = Kf_1$, then the same frozen image aspect will occur, with the mark visible in only one position. Then the frequency of flashes must be decreased until the next frozen image appears, which happens at frequency f_2 , such as $N = (K - 1)f_2$. Then $1/N = 1/f_2 - 1/f_1$ or $N = f_1 f_2 / (f_1 - f_2)$ is obtained.

Stroboscopes are an easy and straightforward method of measuring speed that can be used without any mechanical setting and applied to any periodically moving mechanism. However, they have the disadvantage of not furnishing an automated output. The range, precision, and light intensity of these devices vary from maker to maker. Ranges from 5 Hz (300 rpm) to 300 Hz (18,000 rpm) or even up to 417 Hz (25,000 rpm) are available, with accuracy on the order of 1%. The light intensity of each flash may be on the order of 1500 lx.

FREQUENCY MEASUREMENT

Analog Frequency Measurement

There are several methods for analog frequency measurement, but we shall limit the discussion to those most often used in tachometers. These are the conversion of the frequency into a proportional dc voltage, which is measured with a common dc voltmeter, or into a dc current, which is measured with a dc ammeter.

Frequency Voltage Conversion. The frequency voltage converter (Fig. 6) is based on the fact that the average value V of a train of pulses of constant amplitude U , constant duration T_0 , and period T [Fig. 6(a)] is $V = UT_0/T$. With these assumptions, $UT_0 = A$ is a constant (the constant area of each pulse), and $1/T = f$ is the frequency to be measured. Hence, $V = Af$ results. Each constant amplitude, constant duration pulse is produced by a monostable circuit, which must be accurate and stable. Its pulse duration must, of course, be shorter than the minimum period corresponding to the maximum frequency to be measured.

The input signal is fed to a shaping circuit [Fig. 6(b)], generally a Schmitt trigger and a differentiator, in order to get new short and sharp pulses synchronized with the incoming ones. The shaped pulses attack the monostable circuit, each pulse causing the output of a constant-area pulse. The train of these constant-area pulses is fed to an averaging circuit

Figure 6. Frequency measurement by frequency-voltage conversion. (a) Time diagram of a train of constant-area voltage pulses. (b) Block diagram of a frequency-voltage converter.

(an RC circuit, or an integrating amplifier with discharging resistor), functioning as a low-pass filter of time constant τ . Its output will be the average value V , with a ripple $V_R = V/(f\tau)$.

For the propose of visual reading of the frequency with a voltmeter, there is no need for a high-quality filter, as the mechanical inertia of the meter itself has an averaging effect. For use in an automated measurement chain, a tradeoff must be made between the presence of output ripple and response time of the filter.

Frequency-Current Conversion. Another analog method of frequency measurement, similar to the first, is to convert the frequency into an average value of a capacitor charging current (Fig. 7). The alternative input signal whose frequency is to be measured, by any way, controls a switch that can be commuted between two positions [Fig. 7(a)]. The positive part of the signal causes the switch to apply a dc voltage U to an RC series circuit. The negative part of the signal commutes the switch to a position where it short circuits the same RC circuit. The time constant $\tau = RC$ remains the same during the charge and the discharge, and the circuit is dimensioned to be $\tau < T/2$ where T is the period of the signal.

For fast signals, the switch must be electronic. For signals up to a few hundred hertz, reed relays can be used. This is generally the frequency range of the signals involved in rotation speed measurements; therefore, the speed can be measured by using some kind of generating device driven by the shaft to produce an alternating voltage and using this voltage to drive an electromechanical reed relay. However, it is much simpler to actuate mechanically the reed of the switch with a cam geared

Figure 7. Frequency measurement by frequency-current conversion. (a) Circuit. The reed actuator is not shown. (b) Time diagram of the charging current of the capacitor.

with the shaft, or magnetically actuate the reed by a magnet that is fixed to the shaft and rotates with it. Thus, the frequency of the rotation can be measured without the need of generating an electric signal just for the purpose of actuating a relay.

If $\tau < T/2$ one can assume that the capacitor is totally discharged when the switch causes the voltage U to be applied and that the capacitor totally charges before it is shorted again. In this assumption, a relative error $e = e^{-T/2\tau}$ is neglected compared with 1, for which it must be $T > 10\tau$, if the error e is to be $e < 0.5\%$, or $T > 14\tau$, if it is to be $e < 0.1\%$. Therefore, the charging current i_C is a quick pulse that ends before the next commutation [Fig. 7(b)], and it carries the total final charge $Q = CU$.

The charge being the time integral of the current, and there being no more charging current for the rest of the interval T , we obtain

$$\int_T i_C dt = Q = CU$$

that is to say, the area of the pulse is constant and is equal to CU . Therefore, the average value I_{av} of the current i_C during a period is proportional to the frequency, as it is

$$I_{av} = \frac{1}{T} \int_T i_C dt = \frac{CU}{T} = CUf$$

For control purposes, this current must be converted into a voltage and averaged, to obtain a dc voltage signal. For reading purposes, however, it is enough to read the charging current with an averaging ammeter, such as the moving coil type.

Digital Frequency Measurement

Digital frequency measurement (Fig. 8) consists of counting the number of the signal periods that fit in a certain time interval

(for instance, 1 s). For this, the input signal of frequency f_s is fed into a conditioning and shaping circuit [Fig. 8(a)], which generates a train of pulses synchronized with that signal, and with appropriate amplitude for the next electronic blocks. This first circuit generally includes an attenuator, an amplifier, a trigger, and a differentiator.

The synchronized train of pulses is fed into a digital counter, through an electronic gate that is generally an AND gate. The gate is kept opened for a unit period time T_c , because, in its control input, a signal from an internal clock is applied. An edge-triggered flip-flop maintains the gate-opening control signal on for an entire clock period T_c [Fig. 8(d)]. In this way, the digital counter counts the number of input signal periods during a unit time (that is, measures the frequency).

Generally, the clock consists of a high-accuracy crystal oscillator of 1 MHz (or of 100 kHz) and a series of six (or five) frequency dividers [Fig. 8(c)]. Each one receives a signal from the previous divider (or from the oscillator, if it is the first divider), divides the signal frequency by 10, and passes the resulting signal to the next divider. In this way, clock signals of 1 MHz (or 100 kHz) down to 1 Hz are available. The digital counting error is of one unit, and the counting is $f_s T_c$. Therefore, the relative error is $\epsilon = 1/(f_s T_c)$. For increased accuracy, the measurement should be made by counting as many input signal periods as possible, which means counting during the longest internal clock period possible.

If the input signals come from a pulse tachometer that generates only a few pulses per rotation, then the input frequency may be low and the machine may be turning very slowly. Therefore, the speed measurement may demand too much time for use in control purposes. As it is the number of turns per time interval that is counted, it is the average speed in that time interval that is obtained. In the case of slow motion and long counting time intervals, this average speed may differ significantly from the usually desired instantaneous speed. In that

Figure 8. Digital frequency measurement. (a) Block diagram of the circuit for frequency measurement. (b) Block diagram of the circuit for period measurement. (c) Block diagram of the clock. (d) Block diagram of the gate.

case, instead of measuring the number of turns per unit time, the inverse measurement is more appropriate. The duration of a single rotation is measured. This is done by reversing the roles of the input-synchronized and the clock pulses [Fig. 8(b)]: The input-synchronized pulse is applied to the edge-triggered flip-flop, keeping the gate opened during an input period $T_s = f_s$, and the counter counts the number of clock ticks that fit in an input period. The result is the time between input signal pulses, or signal period, and the frequency is its inverse.

Using a clock of frequency $f_c = T_c$, the count will now be $f_c T_s$, and the error of one unit represents a relative error $\epsilon = 1/(f_c T_s) = f_s T_c$ (the inverse of the former case). Good accuracy requires that a quick clock signal be used, and so the measurement may be done in a short time. This is appropriate for the measurement of slow signals, such as those from a tachometer installed in a slow machine.

Inverting the time measured, an (almost) instantaneous speed of rotation is obtainable. This is sometimes called the division by time technique for speed measurement. Because the result of the operation is a digital number, the output circuitry may include a processor to execute the operations needed to convert the count into the appropriate speed units, usually rpm, if the number is to be displayed on the tachometer.

GYROMETERS

Gyrometers are devices for measuring the velocity of rotation of a vehicle with respect to an inertial frame. There are several types of gyrometers, such as mechanical spinning gyroscopes (rate gyros), mechanical vibrating gyroscopes, gas-jet nongyro rate transducers, and optical interferometers gyros (optical gyros).

Spinning Rate Gyros

Mechanical rate gyros are single degree of freedom gyroscopes. A gyroscope is essentially a spinning wheel (Fig. 9) whose spin axis coincides with its principal geometric axis of rotation. The wheel's axle is supported by bearings located in a frame that surrounds the wheel. The supporting frame itself has an axle, orthogonal to the wheel's axle. The frame can also be rotated about its axle, which is supported by a second pair of bearings. This second pair of bearings can be fixed to the device case. Therefore, the frame is free to rotate about its axle, permitting the wheel's spinning axis to have a rotation movement on a plane perpendicular to the frame's axle. The device just described is called a single degree of freedom gyroscope [Fig. 9(a)].

Alternatively, the bearings supporting the frame may be fixed to a second outer frame. This second frame has a (third) axle of its own, perpendicular to the axes of both the wheel and first frame, and now this third axle is supported by a third pair of bearings fixed in the mechanism case. With this doubly articulated suspension, the wheel's spinning axis can rotate in two perpendicular planes and can thus assume any direction in space. This is the double degree of freedom gyroscope [Fig. 9(b)]. The supporting frames are called gimbals. They are also called Cardan suspensions, after the sixteenth-century mathematician and physician Gerolamo Cardano (1501–1576), discoverer of the solution of the third-degree equation and inventor of this suspension.

If the wheel's angular velocity is Ω , then its angular momentum equals $\mathbf{H} = \Theta \cdot \Omega$, where Θ is the momentum of inertia of

Figure 9. Spinning wheel gyroscope. (a) Single degree of freedom. (b) Double degree of freedom gyroscope. (c) Rate gyro.

the wheel. Both $\mathbf{H}$ and Ω are axial vectors, and Θ is a tensor. However, if the component of the rotational velocity of the wheel around its axis is much greater than any other components, then $\mathbf{H}$ may be considered parallel to Ω , and Θ may be considered a scalar constant. This requires that the wheel be spun at high speed.

Newton's second law applied to rotating bodies states that $\mathbf{T} = d\mathbf{H}/dt$, where $\mathbf{T}$ is the torque acting on the body and $d\mathbf{H}/dt$ is the time derivative of the angular momentum computed in an inertial reference frame. It follows from this law is that if no torque is applied to the wheel (i.e., $\mathbf{T} = 0$), then its angular momentum will be kept constant. The wheel's spin will maintain its speed and its axis will maintain its direction with reference to the distant galaxies.

This principle is the basis for the use of a double degree of freedom gyroscope as an inertial navigation device. The case of this apparatus is fixed to a moving vehicle. The vehicle's rotational motion causes the axis of the gimbals to rotate with it, with respect to an outer, inertial reference frame. Assuming that the bearings are frictionless, the movement of the gimbals transmits no torque to the spinning wheel. Therefore, in the interior of the revolving gimbals, the spinning wheel maintains the direction of its axis of rotation. The angles between the axis of the wheel and the outer case indicate the attitude (angular orientation) of the vehicle. In practice, the friction in the bearings and other causes impart a small torque to the wheel, and, therefore its axle will have slow motions, which are the major source of error in this type of mechanism. Special care is taken in their construction to reduce and compensate for these torques. However, the spatial attitude normally is measured with rate-integrating gyros (to be described later) because less error is obtained using three rate-integrating gyros (one for each spatial axis).

For measuring the turning speed (turning rate) of a vehicle, single degree of freedom gyros can be used in a configuration that is called rate gyro [Fig. 9(c)]. This device can sense a vehicle's rotation speed around one axis. To sense the rotation around the three space directions, three orthogonal rate gyros are needed.

A rate gyro is a spring-restrained single degree of freedom gyro. The gyro's single frame can execute small rotations around its own axle, but this movement is restrained by restitution springs, which impart a restitution torque proportional to the inclination of the frame about its axle. Generally, this movement is also slowed down by mechanical or electric dampers connected to the frame. The entire apparatus is fixed to its case and to the vehicle. If the vehicle turns in a plane parallel to the frame plane, the whole set is forced to turn with it.

Consider a moving referential xyz fixed to the gyroscope, with the xx axis aligned with the wheel's spinning axle, and the xOy plane coincident with the gimbal. Then the frame can oscillate about the yy axis, and the device will be able to detect the vehicle's motion about the zz axis.

In this moving referential, the vector $\mathbf{H}$ can be expressed as $\mathbf{H} = H \cdot \hat{\mathbf{u}}_x$ where H is its magnitude and $\hat{\mathbf{u}}_x$ is the unitary vector along the xx axis. Then Newton's law can be written as

$$\mathbf{T} = \frac{d\mathbf{H}}{dt} = \frac{dH}{dt} \cdot \hat{\mathbf{u}}_x + H \cdot \frac{d\hat{\mathbf{u}}_x}{dt} = \Theta \left(\frac{d\Omega}{dt} \cdot \hat{\mathbf{u}}_x + \Omega \cdot \frac{d\hat{\mathbf{u}}_x}{dt} \right)$$

The first parcel in the right-hand side of the equation represents a variation of the magnitude of the wheel's spinning speed Ω caused by any possible accelerating or braking component of the torque along the xx axis. If the torque is perpendicular to the spinning axle, however, then the speed will be kept constant in magnitude, $d\Omega/dt = 0$, but the spinning axis will deflect in the direction of the torque. It is equivalent to saying that the direction ϕ of its axis $\hat{\mathbf{u}}_x$ will be rotated toward the yy axis with angular speed $\omega = d\phi/dt$, resulting in

$$\frac{d\hat{\mathbf{u}}_x}{dt} = \frac{d\phi}{dt} \hat{\mathbf{u}}_y = \omega (\hat{\mathbf{u}}_z \times \hat{\mathbf{u}}_x)$$

Substituting this relation in the former expressions and using the axial vector $\omega = \omega \cdot \hat{\mathbf{u}}_z$ to represent the angular turning speed of the entire frame (and of the vehicle) around the zz axis, it follows from Newton's law that $\mathbf{T} = \omega \times \mathbf{H}$.

The final conclusion is that, by keeping the wheel's spinning speed constant, the angular motion of the vehicle about the zz axis (called the rate input axis) causes the frame to move about the yy axis (called the output axis), under the influence of a torque proportional to the turning rate. The frame inclination about the output axis reaches an angular value α at which the restitution torque from the restraining springs, $T_r = K\alpha$, balances the gyroscopic torque, which is $T_g = H\omega$ (assuming that the turning rate and the angular momentum are kept perpendicular). A pointer fixed to the frame shows, on a scale fixed to the case, this angle α , which measures the turning rate ω about the input axis. At equilibrium $\alpha = S\omega$, where $S = H/K$, the device static sensitivity has the dimensions of time and is measured in seconds.

Note that these results are true only if the angle α is kept small enough to allow to consider approximately $\sin(\pi/2 - \alpha) = 1$. As the gyroscopic torque results from a vectorial product, its magnitude is indeed $T_g = H\omega \sin(\pi/2 - \alpha)$, which only can be

taken as $T_g = H\omega$ for a small inclination α . Using the approximation $\sin(\pi/2 - \alpha) = 1$ introduces a relative error ϵ , which is $\epsilon < 1\%$ if $\alpha < 8^\circ$, and $\epsilon < 1.5\%$ if $\alpha < 10^\circ$ in the expressions deduced.

Note also that if the gyroscope's frame is allowed to rotate unrestrained until the angle α reaches 90° , a singular situation is reached: The input axis and the spinning axis coincide at that point, the angle between them becomes null, and, therefore, the torque becomes $\mathbf{T} = \omega \times \mathbf{H} = 0$. Without torque, this situation will not be further modified, and all the orientation information will be lost. This situation is referred to as "the gimbals lock."

Instead of a pointer, a potentiometric position sensor may give an electric signal that measures the frame's deflection. Alternatively, the restitution springs may be replaced by restitution electric motors, usually called torquers, controlled by a feedback system that maintains the frame in its original position. These motors must generate a torque with the same magnitude as the gyroscopic torque, for which they require a proportional feeding current. Therefore, this current is the measure of the turning rate. The use of these motors has the advantage of measuring the torque without requiring a real displacement α , thus allowing the orthogonality between the input and the spinning axis to be maintained. Otherwise, the restraining springs require the displacement to generate the torque.

The operation of the device intrinsically involves a rotation movement of the frame about the output axis. Therefore, its dynamic motion is determined by the equilibrium of the acting gyroscope torque $T_g = H\omega$, the resisting spring torque $T_r = K\alpha$, the friction torque opposing the movement $T_f = D(d\alpha/dt)$, and the inertia torque $T_i = \Theta_y(d^2\alpha/dt^2)$, where D is the dumping coefficient and Θ_y is the moment of inertia of the whole set about the yy (output) axis. This leads to a second-order differential equation, the solution of which shows the possible existence of oscillations with a natural frequency $\omega_{a0} = (K/\Theta_y)^{1/2}$ and a dumping degree $\beta = D/(2(K\Theta_y)^{1/2})$. As is customary in moving measurement apparatus, the dumping degree is usually chosen to be $\beta = 0.707$, and D is computed to achieve this goal.

The preceding expressions show that a high sensitivity $S = H/K$ is obtained using a spinning wheel of high angular momentum, which must be achieved by spinning it at as high speed as possible. Reducing the spring constant K will also increase the sensitivity, but this will also reduce the resonance frequency $\omega_{a0} = (K/\Theta_y)^{1/2}$.

To obtain high angular momentum, the wheel must have a high momentum of inertia and a high spinning speed, but these goals must be traded off against excessive device mass and size, as well as the spinning motor power required. The momentum of inertia may be increased by the use of wheels provided with a thick rim around them. The wheel may be driven by a variety of motors. It can be connected to a turbine moved by a jet of compressed air or by combustion exhaust gases. In short-life gyros used in rockets, the hot gas jet may be produced by a pyrotechnic charge. The most common solution is an electric drive, ac as well dc motors being used. In some devices, the spinning wheel is the rotor of an induction motor.

The typical spinning speed for the inertia wheel is on the order of tens of thousands rpm. Rate gyros have typical rate resolution of 0.01° per second and range up to 2000° per second. Their natural frequency is on the order of some units to a few tens of hertz.

Rate-Integrating Gyros. The measurement of a vehicle's attitude can be made with a pair of double degree of freedom gyroscopes. However, spurious torques cause unwanted movements of precession and mutation of these gyroscopes, diminishing their accuracy. Therefore, it is usual to compute the attitude as a time integral of the turning rates about the three space axes.

This integration can be made electronically and is generally so done when the sensors are part of a wider measurement or control system. Sometimes, especially if only a visual indication is needed, a rate-integrating gyro is used. This rate-integrating gyro has the same structure as the rate gyro just described, except for the fact that it has no restraining springs. Instead, the dumping coefficient D of the frame rotation is increased. This increased dumping can be achieved electrically or mechanically (for instance, by making the frame rotation drive a paddle wheel rotating inside a viscous liquid).

Therefore, the acting torque developed has the same expression as in the former gyro, $T_g = H\omega$. But in the equation of its dynamic motion, $T_g = T_r + T_f + T_i$, the restraining-spring torque T_r is null, leaving $H\omega = D(d\alpha/dt) + \Theta_y(d^2\alpha/dt^2)$. In equilibrium, the acceleration $d^2\alpha/dt^2$ will be null, leaving the frame rotating at the speed $d\alpha/dt = (H/D)\omega$, proportional to the vehicle's turning rate. Except for initial values that can be zeroed at the beginning of the operation, the integrals of both rotating speeds will also be proportional. Therefore, the vehicle's attitude angle ϕ and the frame position angle α will keep the relation $\alpha = (H/D)\phi$. The constant (H/D) is the sensitivity of the rate-integrating gyro and increases with the inertia wheel's speed. The differential equation is of the first order, which means the device has no oscillations but has a time constant $\tau = \Theta_y/D$.

Vibration Gyros

These devices make use of pendulums, instead of rotating wheels, to conserve momentum. A pendulum without a transversal torque applied will conserve its plane of oscillation in a inertial reference frame—in the same way that a spinning wheel conserves the direction of its axis. If the plane of oscillation is forced to rotate about an axis coincident with the pendulum's equilibrium position, then a torque will result, which tends to bend the pendulum. Instead of free pendulums, vibrating cantilever beams are used. The rotation rate of the vibration plane causes bending of the beams. This generates a strain that can be measured and that is proportional to the turning rate and to the frequency of vibration.

This principle allows for the construction of very small and accurate vibrating gyroscopes. The cantilever beams used are bars a few centimeters or millimeters long. They have a piezoelectric material incorporated that, being fed by an electric power source, drives the vibration at a frequency on the order of tens of kilohertz. Other piezoelectric pieces are fixed to the other faces of the vibrating bar and act as strain gages to sense the transversal strain. Generally, these sensors are fixed to opposite faces of the beam and are connected in a bridge configuration for higher sensitivity to changes of strain and noise cancellation.

This technology allows for the production of very small and lightweight devices, with size on the order of $2\text{ cm} \times 3\text{ cm} \times 6\text{ cm}$ and weight about 40 g, including the necessary circuitry. Their maximum input is about 90 degrees per second, their output is on the order of $20\text{ mV/degree}\cdot\text{s}^{-1}$, and their linearity is on the order of 0.1% of the range.

Gas-Jet Rate Transducers

Gas-jet nongyro rate transducers are inertial devices, but instead of conserving the angular momentum as the gyros and vibrating beams do, they are based on the conservation of linear momentum: A particle thrown in free space will travel along a straight line. The particles they use are the molecules of a stream of gas, usually helium, which is blown through the top of a cylindrical metallic box by a nozzle that forms a laminar flow beam. The gas beam travels in a straight line to the opposite side of the cylinder, where it reaches an exhaust hole to which it is pumped and recirculated. The nozzle format and the pumping are crucial, as the travel time of the gas along the cylinder must be kept constant. Generally, the pump is a vibrating circular crystal driven by an external oscillator.

If the box is made to rotate about an axis perpendicular to the gas beam, the beam will no longer reach the same point of the opposite face. The gas will travel in a straight line with reference to an inertial frame but, as it travels, the target point will move in the sense of the angular rotation. Seen in the box referential, the gas beam seems to have been deflected in the lagging direction of the rotation. As the traveling velocity of the gas is kept constant, the lag of the beam is proportional to the speed of the rotation.

To sense the lagging of the beam, two equal and parallel wires are positioned, one at each side of the beam and equidistant to the equilibrium position of the beam. Both wires have equal currents, so they reach the same temperature. They are connected in a bridge configuration, so their voltages balance each other.

When the set is rotating, the gas blows preferably over the lagging wire than over the leading wire. Therefore, the lagging wire cools and its resistance decreases, while the leading wire heats up and its resistance increases. This unbalances the bridge and causes a voltage output that is a linear measure of the magnitude and direction of the turning rate.

These devices have no moving parts, so they are very rugged and have long operating lives. They are closed systems, having only electric contact with the outside world, and thus are adequate for operating in unfriendly environments, such as under water, in outer space, or in aggressive atmospheres. A variety of models and sizes are available, and small devices can be found. The cylinder can be a few centimeters in diameter, though its length is generally a little longer, and it can be as light as 60 g. A typical range is 10° to 5000° per second, with an output of about $0.01\text{ mV/degrees}\cdot\text{s}^{-1}$ to $0.5\text{ mV/degree}\cdot\text{s}^{-1}$, and linearity of 1% full scale.

Optical Gyros

The principle of operation of optical gyros is the intrinsic modification of some characteristics of light due to the motion of the medium in which the light travels (Sagnac effect). This modification is sensed through the observation of light interference patterns.

When a surface is illuminated by monochromatic light coming from a small light source, the distance the light must travel from the source to each point on the surface is point dependent. Therefore, the light reaches different points with different delays. Because the light is a sinusoidal oscillation of the electromagnetic field, the different delays cause the sinusoids to have different phases at the different surface points. If there is a second light source of the same wavelength illuminating the

same surface, the second light beam will also reach different surface points with different phases. At the points on the surface where the two impinging beams are in phase, the beams interfere constructively, their fields are added, and the illumination of those points is increased. At the points where the two beams are in opposition, the beams interfere destructively, their fields are subtracted, and the illumination of those points decreases. If both the frequency and phase difference of the two beam sources are constant, the zones of constructive and destructive interference stand still, and a stationary pattern of dark and bright fringes becomes visible.

If the phase of one of the sources is shifted relative to the other, the correspondent wave will strike each surface point with the same phase shift. Therefore (assuming that the shift was not an integer of 2π), at the points where the two light beams were in phase, they will cease so being and no longer interfere constructively. However, the two beams will meet together in phase at new points on the surface. As a consequence, the interference fringes move about the illuminated surface, their spatial shift being proportional to the phase shift that occurred at the light source. The measurement of these interference fringes' shift is at the heart of optical gyros, because the shift is due to the motion of the optical devices relative to an inertial reference frame, as shown next.

A beam of light will take a time $t = L/c$ to travel along a path of length L , where c is the speed of light in the propagation medium. If the medium itself is moving with velocity v in the same direction as the light is, then the end of the path will have traveled the displacement $dL = vt = Lv/c$ by the time the light reaches it. This is an extra length that the light must travel, and therefore the total length traveled by the light is $L_1 = L(1 + v/c)$. In an analogous way, if the light travels in a direction opposite to the movement of the medium, the total length is now $L_2 = L(1 - v/c)$. Two beams traveling in opposite direction will go through different distances, the difference being $\Delta L = L_1 - L_2 = 2Lv/c$. If the path is circular with radius r , then $L = 2\pi r$. And if the path is rotating about its center, in a fixed plane, with angular speed Ω , then $v = \Omega r$, and therefore $\Delta L = 4\pi r^2 \Omega / c = 4A\Omega / c$, where A is the area enclosed by the path. Although the preceding equation was derived for a circular path, it can be shown that the final result holds for any planar closed path. The difference ΔL can now be used in different ways to measure the motion of a body by exploring interference phenomena, originating the laser ring gyros (LRGs) and the fiber-optical gyros (FOGs).

Laser Ring Gyros. Laser ring gyros are usually used as attitude sensors. In the case of motion on a single plane, they measure the angle between an initial direction that is taken as a reference and the current direction of the main body axis of the moving vehicle or platform. At a particular instant, this angle is proportional to the number of wandering interference fringes that will have already passed in front of an optical detector, as described next.

In laser gyros, the light source is a gas laser tube, the most usual choice being an He-Ne gas laser. The tube emits in both directions and is inserted in a closed optical path. The path is a closed polygon, usually a triangle, made of ceramic glass. Mirrors at the corners of the triangle reflect the light around the corners. One of the mirrors is a partially transmitting mirror. The light coming from one direction of the path goes partially through this mirror directly into an optical interference

sensor. Light coming from the other direction crosses partially the mirror, is reflected back by a prism, and impinges on the same optical sensor.

The whole optical path works as a resonant cavity, tuned in such a way that two laser beams are established, both having a wavelength λ that is an integer submultiple of the length L of the path. The two beams travel in opposite directions.

When the whole path rotates, the beams travel different distances and therefore each beam is tuned to a different wavelength. The difference of the two wavelengths is proportional to the difference in the distance traveled: $\Delta\lambda/\lambda = \Delta L/L = 4A\Omega/(cL)$. Because $\lambda = cf$, it follows from the preceding expressions that $\Delta f/f = -\Delta\lambda/\lambda$, where f is the frequency of the light. Therefore, the rotation of the laser ring makes the two beams acquire a frequency shift $\Delta f = -4A\Omega/(\lambda L)$.

This frequency shift is very small, as the preceding equations show: In devices about 10 cm across, movements of one rotation per second result in $\Delta f/f \sim 10^{-9}$. With such a small frequency difference, for practical purposes the two beams may be viewed as having the same frequency but a nonconstant phase difference. Thus, they behave as if one of them is lagging the other by an uniformly growing phase difference $\Delta\phi = 2\pi\Delta f t$. The speed at which the phase lag increases is $2\pi\Delta f$.

The interference of the two beams at the receiving surface will show a fringe pattern that will be shifted by a distance proportional to the phase lag. Therefore, as the phase lag uniformly increases, the pattern will wander over the receiving surface. The wandering velocity of the fringes over the surface is proportional to the rate of the phase difference. Over a particular point, a new fringe passes each time the phase difference $\Delta\phi$ increases by 2π . Therefore, the fringe rate, expressed in the number of fringes over a point per unit time n_f/s , equals Δf . The final result is that the wandering rate of the fringes is proportional to the rotation speed of the optical laser gyro with respect to an inertial frame; that is,

$$\frac{n_f}{s} = \frac{4A}{\lambda L} \Omega$$

The interference sensing device consists of an optical sensor, typically a photodiode, that senses the bright fringes and generates an electric pulse for each fringe that passes over it. The wandering rate of the fringes can be measured by counting the number of pulses per unit time, and this provides a measure of the angular speed of rotation. However, the most usual utilization of laser ring gyros is for measuring angular position, not angular speed. Since the angular position α is the time integral of the rotation speed, α can be determined from the number N of fringes that have passed over the diode since the beginning of operation. Thus, by simply maintaining a permanent account of the fringes that have passed, the angular position is measured. A double photodiode is needed, with both detectors mounted in quadrature, to sense the wandering direction of the fringes and therefore properly increment or decrement the counter.

From the preceding equations, it can be seen that $\alpha = N(L\lambda/4A)$. The factor $S = L\lambda/4A$ is called the nominal scale factor of the ring laser gyro. For an He-Ne laser ($\lambda = 633$ nm) and a triangular ring of 10 cm side length, $S = 1.1 \times 10^{-5}$ rad/pulse, or $S = 2.3(\text{arcsec})/\text{pulse}$.

Laser ring gyros are very sensitive devices; they are small and light. They have a fast warm-up and rapid response, and they are insensitive to linear motion. They also are free from

multiaxis cross-coupling errors. Their price is decreasing and is competitive with the price of other types of gyros. Therefore, laser ring gyros tend to replace other inertial attitude sensors in air- and spacecrafts.

Rate Fiber-Optic Gyros. Fiber-optic gyros are commonly used as rate gyros; the phase difference between two light beams provides a measurement of the turning angular velocity of a platform (this is the principle of the interference fiber-optic gyros, or IFOGs). However, the phase measurement cannot be simply executed by the procedure of counting interference fringes, as will be explained next. The new measurement procedures can lead to resonant and Brillouin fiber-optic gyros.

Fiber gyros are a variant of the Sagnac ring interferometer. A light beam from a laser source is divided in two beams by a beam splitter. The two new beams enter in opposite extremes of an almost closed path (in former Sagnac rings, a polygon with mirrors on the corners was used), travel in opposite directions around the path, and come back to the beam splitter. The splitter combines the two arriving beams and projects them on the screen of an interferometer, where the beams interfere, creating an interference fringe pattern.

The two beams travel equal distances, so they are in phase when they interfere. If the closed path rotates on its plane, one beam travels a longer distance than the other, and therefore its phase on arrival will lag the other beam's phase.

Notice that the two beams result from the splitting of an already existing beam generated by a single laser source. Therefore, contrary to what happens with the laser ring gyro, traveling different distances causes no frequency shift between the two beams, but only a phase shift. The shift between the beams' phases causes a stationary shift of the position of the interference fringes on the plane of the screen (and not the permanent wander of the fringes, as is the case for the ring laser's frequency shift).

As seen before, the difference of the paths' length is $\Delta L = 4A\Omega/c$, where A is the area enclosed by the closed path. With the same wavelength for the two beams, this difference in distance corresponds to a difference of phase $\Delta\phi = 2\pi\Delta L/\lambda = (8\pi A/c\lambda)\Omega$. As a result, the phase shift is proportional to the rotating rate of the gyro, Ω . However, for small devices with about 10 cm across, the proportionality constant is very small, on the order of 10^{-4} rad/rad·s $^{-1}$, causing the phase shift $\Delta\phi$ to be very small when the rotation rate Ω is kept moderate.

One way of increasing the sensitivity is to increase dramatically the length L of the path, or the area A it encloses, but without increasing the size of the device. To achieve this purpose, the path is made with an optical fiber wound as a coil of several turns. Modern silicon fibers present an attenuation on the order of 0.2 dB/km, at a wavelength of 1550 nm. Therefore, several hundreds or even thousands of meters of optical fiber can be used, almost without attenuation. The fiber is wound a number N_t of turns, and the total area enclosed to be considered in the equations is now $A' = N_t A$, where A is the area of the surface physically occupied by the device, which remains on the order of 10 cm or 20 cm in diameter. However, noise and other sources of signal perturbation increase with the length of the fiber. Even when special techniques are used to minimize these effects, they end up putting a limit on the maximum length of the fiber.

The rotating rate Ω cannot be measured by counting the number of fringes that shift in front of a photodiode, as was

done in the case of the laser ring. Indeed, the distance of two consecutive fringes on the screen corresponds to a phase shift of $\Delta\phi = 2\pi$. For example, considering a one-coil path with a diameter of 10 cm and a wavelength $\lambda = 1550$ nm, that phase shift corresponds to the astounding turning rate of 15000 rad/s per fringe. Therefore, it is necessary to measure phase shifts much smaller than 2π by any method other than a simple digital count of the fringes.

In the fringe pattern, the light intensity does not vary abruptly between the bright and dark fringes. Instead, the light intensity has a sinusoidal variation between the fringes. Sensing both the illumination intensity and its gradient around a point is a way of detecting the position of that point with respect to the fringe pattern and therefore computing the phase shift. Many processes of detecting and measuring very small phase shifts, on the order of 10^{-7} rad, have been developed and implemented, some of them using sophisticated modulation techniques. Some of these modulation techniques rely on using some external physical action to modify the fiber's light propagation characteristics in a manner that these characteristics become direction dependent. Being nonreciprocal (direction sensitive), this additional action increases the difference in the behavior of the two beams, hence facilitating the measurement of the length variation ΔL .

One of the techniques consists of having two rings optically coupled so as to form a multipass optical resonator. One of the rings is a small rotating ring of fiber (only about 10 m long) that acts as rotation sensing coil. The Sagnac effect changes the frequency of resonance by an amount Δf proportional to the rotation rate Ω , and the frequency shift is measured (the equation for Δf is the same that was determined for the laser ring gyro). These devices are called resonance fiber-optic gyros (R-FOGs).

Another technique is based on the fact that mechanical vibrations (acoustic waves) can interact with light waves, causing a frequency shift of the light (Brillouin effect). This effect is induced in such a way that the two beams are affected differently. The result is that the two beams acquire different frequencies, behaving in a way similar to the laser ring gyros, although the physical mechanism is different. Devices based on this technique are called Brillouin fiber-optic gyros (B-FOGs).

Using fibers up to a thousand meters, and accurate interferometer methods of reading phase shifts, a sensitivity of up to the order of 10^{-2} degrees per hour is reached for I-FOGs, which is adequate for inertial navigation systems for aircraft. This kind of gyro is currently in use in commercial airplanes. R-FOGs and B-FOGs can have a sensitivity on two or three orders of magnitude higher.

FIBER-OPTIC SENSORS

Numerous parameters of light guided by optical fibers or transmitted by optical devices may depend strongly on the external environment. In some applications, this dependence is not welcome, as with fiber-optic telecommunications systems, where, for instance, attention is typically directed to avoiding bend- or stress-induced attenuation in optical cables. In other applications, however, this process may purposely be amplified, usually to make a specific light parameter selectively sensitive to a chosen environmental measurand. When optical fibers are used either to transmit the modulated light signals or to modulate some parameters of these signals directly via a specific physical phenomenon, the process is known as *fiber-optic sensing* (FOS) and the corresponding devices are known as *fiber-optic sensors*.

The need for fiber-optic sensors in the broad area of engineering is now widely accepted, especially in those applications where the benefits offered by this still novel technology are already more significant to the users than the higher costs of fiber-optic instrumentation in comparison with other sensor systems. One such application area is monitoring of civil engineering structures, including highway and railway bridges, dams, tunnels, large buildings, and underground mines. Such structures must resist environmental and in-service loads due to winds, earthquakes, traffic, thermal effects, construction, or environmental damage. For safety and maintenance their response must be carefully monitored. This information is needed to assess their overall "health" and to increase engineering knowledge for future projects. Pressure and strain gauges, stress cells, extensometers, accelerometers, and tiltmeters are among the variety of electrical and nonelectrical transducers that can be directly embedded in concrete, earth, rock, bore-hole or tunnel lining to sense and monitor structural loads and responses. None are well suited, however, to more demand-

ing environments. Nonelectrical hydraulic devices are costly in labor-intensive inspection, maintenance, and repairs; they are difficult to multiplex and impossible to use for dynamic measurements. Electrical measuring devices are out of the question in open-air structures (risk of lightning) and in mining environments (risk of explosion). For these and similar applications, fiber-optic sensor technology offers strong potential for significant metrological improvement: electrical passivity, high bandwidth, safety in corrosive or explosive environments, immunity to electromagnetic interference, high sensitivity, miniature dimensions, possibility of remote operation, and direct compatibility with increasingly common fiber-optic data transmission and communication networks.

BASIC PRINCIPLES

A fiber-optic sensor is a device capable of converting a given, variable physical quantity into a modulated optical signal and then decoding it as a normalized electrical signal. For measurement purposes, this output signal is usually calibrated against a primary standard of the physical quantity of interest. The sensor then becomes a true secondary measuring instrument of this quantity. Figure 1 shows a schematic view of a basic fiber-optic sensor, where the sensing element S can be an optical fiber or another external optical element.

Definition

The sensing element S of the optical fiber sensor shown in Fig. 1 can best be formally described by the propagation matrix $M(\mathbf{V}, \lambda)$ which normally depends on the physical environment represented by the vector $\mathbf{V}$ (depending on every imaginable external parameter) and on the spectral properties of the transmission medium (λ is the wavelength of propagating light beam). We may then describe the action of the sensor using the following equation:

$$\mathbf{E}^M(\lambda) = M(\mathbf{V}, \lambda)\mathbf{E}(\lambda) \quad (1)$$

where $\mathbf{E}(\lambda)$ is the wavelength-dependent input electrical field entering the sensor, and $\mathbf{E}^M(\lambda)$ is the measurand-modulated output electrical field exiting the sensor. By applying appropriate optical and electronic signal processing we can then recover M , $\mathbf{V}$, and finally those components of $\mathbf{V}$ that depend on the specific quantity we intend to measure. It is worth noting that $M(\mathbf{V}, \lambda)$ can conveniently be represented by a product of three separate factors as

$$M(\mathbf{V}, \lambda) = T \exp(i\phi_m) B \quad (2)$$

Each of the three factors on the right side of the above equation is both environmentally sensitive and dispersive (dependent on the wavelength of transmitted light). The first factor, T , is the scalar transmittance, the parameter ϕ_m is the mean phase

Figure 1. Basic configuration of a fiber-optic sensor; S denotes a sensing element.

retardance, and finally B is the birefringence matrix characterizing the sensing element.

Classification

One of the most straightforward classifications of fiber-optic sensors can be derived directly from Eq. (2): *intensity sensors* are those where the measurand-modulated parameter is the scalar transmittance T , and consequently the intensity of transmitted light; *interferometric sensors* are those based on phase modulation; and, finally, *polarimetric sensors* are devices based on birefringence modulation. Both phase and birefringence effects may be recovered using interferometry or polarimetry, depending on specific application. This of course is a somewhat simplified approach; in reality all those parameters may be simultaneously affected, but one type of modulation usually predominates.

Fiber-optic sensors are often classified according to the nature of the sensing element: in *intrinsic* sensors, this element is an optical fiber, and the light is never permitted to exit the fiber into free space; in *extrinsic* sensors, it is a completely different optical part, and consequently in these hybrid structures the fibers are used exclusively for light-guiding purposes. In addition to standard sensors designed to measure a given parameter in one particular location only, we often mention *multipoint* or *multiplexed sensors*, which make it possible to take measurements in several different locations. Finally, it is worth noting that no other classical sensor systems have the same capability as fiber-optic systems to serve as truly *distributed sensors* and to enable the simultaneous detection not only of the magnitude of the modulating factor but also of the precise location of its occurrence and even of its spatial distribution.

Depending on the type of propagation occurring in the optical fibers, it is customary to differentiate between *single-mode* and *multimode sensors*. Depending on the degree of temporal coherence of the light sources involved, we can categorize sensors as *high-coherence*, *low-coherence*, or *incoherent*. In the rest of the paper, we will rely primarily on the notions introduced above, although many other less important approaches to classifying fiber-optic sensors, such as those based on the particular technology or on the application area, can be found in Ref. 1.

FIBER-OPTIC SENSOR COMPONENTS

Many FOS systems are based on standard commercially available components developed primarily for applications in optical fiber telecommunications. However, specifically designed and/or modified optical and fiber elements are also in use, since they can significantly improve the sensitivity and selectivity of

the sensor and the stability of the system. Some examples of the components most often used in optical fiber sensing systems are described below.

Optical Fibers

Different types of FOS require different optical fibers for the transmitting, sensing, and receiving waveguides of the measuring system. For *extrinsic intensity* FOS, standard cylindrical fibers are normally used. The light signal can be intensity-enhanced when large-core multimode fibers or fiber bundles are applied for light-guiding purposes. A similar situation occurs with the fibers used to lead in and lead out the light in *intrinsic intensity* sensors. Specially prepared optical fibers such as doped fibers; hollow-core fibers filled with metal, liquid, gas or liquid crystals; and fibers with partially removed cladding or D-shaped cladding are often used as sensing elements. Since the lasing properties of erbium-doped fibers depend on various external parameters (such as temperature, stress, pressure, etc.), these fibers also can be used as sensing parts of the FOS despite the fact that they were developed originally for applications in optical fiber lasers and amplifiers.

For *polarimetric* and *interferometric* FOS, the methods of signal detection usually require a well-defined state and degree of polarization of the guided light. Therefore, optical fibers designed for these applications should have well-defined birefringence. In ideal cylindrical fibers [using the description of linearly polarized (LP) modes], the fundamental LP_{01} optical mode contains two degenerated orthogonally polarized modes propagating at the same phase velocity. In real fibers, both these modes have randomly different phase velocities, causing fluctuations of the polarization state of the light guided in the fiber. In highly birefringent (HB) fibers (2), the phase velocities for the two orthogonal light polarizations are high enough to avoid coupling between these two modes. Hence, if only one mode is excited, then the polarization of light guided in the fiber is preserved. On the other hand, if both modes in highly birefringent fibers are excited, then the polarization state of the light varies along the propagation distance. The state of the polarization depends on the phase difference $\Delta\phi$ between the two orthogonal linearly polarized modes. Since both these modes "see" the different refractive indices n_x and n_y , the phase difference between them changes at the distance z according to the formula

$$\Delta\phi = \frac{2\pi}{\lambda} \Delta n \cdot z \quad (3)$$

where $\Delta n = n_y - n_x$. Figure 2 shows the changes in the polarization states corresponding to the phase difference and to the propagation distance. These changes are periodical, with the

Figure 2. Evolution of the polarization states along the propagation axis in a HB fiber; input polarization is linear at 45° to the principal birefringence axes.

spatial period defined as the beat length L_B :

$$L_B = \frac{\lambda}{\Delta n} \quad (4)$$

The birefringence of the fiber expressed by Δn is strongly influenced by external forces, and consequently the state of the polarization at the output fiber also depends on the local birefringence changes. This transduction mechanism is utilized in *polarimetric* sensors and will be explained later. High birefringence in optical fibers can be obtained by designing a core and/or cladding with noncircular geometry, or by using optically anisotropic core or cladding material (with intrinsic or induced anisotropy). Several cross sections of typical highly birefringent optical fibers are presented in Fig. 3. While in standard optical fibers the average beat length varies from 0.1 m to 1 m, in highly birefringent fibers it is only a few millimeters. Table 1 shows typical beat lengths at wavelength $\lambda = 830$ nm for commercially available highly birefringent fibers.

Other types of specialty fiber are low-birefringence (LB) fibers with birefringence lower than in standard optical fibers, and circularly birefringent fibers. Both of these fiber types are applied in sensors for magnetic field or electrical current measurements, where the magnetic field modifies the circular birefringence (Faraday effect). Another specialty fiber, recently introduced to the market by 3M, is the so-called polarizing fiber, which at a specific wavelength has a significantly different attenuation for two orthogonally polarized modes. After nonpolarized light is launched into 2 m to 3 m of such fiber, only the light in the low-loss polarized mode is transmitted and the mode with orthogonal polarization is completely attenuated (an extinction ratio of 1:1000 can easily be obtained). This type of fiber is designed with an absorbing metal layer placed close to the fiber core, or as a bent birefringent fiber. The polarizing effect is observed in a specific wavelength region only. Typical spectral characteristics of the attenuation in polarizing fibers are presented in Fig. 4.

Optical Sources and Detectors

In almost every FOS application, semiconductor devices are used as sources and detectors. Other sources and detectors are

Table 1.

Fiber Type	Beat Length L_B (mm)	Birefringence Δn (10^{-3})
Andrew E-type	5.08	0.16
Andrew D-type	4.71	0.18
Corning	2.99	0.28
Fibercore bowtie	2.10	0.39

occasionally used in specialized FOS for which the required parameters of light are not yet available from semiconductor sources (as in the case of sensors measuring luminescence with short-wavelength light sources).

The chosen light source for a specific sensor configuration should have the required stable output power, as well as the required light wavelength and coherence, which is especially important for polarimetric and interferometric systems. The coherence of the light source is described by the spectral linewidth $\Delta\lambda$ or equivalently by the coherence length $L_c = \lambda^2/\Delta\lambda$. The coherence length L_c is the maximal difference of optical path length at which the light can interfere. When the light is divided into two different beams propagating in different fibers then these two beams can interfere according to the phase difference

$$\Delta\phi = \frac{2\pi}{\lambda}(n_1L_1 - n_2L_2) \quad (5)$$

where $L_{1(2)}$ is the length and $n_{1(2)}$ is the effective refractive index of the fibers. The interference can be observed only if the phase difference $\Delta\phi$ is smaller than the phase change at the coherence length:

$$\Delta\phi \frac{2\pi}{\lambda} L_c \quad (6)$$

Similarly, the state of polarization of the light propagating in a birefringent fiber can be defined only if the phase difference between the two orthogonal linearly polarized modes [Eq. (3)] meets the conditions of Eq. (6). Otherwise, the light exiting at the fiber end is depolarized and polarization-based signal processing is clearly not possible.

The coherence length for semiconductor sources varies from micrometers for light-emitting diodes (LEDs) to a few meters for single-mode diode lasers (LDs). The typical coherence of multimode LDs is a few millimeters, while superluminescent diodes (SLDs) have a coherence length of the order of a few tens of micrometers. High coherence is not always required for interferometric and polarimetric measuring systems. Low-coherence light sources are often intentionally used in certain interferometric FOS to reduce signal errors due to the presence of unwanted interference fringes (as in optical fiber gyroscopes). Also, in coherence multiplexing techniques the coherence

should be low enough to avoid interference between the different measuring points. Therefore SLDs or edge-emitting light-emitting diodes are typically used in these systems. Recently even erbium-doped fiber lasers (with high-power 980 nm or 1480 nm LD pumps) began finding application in this area due to the facility of their coupling with other fibers. They are used as superluminescent fiber sources in interferometric systems (3) or fiber-optic amplifiers in FOS networks (4).

The important requirements of optical detectors used in FOS are bandwidth, noise, and dynamic range. The bandwidth determines the detector response time, which can be very long for low-cost discrete sensors but for certain types of distributed sensors and for time-domain multiplexed sensor systems should be very short. Typically, single detectors such as *pin* photodiodes, avalanche photodiodes, and photoconductors are still often used, but fast charge-coupled detector (CCD) lines and matrices are seeing greater use due to their increasing availability. The spatial light distribution or changes in it registered by the CCDs can be directly decoded as a measured quantity or may be further processed in demultiplexing techniques for distributed FOS.

Optical Fiber Components

Such elements as beamsplitters, wavelength filters, wavelength analyzers, polarization controllers, polarizers, phase and intensity modulators, and amplifiers are frequently used in optical sensor systems for optical processing or delivering the light beam to a specific location. All these elements are increasingly manufactured in optical fiber technology (*all-fiber* components) rather than in bulk optics (5) in order to obtain more mechanical and thermal stability as well as to satisfy the typical requirement for low optical losses in sensing systems.

One of the most frequently used all-fiber components is the *directional coupler* (6), which plays the role of a wavelength-selective beamsplitter. A schematic drawing of the bidirectional coupler is presented in Fig. 5. The directional coupler consists of two optical fibers placed close enough to each other to allow tunneling of guided light between the two fiber cores. The input light intensity I_i is partially transferred to both outputs I_{o1} and I_{o2} . For two identical lossless fibers, the energy transfer between them is described by the formulas

$$\begin{aligned} I_{o1} &= I_i \cos^2 \kappa L \\ I_{o2} &= I_i \sin^2 \kappa L \end{aligned} \quad (7)$$

where L is the effective coupler length. For parallel fibers, L

Figure 5. Schematic view of a bidirectional fiber coupler and its cross-section. I_i is input light intensity, I_{o1} and I_{o2} are output light intensities.

Figure 6. Power transmission ratio for a bidirectional coupler as a function of its effective length at two different wavelengths of light.

is simply the length of the coupling region; for curved fibers with a bend radius R , it is given by $L = (\pi R/\gamma)^{1/2}$. The coupling coefficient κ is estimated in terms of coupled mode theory as an integral over the coupler cross section:

$$\kappa = \frac{\pi}{\lambda n} \int (n_c^2 - n_{cl}^2) e_1 e_2 dS \quad (8)$$

where n is the effective refractive index, $e_{1,2}$ are the normalized field envelopes of the guided modes in the fibers, and n_c and n_{cl} are the refractive indices of the fiber core and the surrounding cladding. In the simplest approximated form, coupling coefficient κ depends on the fiber's core separation distance h as follows:

$$\kappa = \frac{\lambda}{2\pi n} \frac{v^2 - \gamma^2}{a^2 - v^2} \frac{K_0(\gamma h)}{K_1^2(\gamma a)} \quad (9)$$

where $v = 2\pi(n_c^2 - n_{cl}^2)^{1/2}/\lambda$, $\gamma = 2\pi(n^2 - n_{cl}^2)^{1/2}/\lambda$, a is the fiber core radius, and K_0 and K_1 are modified Bessel functions. For large core separations $\gamma h \gg 1$, the coupling coefficient is proportional to $\pi/2\gamma h e^{-\gamma h}$.

Note that the energy transfer between the two fibers depends on the length of the directional coupler, on the distance between the fibers, and on the wavelength of the light. This fact allows for convenient design of a directional coupler with the required transmission at the given wavelength. Figure 6 shows that by choosing the effective length of the directional coupler it is possible to obtain almost any power transmission ratio for two different wavelengths. Therefore the directional coupler can play the role of a bidirectional beamsplitter, a wavelength filter, or a wavelength-division multiplexer/demultiplexer. Directional couplers are most often made by polishing the fibers close to the core, by thermal fusion of two fibers, or by chemical etching. Polarization-maintaining couplers using highly birefringent fibers are also manufactured for specific applications. Figure 7 shows three examples of coupler use in fiber-optic sensor systems.

Fiber polarization controllers are often needed in sensing systems dealing with polarized light. The polarization controller transforms any given state of polarization into another state that is required in the particular application. This can be done either by modifying the fiber birefringence or by changing the birefringence axis. The first method is applied in controllers based on electromagnetic squeezing of the fiber. The

Figure 7. Three examples of possible applications of fiber directional couplers (DC) in fiber-optic sensor systems: (a) as a beamsplitter, (b) as a wavelength multiplexer, (c) as a wavelength demultiplexer.

external stress induces proportional birefringence change in a fiber. Therefore the controlled squeezing produces a required value of birefringence in the fiber and consequently the required phase shift between two perpendicular polarizations. The state of polarization has two degrees of freedom, and therefore two such squeezers rotated in relation to one another at a 45° angle are required for polarization controller.

Another type of polarization controller is based on changes of the birefringence axis of two elements playing the roles of a $\lambda/4$ plate and a $\lambda/2$ plate (three $\lambda/4$ plates can also be used for this purpose). The $\lambda/4$ plate introduces a $\pi/2$ phase retardation between two orthogonally polarized waves, while the $\lambda/2$ plate introduces a π phase shift. In the simplest and the most commonly used configuration, both plates are designed as coiled fibers. In bent fibers, the stresses induce birefringence and selection of the appropriate radius of curvature can produce the required phase retardation. Both fiber coils can be rotated relative to the z axis. The desired state of polarization at the output is obtained by adjusting the angle between the coils. Optical polarizers rather than polarization controllers are required in systems with elements depending on the polarization state. In all-fiber systems, often the polarizing fibers play the role of such polarizers, the extinction ratio increasing with the fiber length. Fiber polarizers can also be manufactured as polished fibers with the metal layer attenuating one polarization.

Intensity modulators, phase modulators, and frequency shifters are fiber devices frequently used in sensor systems to improve the performance of their detecting systems. Fiber-optic phase modulators utilize the refractive index changes caused by stretching or squeezing the fiber, and polarization controllers based on electromagnetic squeezing can often be used for these purposes. Typically, the phase modulators are designed as devices using an optical fiber wrapped around a piezoelectric ring, which changes its dimensions, and consequently the fiber length, in response to externally applied voltage. The frequency shifters, on the other hand, are manufactured primarily in integrated optics technology. The integrated optical modulators most widely used are based on the electro-optical Pockels effect occurring in lithium niobate crystals in channel waveguides surrounded by electrical electrodes. The coupling between the integrated channel waveguide in lithium niobate and the external leading optical fibers is inevitably associated with additional losses in the optical system and constitutes an obvious drawback; an important advantage, however, of the integrated

optical chip is that numerous other elements such as integrated polarizers, directional couplers, or polarization controllers can be simultaneously designed and manufactured on the chip.

FIBER-OPTIC SENSORS: OVERVIEW

In this section we consider a representative sample of the most recent and successful embodiments of fiber-optic sensing devices. This overview, however, is by no means exhaustive; researchers worldwide have studied and explored a large number of sensing concepts during the last 15 years. Books such as Refs. 7 and 8 are suggested for anyone wishing to study this subject in more detail.

One focus of early fiber-optic sensor research was periodic measurands, but this work often ignored the issues of stability, repeatability, and temperature drifts and has not led to many practical installations. For this review, we have focused on practicability and on the potential for real implementations, which lead to an emphasis on absolute and quasistatic techniques. A significant majority of the conventional electrical and hydraulic measurement techniques that fiber-optic sensing technology is trying to outperform are in fact absolute and quasistatic, with countless applications including industrial process control as well as stress analysis in civil engineering and geotechnics.

Intensity Sensors

Fiber-optic sensors based on intensity modulation are the simplest sensors, but they are often very successful and cost-effective devices. They can be developed using any kind of optical fiber, and noncoherent sources and simple detector units are usually adequate as other components of these systems. Most research effort in the area of intensity sensors has focused on overcoming one major drawback: finding a reliable referencing technique to compensate for a variety of analog signal instabilities. These instabilities include intensity and wavelength fluctuations of the light source and uncontrolled changes in detector responsivity as well as environmentally sensitive losses in optical fibers, couplers, and connectors.

Loss-Based Fiber-Optic Sensors. In bent optical fibers, higher-order modes tend to leak to the cladding when the bending radius decreases. This effect can be purposely amplified by applying a periodic microbending structure on an optical fiber, with the degree of induced attenuation depending upon the action of the parameter to be measured. If the bending is periodic with the bend pitch p , that is

$$p = C\pi r n (NA)^{-1} \quad (10)$$

where NA is the numerical aperture of the fiber, n is the refraction index of the fiber core, r is the core radius, and C is an index profile factor, then (9) the resonance condition can be achieved when the attenuation is maximum. Figure 8 shows a typical structure of a microbending force sensor using multi-mode fiber: in such a device, an external perturbation increases the bending of the fiber and causes progressive coupling of light energy into the radiation modes leaking out of it.

Based on this principle, many practical embodiments of the microbending sensor have been studied and developed. A good and timely review by Berthold (10) gives a complete analysis of this technology. One successful microbending sensor developed

Figure 8. Basic microbending fiber-optic force sensor.

just recently (11) uses a multimode fiber as a sensing element and single-mode fiber as a lead-in. Such a configuration makes it possible to reduce noise significantly and to use more coherent sources; more importantly, it allows for a sixfold increase in sensitivity over microbending sensors built entirely of multimode fiber.

Like other intensity-based sensors, microbenders are sensitive to the optical power level in the system, and a large amount of research has been devoted to finding adequate referencing techniques to alleviate the problem. This has not been fully successful, since the possible origins of power fluctuations in the optical system are numerous and varied. Changes in output of the optical source, changes in transmission and bending loss along the fiber links, changes in coupling between optical connectors and other optical elements external to the sensor, and finally changes in the modal filtering properties of system components can all be responsible for these perturbations.

One successful self-referencing method, based on time-division normalization, was introduced by Spillman and Lord (12). The method is based on a 2×2 coupler and on introducing a specific time delay between the signals reflected back from the sensing and referencing arms and arriving back at the coupler. The ratio of the two signals is relatively independent of external perturbation sources, provided the time delay is short. Another similar method based on wavelength normalization utilizes a broadband source with two narrow spectral channels, dedicated to the reference and to the sensor signal, respectively (10).

The reported applications of microbending sensors include measurement of pressure (13,14) and temperature (15), as well as acceleration (16), strain (17), and speed (18). The main advantage of microbenders is their relatively high dynamic range of about 40 dB; the reported sensitivities go up to $10^{-10} \text{ m/Hz}^{1/2}$ (10).

Evanescent Sensors. An interesting, quite simple, and surprisingly effective group of sensors is based on the phenomenon of frustrated total internal reflection, where light energy is extracted from the propagating beam in the form of an evanescent wave. This extraction occurs in a predesigned location (a fiber element stripped of cladding or a separate optical element put in contact with a surrounding medium with a higher, or measurand-dependent, index of refraction).

Figure 9 shows a liquid-level sensor developed by Raatikainen et al. (19), where light delivered via a multimode input fiber undergoes two consecutive total internal reflections while passing through a sensing tip and then returns to the

Figure 9. Schematic view of a fiber-optic liquid-level sensor. The magnification shows the light path within the sensor tip.

detection electronics via a multimode output fiber. When the sensing tip hits a liquid, the conditions for total internal reflection no longer exist and the output signal is attenuated at the level of 10 dB due to the evanescence of higher-order modes.

A more advanced configuration of a digital level transducer has been recently developed by Betta et al. (20). It is based on an optical fiber extended over the whole depth of a tank, with the optical cladding removed in 40 zones 0.5 mm long and with 25 mm of spacing between them. Each time the liquid level reaches or leaves one of those zones, the change in output power and the direction of this change are registered, giving information sufficient to determine the absolute value of the liquid level. A prototype with 1 m range and 25 mm resolution was manufactured and tested. It displayed no hysteresis, good repeatability, and accuracy of 25 mm.

Absorption Sensors. It is well known that the energy band structure in some semiconductor materials, especially in gallium arsenide (GaAs), depends strongly on the parameters of the external environment. Several successful approaches to the design of fiber-optic temperature and pressure sensors (21) rely on this effect, and some of them have already been commercialized (22).

The working principle behind this type of sensor is the displacement of the wavelength transmission limit in a GaAs crystal induced by pressure and/or temperature change. Pure GaAs crystal is transparent to infrared radiation and opaque to visible light; the optical absorption edge at 300 K and atmospheric pressure is 867 nm. Assuming isotropic compressibility of the crystal, a pressure change at constant temperature causes a change in the bandgap described by the following coefficient:

$$\gamma_p = \frac{dE_g}{dp} = 11 \times 10^{-5} \text{ eV/MPa} \quad (11)$$

The energy bandgap in GaAs will broaden with pressure, contrary to the conventional wisdom that all materials should become "more metallic" under pressure. Broadening of the bandgap will result in a displacement of the optical absorption edge illustrated in Fig. 10 and following the equation

$$\frac{d\lambda}{dp} = -0.0667 \text{ nm/MPa} \quad (12)$$

Figure 10. Transmission curve of GaAs and its dependence on temperature and pressure. The emission spectrum of the light source (dashed line) has to be carefully chosen to assure proper sensor operation.

The negative value of $d\lambda/dp$ indicates that the band edge will move toward shorter wavelengths with increasing pressure. Similarly, the GaAs energy bandgap will narrow with increasing temperature with the coefficient

$$\gamma_T = \frac{dE_G}{dT} = -4 \times 10^{-4} \text{ eV/K} \quad (13)$$

which corresponds to a positive shift of the optical absorption edge at a rate of 0.28 nm/K.

The emission spectrum of the LED light source used with the sensor should overlap on both sides of the optical absorption edge. The displacement of this edge induced by temperature or by pressure changes modifies the fraction of light that falls into the absorption band, meaning that the transmitted intensity will change. A successful temperature sensor system based on this principle is presently manufactured by Nortech Fibronic Inc. (Canada) and allows a 32-channel measurement of temperature in range from -200° to 250°C . The maximum length of the optical cable between a sensing probe terminated with a semiconductor tip and the processing unit is 1 km (22).

Another configuration has been used to develop a pressure sensor based on the same principle (21), with special attention paid to compensation of the temperature artifact and to amplification of the pressure effects. If we assume that pressure and temperature effects on a sensor are factorizable, the output signal at a detector will be proportional to the intensity of the source multiplied by the factors related to temperature and pressure:

$$I(p, T) = I_0 f(T) g(p) \quad (14)$$

Figure 11 shows a two-source compensation setup of a GaAs pressure sensor developed using this assumption and following the suggestion by Culshaw et al. (23). Two separate light sources supply light signals modulated at different frequencies f_1 and f_2 . By using two reference arms in addition to two sensor arms, the influence of different individual detector responsivities is eliminated. It can be shown that the ratio of two signals registered at two detectors a and b is described by

$$\frac{I_a}{I_b} = g(p) \quad (15)$$

Figure 11. Compensation setup of a GaAs pressure sensor in two-source configuration.

and depends directly on the pressure factor, assuming the light entering the two fibers is of equal intensity, with other effects canceled out. This assumption of equal intensity is problematic due to the fluctuations in ambient temperature and due to laser mode hopping resulting in uncontrollable deviations of compensation; however, equal intensity can be achieved by separately adjusting the coupling of light into each of the fibers. The output signal of the thermally compensated pressure sensor (21) clearly illustrates the benefits of the presented configuration. Good compensation has been achieved, especially at the lower range of temperatures from 5° to 25°C : in the worst case, the temperature error was reduced by more than an order of magnitude to less than 0.15 MPa/K. Further improvement can be achieved by controlled doping of the semiconductor material and by digital processing of the temperature-calibrated sensor signal.

Polarimetric Sensors

Polarimetric sensors may function in a single-mode or in a few-mode regime of propagation. Depending on the selected regime of operation, the different propagation constants shown in Fig. 12 have to be considered in order to understand the

Figure 12. Propagation constants and mode patterns in HB bimodal fibers. Arrows indicate different possibilities of interference and show the corresponding phase shifts.

behavior of a specific sensor (24). Single-mode operation occurs when only one spatial mode LP_{01} or LP_{11} is excited at the fiber's input. No intermodal interference is observed in this case, as the second mode is absent.

Single-Mode Operation. If quasimonochromatic light linearly polarized at an angle ϕ with respect to the fiber's x axis is launched into the fiber and an analyzer turned to an angle α is placed at the output of the fiber, then the optical intensity detected will be

$$I = \frac{1}{2}(1 + \cos 2\alpha \cos 2\phi + |\gamma| \sin 2\alpha \sin 2\phi \cos \Phi_0) \quad (16)$$

where $\Phi_0 = \Delta\beta_{01} L$ is the phase. When external perturbations are introduced, they cause changes in the phase $\Phi_0 = \Delta\beta_{01} L$ of the fundamental LP_{01} mode (or correspondingly $\Phi_1 = \Delta\beta_{11} L$ for the LP_{11}). These will lead to a cosine variation of the observed intensity I measured after the analyzer, a variation that is in fact a polarization interference. The setup is then a *polarimetric sensor*. The interfering waves in this case are the LP_{01}^x and the LP_{01}^y polarization modes. With $|\gamma|$ we represent the correlation function between the polarization modes. This is a function of the product of the length L of the fiber, its polarization dispersion $\delta\tau$, and the spectral half-width $\delta\lambda$ of the source. The visibility V of the observed polarimetric response is

$$V = \frac{I_+ - I_-}{I_+ + I_-} = |\gamma| \frac{\sin 2\alpha \sin 2\phi}{1 + \cos 2\alpha \cos 2\phi} \quad (17)$$

An input polarizer (if the light is not linearly polarized) acts as a splitter, and the analyzer acts as a recombiner. If we define $k_1 = \sin^2 \phi$ and $k_2 = \sin^2 \alpha$ as the power coupling coefficients of the splitter and the recombiner, then the expression for visibility becomes

$$V = |\gamma| \frac{4\sqrt{k_1 k_2 (1 - k_1)(1 - k_2)}}{1 + (1 - 2k_1^2)(1 - 2k_2^2)} \quad (18)$$

This expression is analogous to the well-known formula for visibility in classical two-beam interferometry (8). So maximum visibility is obtained if $k_1 = k_2 = 0.5$, that is, for $\phi = \alpha = 45^\circ$. In other words, maximum visibility occurs when the LP_{01}^x and LP_{01}^y polarization modes are equally excited by launching $\pm 45^\circ$ linearly polarized light. In this case, the observed intensity and the visibility become

$$I = \frac{1}{2}(1 + |\gamma| \cos \Phi_0) \quad \text{with} \quad V = |\gamma| \quad (19)$$

Evidently, if a monochromatic source is used, $\delta\lambda = 0$ and then the visibility will be $|\gamma| = 1$.

Two-Mode Operation. For a two-mode regime of operation, a bimodal sensing fiber must be used and the interference between either x - or y -polarized LP_{01} and LP_{11} spatial modes is observed. By letting $\Phi_x = \Delta\beta_x L$ and $\Phi_y = \Delta\beta_y L$, the intensity observed at the output of the fiber excited with x - or y -polarized quasimonochromatic light can be obtained (25) as

$$\begin{aligned} I_x(x, y, z) &= \eta_0 f_0^2(x, y) + \eta_1 f_1^2(x, y) + 2\eta_{01} f_0(x, y) f_1(x, y) \cos \Phi_x \\ I_y(x, y, z) &= \eta_0 f_0^2(x, y) + \eta_1 f_1^2(x, y) + 2\eta_{01} f_0(x, y) f_1(x, y) \cos \Phi_y \end{aligned} \quad (20)$$

In the equations above, η_0 and η_1 are the relative optical powers carried by the spatial modes. Depending on the detection setup, different expressions for the visibility can be obtained. Assuming the Gaussian approximation (26), the distributions of the two modes are expressed as

$$\begin{aligned} f_0(x, y) &= \frac{1}{\sqrt{\pi \omega_x \omega_y}} F(x, y), \quad f_1(x, y) = \sqrt{\frac{2}{\pi \omega_x \omega_y}} \frac{x}{\omega_x} F(x, y) \\ F(x, y) &= \exp \left[-\frac{1}{2} \left(\frac{x^2}{\omega_x^2} + \frac{y^2}{\omega_y^2} \right) \right] \end{aligned} \quad (21)$$

The following three important subcases can readily be outlined: visibility at a point (pixel), visibility when half the pattern is detected, and visibility when an offset single-mode fiber is used. The visibility is then presented in the form $V(z, \eta_1) = |\Gamma_{x,y}| V_0$, where V_0 is a factor depending on the relative excitation coefficient of the second mode as well as on the detection scheme while $|\Gamma_{x,y}|$ are the correlation functions between the two interfering modes. In all of the cases, maximum visibility is obtained if the source is monochromatic and both modes are equally excited, that is, $\eta_0 = \eta_1 = 0.5$.

It is important to note that a fiber may be used simultaneously in the single- and the two-mode regime by operating it at two wavelengths at the same time. Thus e -core, D-shape, and bowtie fibers designed for single-mode operation at 850 nm (laser diode) will be bimodal when operated at a shorter wavelength of 633 nm or 670 nm, depending on the laser source. Alternatively, a polarimetric setup can be designed for 850 nm, and a polarization-sensitive intermodal interferometer for 633 nm. The setup illustrated in Fig. 13 could be utilized for this purpose. Note that the input and output polarization conditions

Figure 13. Basic configuration of a single-mode or bimodal polarimetric pressure sensor (A—analyzer, B—polarizer).

in the single- and two-mode regimes are different. If the fiber is operated at both wavelengths and all possible polarizations, then three independent cosine responses can be obtained.

Differential Phase Shifts. When an external perturbation such as pressure, strain, or temperature is applied to a fiber of length L , it will change the phases $\Phi_i = \Delta\beta_i L$ ($i = 0, x, y$) by the amount

$$\delta\Phi_i = \delta(\Delta\beta_i)L + \Delta\beta_i\delta L \quad (22)$$

If the external perturbation is hydrostatic pressure p , then an increase by δp will cause both $\Delta\beta_i$ and L to change by $\partial(\Delta\beta_i)/\partial p$ and $\partial L/\partial p$. So from Eq. (22) we can obtain

$$\frac{\delta\Phi_i}{\delta p} = \frac{\partial(\Delta\beta_i)}{\partial p}L + \Delta\beta_i\frac{\partial L}{\partial p} = \frac{2\pi}{T_{i,p}} = \Lambda_{i,p} \quad (23)$$

The above equation can also be rewritten as

$$\delta\Phi_i = \left(\frac{\partial(\Delta\beta_i)}{\partial p}L + \Delta\beta_i\frac{\partial L}{\partial p} \right) \delta p = \frac{2\pi}{T_{i,p}}\delta p = \Lambda_{i,p}\delta p \quad (24)$$

Note that $T_{i,p}$ ($i = 0, x, y$) has the dimensions of pressure, while $\Lambda_{i,p}$ has the inverse dimensions. These are experimentally measurable parameters and determine the sensitivity of the sensor to a given external perturbation [equations similar to Eq. (24) describe the phase changes induced by temperature or strain].

Polarimetric Pressure Sensor. The design of a practical high-hydrostatic-pressure polarimetric sensor with a predesigned sensitivity as expressed by the parameter $T_{i,p}$, is based on an important relation expressed simply as (24):

$$T_{i,p}L = C_i \cdot \lambda \quad (25)$$

where C_i is a constant. Thus, a longer fiber will exhibit greater sensitivity and vice versa. Note that if the source is not monochromatic, a longer fiber will produce a lower value of the correlation function $|\gamma|$, which in turn will null the cosine response of the sensor. Therefore, proper choice of the laser source is essential.

For pressure measurement (considering temperature to be a disturbing parameter), temperature- and pressure-induced

phase shifts $\Delta\phi_S(p, t)$ will then be transformed into intensity changes $I_S(p, t) - I_0$ in accordance with the equation

$$I_S(p, t) = I_0[1 - \cos \Delta\phi_S(p, t)] \quad (26)$$

Figure 14 shows a topology of a polarimetric pressure sensor (PPS) in both reflection and transmission configurations, employing the principle of temperature self-compensation (27). The sensing (L_2) and compensating (L_1) parts of the sensor are assumed to be equal. The advantage of the reflection configuration is that only one fiber leadthrough is required to connect the sensor to the laser source and to the detection electronics. The advantage of the transmission version lies in the much higher level of optical signal, allowing for longer transmission distances and/or multiplexing of several sensing devices. The polarization axes of the sensing and the compensating fiber elements are rotated by 90° , while the input and output fibers are rotated at 45° relative to the sensing and compensating parts, respectively. Ideally, if equal sensing and compensating elements remain at the same temperature, their temperature-induced phase retardations will cancel out, and if they are placed under different pressures, the pressure-modulated output signal will be immune to temperature changes. In reality, however, if such an arrangement is to satisfy the requirements for an accurate pressure-measuring instrument, several important first- and second-order coefficients have to be considered to allow for simultaneous pressure and temperature effects on fiber birefringence. In a polarimetric cross-spliced sensor, the resulting unwanted sensitivity to temperature will still be present and can be described by differentiation of the phase retardation with respect to temperature (28):

$$\begin{aligned} \rho_t &= \frac{\partial \Delta\phi_S}{\partial t} = \Delta L K_t + L K_{tp} \Delta p \\ K_t &= \frac{1}{L} \frac{\partial \phi}{\partial t}, \quad K_{tp} = \frac{1}{L} \frac{\partial^2 \phi}{\partial t \partial p} \end{aligned} \quad (27)$$

where $\Delta L = L_1 - L_2$, K_t is the first-order phase sensitivity to temperature, and K_{tp} is the temperature–pressure cross-sensitivity coefficient. This simple but informative equation provides important insight into designing a sensor with minimum temperature error. The first term in it can be minimized by choosing a small ΔL . The second term depends on fiber properties but will always be nonzero, and can only be minimized

Figure 14. Temperature-compensated polarimetric fiber-optic sensor in (a) transmission and in (b) reflection configuration.

by carefully adjusting the fiber's technological and construction parameters.

Polarimetric Current Sensor. The need for fiber-optic sensing technology for high magnetic field and large current monitoring is now well documented. Conventional magnetic field and current sensor systems suffer from high susceptibility to electromagnetic interference, may lack the necessary bandwidth, are difficult to miniaturize, and cannot accommodate large numbers of measuring points at remote locations. Such monitoring can be especially valuable for protection, control, and fault detection in power plants, high-power transmission lines, substations, and distribution lines, where the high intrinsic electrical insulation of optical fibers is a significant advantage. Several techniques for fiber-optic magnetic field sensing have already been proposed (29), but only two approaches appear to be viable. The first is based on detection of a magnetic field by magnetostrictive effects, involving measuring the longitudinal strain produced in the optical fiber to which a magnetostrictive material has been bonded. The performance of such sensors is limited by the coupling efficiency of the magnetostrictive material and the optical fiber. Although various bonding and coating techniques have been explored, all usually lead to substantial hysteresis, temperature drift, and changes of fiber birefringence. The second approach is based on the well-known Faraday effect (30), consisting of a nonreciprocal circular birefringence induced in the propagation medium by a magnetic field and characterized by the Verdet constant V . The most convenient detection approach in this case is polarimetric sensing.

The Faraday effect may occur directly in standard or specifically doped optical fibers, but as V in silica fiber is very small, this type of sensor needs to be very long and as such will be prone to a variety of instabilities. For N turns of fiber around a conductor with a current I the Faraday rotation is given by

$$\Phi_F = \int_{L_F} V(\lambda, T) \mathbf{H} \cdot d\mathbf{L}_F \quad (28)$$

where L_F is the propagation path and $\mathbf{H}$ is magnetic field. The material-dependent Verdet constant $V(\lambda, T)$ is dispersive and often varies strongly as a function of temperature. To assure successful operation of a sensor based on the fiber-sensitive element, it is extremely important to avoid intrinsic birefringence induced by core ellipticity or stress in the core-cladding area, and extrinsic birefringence induced by packaging and mounting. This parasitic effect can be alleviated to some extent by annealing the fibers at an elevated temperature (31). Figure 15 shows a simple polarimetric sensor based on this principle. Coils with 5 mm to 10 cm diameter and up to 300 turns have been produced, and a temperature sensitivity of $1.7 \times 10^{-4} \text{ K}^{-1}$ has been demonstrated over a -20° to 120°C range. This technology has been transferred from NIST to the 3M Corporation for commercialization.

An approach based on extrinsic polarimetric sensors seems, however, to be more promising. The Faraday effect in ferrimagnetic garnets such as single-crystal yttrium iron garnets (YIG), Bi-doped YIG (BIG), and gallium-substituted YIG (Ga:YIG) (32,33) has been explored, since their Verdet constant can be greater than that of silica fibers by a factor of several thousand. Although the large V gives such sensors an impressive advantage over the all-fiber configurations, inherent problems asso-

Figure 15. Polarimetric fiber-optic current sensor.

ciated with the ferrimagnetic domain structure of these materials are large hysteresis, temperature drift of about $0.2\%/K$, nonlinearities, saturation at relatively low fields of about 0.1 T , and vanishing of response at frequencies of about 500 MHz . Recently, however, Inoue and Yamasawa (34) reported obtaining a Bi-doped garnet by liquid-phase epitaxy that shows a flat temperature characteristic from -10° to 80°C . Also, since the recent discovery of the large Faraday effect in $\text{Cd}_{1-x}\text{Mn}_x\text{Te}$ (CMT) (35), interest in this group of materials has been steadily growing with a view to their application not only in optoelectronic devices such as modulators and magneto-optic insulators, but also for polarimetric current sensors. These materials have improved thermal stability and can work at much higher fields (up to 25 T) and at higher frequencies (up to 5 GHz).

Interferometric Sensors

Fiber-optic interferometric sensors are usually designed following classical configurations of optical interferometers (8). In these devices, a range of physical measurands can induce modulation of phase in a sensing signal light beam, while the reference light beam remains unchanged. This phase change then has to be electronically processed, often by complex and sophisticated systems, to produce a useful intensity-type output signal from the interferometer proportional to the measurand. Although this technique offers very high sensitivity, it is extremely difficult to use outside the laboratory due to the unavoidable interference caused by environmental perturbations. One notable exception is low-coherence (or white-light) interferometry, which is presented later in more detail.

Classical Fiber Interferometers. Figure 16 shows the three best-known configurations of two-beam fiber-optic interferometers: (a) the reflective all-fiber Michelson interferometer, (b) the all-fiber Mach-Zehnder interferometer, and (c) a remote Fabry-Perot interferometer. Another configuration—the reciprocal Sagnac interferometer—is discussed separately. The demodulation systems for interferometric sensors are usually based on *homodyne* detection, where the sensing and reference beams have the same frequency, or on *heterodyne* detection, where the reference beam has a fixed frequency that is different from that of the signal beam.

The all-fiber Michelson interferometer is based on a bidirectional single-mode fiber coupler that divides the input light beam from the laser source into two components—one propagated by the sensing arm, the other by the reference arm of the interferometer—and then combines the two reflected beams so

Figure 16. Three configurations of two-beam fiber interferometers: (a) Michelson, (b) Mach-Zehnder, (c) Fabry-Perot.

that their interference can be registered by the photodetector. Assuming for simplicity that the polarization effects can be ignored, the electric fields propagating in the signal arm and in the reference arm can be treated as scalars and described as

$$\begin{aligned} E_S &= E_{S0} \cos \left[\omega t + 2 \left(\frac{2\pi L_S}{\lambda} \right) \right] \quad \text{and} \\ E_R &= E_{R0} \cos \left[\omega t + 2 \left(\frac{2\pi L_R}{\lambda} \right) \right] \end{aligned} \quad (29)$$

In this equation, E_{S0} and E_{R0} denote the amplitudes, λ is the wavelength of the light, and ω is its angular frequency. The phase difference will then be proportional to the path difference ΔL and can be expressed as follows:

$$\Delta\phi = \frac{4\pi}{\lambda} (L_S - L_R) \quad (30)$$

It may finally be shown that the irradiance at the detector is proportional to the absolute value of the squared sum of the superimposed electrical fields. The resulting formula is given by

$$I_d = I_0(1 - V \cos \Delta\phi) \quad (31)$$

(and corresponds to that of the polarimetric and dual mode sensors (Eq. (19)), where V is the visibility defined as in Eq. (17) and depending on both the reflectivity of the fiber ends and the coherence properties of the light source, but independent of the splitting ratio of the coupler. The maximum visibility occurs at the so-called quadrature condition when $\Delta\phi = \pi/2$ or when the path difference is equal to $\lambda/4$.

The Mach-Zehnder interferometer is based on two bidirectional fiber couplers, the first to divide the light beam into two components and the second to recombine the two beams exiting from the sensing arm and from the reference arm of the system. The sensitivity of this interferometer is only half that of the Michelson interferometer, as light propagates in each arm only once, and the phase difference is consequently

described by

$$\Delta\phi = \frac{2\pi}{\lambda} (L_S - L_R) \quad (32)$$

The Mach-Zehnder configuration has, however, two significant advantages that more than compensate for the lower sensitivity. Two antiphase output signals from two photodetectors,

$$\begin{aligned} I_A &= I_0(1 - V \cos \Delta\phi) \\ I_B &= I_0(1 + V \cos \Delta\phi) \end{aligned} \quad (33)$$

can conveniently be used to provide a feedback loop for assuring operation at maximum sensitivity (quadrature condition when $\Delta\phi = \pi/2$). This configuration is also characterized by much lower backreflection into the laser diode, which assures the higher wavelength and power stability of the system.

A useful and more practical example of the multiple-beam technique is the fiber Fabry-Perot interferometer (FFPI). A resonant cavity of this device may be contained within the fiber, with semireflective splices (36), cleaved or mirrored (37) end faces, or Bragg gratings (38) serving as reflective surfaces. This cavity may also be external to the fiber, taking the form of an air gap between two cleaved fiber end faces, or between a fiber end face and a thin moving or deformable diaphragm (39). Following classical textbooks (40), the transfer function of an FFPI for the transmitted signal can be expressed by

$$I = \frac{I_0}{1 + F \sin^2(\phi/2)} \quad (34)$$

where F is a parameter describing the phase resolution and known as the *fineness* of the interferometer, and ϕ is the phase retardance after the light has passed through the cavity twice. When attenuation is disregarded, F may be described in terms of the mirror reflectance R :

$$F = \frac{4R}{(1 - R)^2} \quad (35)$$

In the case of the frequently used low-finesse interferometer, the reflective surfaces may simply be the normally cleaved uncoated fiber ends, for which $R = 0.04$. The FFPI is then operated in a reflective configuration with visibility approaching 1 as the reflectivity is decreased. For $R \ll 1$ the FFPI signal may be approximated by the signal of the two-beam interferometer (Eq. (31)): $I_r = I_0 2R(1 - \cos \phi)$ for the reflective case and $I_t = I_0[1 - 2R(1 - \cos \phi)]$ for the transmitted signal.

Recently several quite interesting low-finesse Fabry-Perot-based fiber-optic sensors have been reported for a wide range of different measurands. Beard and Mills (41) developed an extrinsic optical fiber ultrasound sensor based on a thin transparent polymer film serving as the resonant cavity and mounted at an end face of a multimode fiber. The device can then be used for the detection and measurement of ultrasound with a sensitivity of about 60 mV/MPa. A phase-shifted extrinsic FFPI for dynamic strain measurements has been developed (42) using two laterally displaced single-mode fibers inserted into a hollow silica tube. Through an air gap these fibers face a multimode fiber acting as a reflector and forming a Fabry-Perot cavity. A high-sensitivity low-pressure sensor up to 13 kPa (100 Torr) has been developed (37) using a diaphragm bonded

to the strained fiber containing the interferometer with two in-fiber mirrors, with the motion of the diaphragm producing a change in the length of a Fabry-Perot cavity. Even a fiber-optic sensor for electric field measurement has been developed around the concept of a low-coherence FFPI using a miniature cantilever beam, the deflection of which depends on the electrical charge induced by the external field to be measured (39).

For most of these sensors, however, active phase control and complex polarization control systems are usually required to keep them at their optimum operating points, at the expense of significant cost, high system complexity, and low potential for wide practical implementations. Recently Fürstenau and Schmidt (43) made a significant breakthrough in this area by proposing a two-wavelength passive quadrature demodulation system for FFPI vibration sensors, based on a low-coherence source in combination with adjustable interference filters and an electronic switching unit. This novel and cost-effective sensing system is now undergoing tests in an application for airport ground traffic monitoring.

White-Light Interferometry. Although low-coherence or white-light interferometry (WLI) has been known in fiber-optic sensing since the late 1980s (44), a significant research effort in this area became noticeable only around 1990. By then, the deficiencies of high-coherence classical interferometry, especially its inability to deal with absolute measurements and the enormous costs of the decoding equipment involved, were becoming more apparent. Since that time, significant advances in WLI sensor design, signal processing, and sensor multiplexing have been reported, and all prove that this technology has indeed matured to the point of becoming one of the most promising in fiber-optic sensing, thanks to its practicality and cost-effectiveness. Due to its youth, this technology has not yet received much book coverage, although several excellent reviews such as Ref. 45 have been devoted to this topic.

The principle of a WLI sensor system is illustrated in Fig. 17 in a reflective configuration. A broadband source, typically an SLD or a LD operated below threshold, launches light into a bidirectional coupler and into the sensing interferometer located in the measurand field. The modulated output signal of this interferometer is then coupled back through the coupler into the local receiving interferometer. When the optical path differences of the two interferometers are matched one to another within the coherence length of the white-light source, interference fringes with their amplitude modulated by the contrast function will be observed at the output of the receiving

Figure 17. Basic configuration of a white-light interferometric fiber-optic sensor.

interferometer assuming a Gaussian spectral distribution of the source. The interferogram obtained at the photodetector can then be described (45) by

$$I = I_0 \left\{ 1 + \frac{1}{2} \exp \left[- \left(\frac{2\Delta X}{L_c} \right)^2 \right] \cos(k\Delta X) \right\} \quad (36)$$

where L_c is the coherence length of the source, $\Delta X = X_1 - X_2$ is the mismatch between the optical path differences of the sensing and the receiving interferometers, k is the wave number, and I_0 is the total optical intensity arriving at the photodetector. Note that the necessary condition for the system to work is $\Delta X < L_c$. It is clearly evident that any change of the external measurand acting upon the sensing interferometer will result in the interference pattern being shifted. This shift can then be easily registered or compensated for at the receiving interferometer, giving an absolute measurement of the external parameter in question. Many application-specific sensor systems have been developed to measure temperature (46), strain (47), pressure (48), and force (49) using an often complex variety of signal-processing techniques (45). In recent years, processing based on electronic scanning for low-coherence sensing systems has attracted much attention, since it does not require any piezoelectric or mechanical scanning devices and makes the system more compact, more stable, and less expensive.

An example of an electronically scanned WLI strain sensor based on HB fibers and with a Wollaston prism serving as a receiving interferometer (50) is shown in Fig. 18. The light source is an SLD with a central wavelength $\lambda_0 = 820$ nm and a coherence length of about $15 \mu\text{m}$. The input light is linearly polarized by the polarizer (or by a polarizing fiber) aligned at 45° to the polarization axes of the sensor in order to excite both polarization modes equally. The sensor itself is composed of two exactly equal lengths of the HB fiber spliced with their corresponding polarization axes rotated at 90° and giving a total phase shift at the output of the system close to zero. Light from the output of the sensor is collimated by lens L and passes through the Wollaston prism WP, which is made of crystalline quartz. The polarization axes at the output of the sensor are aligned to be parallel to the polarization axes of the WP. Therefore, the x - and y -polarized modes of the sensor are spatially separated by the Wollaston prism with the bisection angle α equal to 2° . The two modes interfere after passing through the analyzer A, which has its transmission azimuth aligned at 45° to polarization axes of WP. The cylindrical lens CL focuses the output beam on the CCD camera (or a CCD array) with a horizontal resolution of 1024 pixels, enabling registration of the resulting interference pattern with an adequate signal-to-noise ratio.

At an arbitrary point along the horizontal direction of the CCD camera, the two polarization modes intersect at an angle α , and the resulting intensity of the interference pattern may be written as

$$I(y) = I_0(y) [1 + \gamma(\phi_s + \phi_{WP}) \cos(\phi_s + \phi_{WP})] \quad (37)$$

where $I_0(y)$ is the bias intensity profile of the output beam; ϕ_s is the phase imbalance between the polarization modes at the output of the sensor; $\phi_{WP}(y)$ is the phase difference introduced

Figure 18. Electronically scanned white-light interferometric strain sensor in temperature-compensated configuration: (a) general setup, (b) detail of the output pattern exiting the receiving interferometer.

by the Wollaston prism, which can be expressed as

$$\phi_{WP} = \frac{2\pi}{\lambda_0} \alpha (y - y_0) \quad (38)$$

and γ is the coherence function of the light source. The longer wedge of the Wollaston prism may be shifted transversely across the beam, allowing for adjustment of the zero position of the interference pattern with respect to the scanning area of the CCD camera. The parameter y_0 in Eq. (38) indicates the position of the center of the longer wedge with respect to the edge of the scanning area. Assuming that the sensor is initially perfectly balanced, the phase shift occurring at the output due to the elongation of the sensing part of the fiber will be

$$\phi_s = L_0 \left(\Delta\beta + \frac{\partial \Delta\beta}{\partial \epsilon} \right) \epsilon \quad (39)$$

where L_0 is the initial length of the sensing part of the fiber and ϵ is the strain applied. An increase in the output phase shift ϕ_s results in a transverse shift Δy of the white-light interference pattern, proportional to the absolute value of ϵ :

$$\Delta y = \frac{\lambda_0 L_0}{2\pi \alpha} \left(\Delta\beta + \frac{\partial \Delta\beta}{\partial \epsilon} \right) \epsilon \quad (40)$$

Consequently, it is clear that processing of the signal digitized by the CCD camera needs to establish the location of the center of the white-light interference pattern determined by the symmetry axis of the coherence function $\gamma(\cdot)$. This can be achieved in a three-step procedure as discussed in detail in Ref. 45. First, the bias intensity function is determined by simple numerical filtering-out of higher harmonics from the output intensity. Then, in the second step, the coherence function is determined, and finally, in the third step, the upper part of the coherence function is approximated by a parabolic function, the symmetry axis of which determines the central position of

the white-light interference pattern. This position may thus depend on the action of the selected measurand. For instance, in the case of strain measurement illustrated by Fig. 19, an operating range of 4000×10^{-6} was achieved with an absolute accuracy of 0.5% of full scale (FS) (including temperature drift of 40°C) and a resolution of about 10^{-3} with no hysteresis effect. Similar performance has been achieved in pressure measurement up to 100 MPa with an almost identical configuration, the only difference being that the sensing element was subjected not to elongation but to hydrostatic pressure (51).

Bragg Grating Sensors

Periodic changes of the refractive index profile in optical waveguides are equivalent to gratings and constitute a source of scattering for the guided light. When the spatial period of such a grating is matched with the light wavelength, the scattered light can be guided as a backreflected wave. This phenomenon is applied for instance in distributed feedback resonators in semiconductor lasers, in distributed fiber Bragg reflector structures, and in sensing structures (52).

Figure 19. Example of output signal of the WLI strain sensor: position of the center of interference pattern versus strain.

Assuming that the refractive index profile n_p in an optical fiber changes with the spatial period Λ as

$$n_p = n_0 + \Delta n \cos\left(\frac{2\pi}{\Lambda} z\right) \quad (41)$$

the complex amplitudes of the forward mode A and the backreflected mode B fulfill the coupled equations (53)

$$\begin{aligned} \frac{dA}{dz} &= -i\kappa B \exp(2i\delta z) \\ \frac{dB}{dz} &= i\kappa A \exp(-2i\delta z) \end{aligned} \quad (42)$$

A normalized frequency δ represents the mismatch between the wavelength λ and the spatial period of the grating:

$$\delta = \frac{2\pi n}{\lambda} - \frac{\pi}{\Lambda} \quad (43)$$

where n is the effective refractive index of the guided wave. The coupling coefficient κ depends on the effective depth of the refractive index modulation:

$$\kappa = \frac{\pi}{\lambda n} \int 2n_0 \Delta n e_1 e_2 dS \quad (44)$$

where $e_{1,2}$ are the normalized electric field envelopes of the guided modes, and the integration is over the fiber cross section. Solution of Eq. (42) for a grating with length L gives the following expression for the reflectivity:

$$R = \frac{|B(z=0)|^2}{|A(z=0)|^2} = \frac{\kappa^2}{\gamma^2 \coth^2 \gamma L + \delta^2} \quad (45)$$

where $\gamma^2 = \kappa^2 - \delta^2$. The reflectivity depends strongly on the length of the grating, and consequently the backreflection can be high even when the index of refraction has a small modulation amplitude Δn . The maximum reflection, as illustrated in Fig. 20, is obtained at a specific wavelength λ_B that is twice the period of the grating within the fiber:

$$\lambda_B = 2n\Lambda \quad (46)$$

Bragg gratings also make it possible to couple two modes copropagating inside a multimode fiber core, or to couple core

Figure 20. Theoretical dependence of the reflectivity in Bragg grating structures on wavelength ($\kappa = 1 \text{ mm}^{-1}$, $L = 2 \text{ mm}$, $\lambda_B = 1330 \text{ nm}$).

and cladding modes. This phenomenon occurs when Eqs. (43) and (46) are fulfilled with $2n$ replaced by the difference between the effective refractive indices of the two coupled modes, $n_1 - n_2$. In this case, the resonant Bragg wavelength λ_B corresponds to longer grating periods Λ . Typically the spatial period Λ in such long periodic gratings is hundreds of micrometers long, while in reflecting fiber Bragg gratings a period of only hundreds of nanometers is typical.

Fiber Bragg gratings are manufactured by writing a permanent periodic modulation of a fiber's index of refraction within the fiber using a photoinduced effect. This effect is particularly useful in germanium-doped silica fibers. The resulting pattern of the refractive index is induced by the interference fringes generated by the interfering ultraviolet or near-ultraviolet radiation. The effect may be obtained using either a standing wave created by the light guided by the fiber, or the diffraction and interference of light externally illuminating the fiber.

The wavelength λ_B of the backreflected light depends strongly on temperature T , a fact that constitutes a major drawback of this method:

$$\frac{\partial \lambda_B}{\partial T} = 2 \left(\Lambda \frac{\partial n}{\partial T} + n \frac{\partial \Lambda}{\partial T} \right) \quad (47)$$

Obviously this wavelength also depends (in a manner similar to that expressed in the above equation) on a variety of potential external measurands such as strain or pressure. Several complex techniques have been proposed (54), with very limited success, to solve this fundamental problem of discrimination between temperature effects and those induced by the measurand in question. Proposed solutions involve (1) using two gratings, one isolated from strain and playing the role of a reference grating; (2) using two gratings for different wavelengths; and (3) using two gratings for the same wavelengths, but with different strain sensitivities (e.g., formed in different fibers). Measured sensitivities of 10 pm/K, 1 pm/(μm/m), and 5 pm/MPa have been reported (55) to temperature, strain, and hydrostatic pressure, respectively. The difficulty of the measurement is increased by the requirement for high-precision wavelength measurement: λ_B may change by as little as 1 nm within the full scale of the intended measurement. The simplest FOS systems with fiber Bragg gratings use a broadband source to encompass the Bragg wavelength and a wavelength-selective detector to measure the reflected wave (Fig. 21). Using several different gratings with different λ_B , we can construct a quasidistributed sensor system with wavelength-division multiplexing techniques.

Figure 21. Basic configuration of a fiber Bragg grating sensor, with two Bragg gratings BG1 and BG2.

Figure 22. Sagnac effect in optical fiber ring.

Fiber-Optic Gyro

Fiber-optic gyros (FOGs) are most mature of all fiber-optic sensors and are now widely considered in altitude and heading reference systems, and for car navigation systems with reduced requirements. A solid-state configuration gives them a significant advantage over conventional mechanical gyros based on the principle of inertia of spinning masses. FOGs have found practical application in aircraft, tactical missiles, trains, autonomously guided vehicles, and marine gyrocompasses (56).

The principle of operation of FOGs is based on the rotationally induced phase shift of the light propagating in the fiber coil (Sagnac effect) (8). When the fiber ring in Fig. 22 rotates in the inertial system, then light propagated in the same direction will traverse a longer path to return back to the initial point A (moved to A') at the ring. The additional path is equal to αR , where R is the ring radius and the angle $\alpha = \Omega\tau$ depends on the rotation rate Ω and the time τ it takes the light to traverse the ring. For a ring length L , the time τ is equal to Ln/c , where c/n is the light speed in a medium with the refractive index n . Consequently, the phase shift ϕ for a light wave with the angular frequency ω that traverses the rotating ring can be expressed as

$$\phi = \left(L + \Omega RL \frac{n}{c}\right) \omega \frac{n}{c} \quad (48)$$

Similarly, for a counterpropagating wave we obtain

$$\phi_c = \left(L - \Omega RL \frac{n}{c}\right) \omega \frac{n}{c} \quad (49)$$

A FOG operates by measuring the phase difference $\Delta\phi = \phi - \phi_c$ between two counterpropagating waves, the difference being proportional to the rotation rate Ω of the fiber coil:

$$\Delta\phi = \phi - \phi_c = 2\Omega RL\omega \left(\frac{n}{c}\right)^2 \quad (50)$$

Three principal passive configurations for a FOG are an interferometer (I-FOG) with an open loop, an I-FOG with a closed loop, and a resonator (R-FOG). In the I-FOG with the open loop (Fig. 23), light from the laser source is divided by a directional coupler into two beams with equal intensity counterpropagating in a fiber coil composed of many turns. Then the outgoing light is mixed again in the directional coupler and the interference of the two waves is measured by the detector. The interference, similarly to the Eq. (31) and (32) for two-beam

Figure 23. Basic configuration of an I-FOG with an open polarization-maintaining fiber loop. PM is a phase modulator.

interferometers, can be expressed as follows:

$$I = I_0(1 + V \cos \Delta\phi) \quad (51)$$

where V is the interferometric coefficient and I_0 is the input intensity modified by any losses in the optical system. To avoid parasitic dependence of interference on the polarization state, the configuration requires use of a polarizer, and the fiber in the coil has to be polarization-maintaining. The detection system can be improved by incorporating a phase modulator (PM) with a fixed frequency f_m at the end of the fiber loop. This induces an additional phase shift

$$\Delta\phi_m = \phi_m \cos(2\pi f_m(t + \tau)) - \phi_m \cos(2\pi f_m t) \approx F \cos(2\pi f_m t) \quad (52)$$

where ϕ_m is the modulation depth and $F = 2\phi_m \sin(\pi f_m \tau)$. In this case, the output signal at the detector can be expressed as follows:

$$I(t) = I_0\{1 + V \cos[\Delta\phi - F \sin(2\pi f_m t)]\} \quad (53)$$

Then the detected signal is modulated with an amplitude that depends on the magnitude of the rotation rate Ω , with the phase dependent on the direction of rotation.

The I-FOG with the open loop is the simplest configuration and the most popular to date. For applications that require higher performance and dynamic range, the I-FOG with the closed loop is more promising. In this configuration, a tunable frequency shifter is added at the fiber coil end. The frequency shifter changes the angular frequency of the first wave when it enters the fiber ring, and of the second wave when it exits the fiber ring. Therefore the phase shift of the first wave is modified in the optical fiber coil as follows:

$$\phi = \left(L + \Omega RL \frac{n}{c}\right) (\omega - \omega_s) \frac{n}{c} \quad (54)$$

where ω_s is the frequency shift induced by the frequency shifter, and the second counterpropagating wave has a phase shift given by Eq. (49). Then the phase difference $\Delta\phi$ is equal to

$$\Delta\phi = 2\Omega RL\omega \left(\frac{n}{c}\right)^2 - L\omega_s \frac{n}{c} \quad (55)$$

Changing the frequency ω_s , one can null the phase-shift difference, and the obtained frequency ω_0 for $\Delta\phi = 0$ gives the

Figure 24. Basic configuration of the resonator-based gyro (R-FOG).

rotation rate:

$$\omega_0 = 2\Omega R\omega \left(\frac{n}{c} \right) \quad (56)$$

The frequency shifter is typically made as an electro-optical modulator in integrated optics technology, mounted together with a Y junction, which plays the role of a beamsplitter (similar to a directional coupler), and with a polarizer. The closed-loop configuration gives a very good bias and stable scale factor (i.e., proportionality between the rotation rate and the output). In both types of I-FOG, low-coherence light sources (such as SLDs or erbium-doped fiber lasers) are used to minimize noise due to reflected and backscattered light. However, the use of low-coherence sources causes fluctuations due to the potential wavelength drift. The sensitivity of I-FOGs depends on the length of the polarization-maintaining fiber in the coil. Increasing the length of the fiber increases costs (polarization-maintaining fibers are expensive in comparison with other elements in FOGs) and also increases noise due to the variable temperature distribution. Some of the above problems can be solved by resonator FOGs.

In R-FOGs (Fig. 24), the phase shifts of the two counter-propagating waves are detected independently. The detector Det1 measures the interference between the light traversing the fiber ring and that incoming from the light source in the same direction. The frequency shifter FS1 changes the frequency to maximize the intensity measured by Det1. Similar processing occurs with the counterpropagating wave, and the difference between the frequencies shifted by FS1 and FS2 is directly decoded as a rotation rate. The R-FOG configuration requires highly coherent and stable sources of light, but the polarization-maintaining fiber loop is much shorter than in I-FOGs. R-FOG systems are still, however, in the research stage. Many other concepts, such as ring laser systems, Brillouin ring lasers, or the use of depolarized light in a fiber coil, could be applied in advanced FOG development. It should be noted that the fiber-optic ring resonators and coils could also be used as sensors for measuring other measurands than the rotation.

Distributed Sensors

Due to the unidimensional structure of an optical fiber, fiber-optic sensing technology offers the unique possibility to simultaneously measure not only a given parameter but also its real-time spatial distribution. Distributed fiber sensors are intrinsic fiber-optic sensors that allow sensing of the variation of

Figure 25. Principle of an OTDR-based distributed sensor.

the measured quantity along the fiber as a continuous function of distance (57). They rely in principle on optical time-domain reflectometry, which is commonly used for diagnostics in fiber telecommunication systems.

Figure 25 shows the principle of operation of the optical time-domain reflectometer (OTDR). A high-power light pulse is launched into the sensing fiber and propagates with the group velocity v_g . The light is reflected at discontinuities and is scattered mainly in the elastic process of Rayleigh scattering, which is caused by the microscopic fluctuations of the refractive index in the fiber. The detector measures the time dependence of the backscattered light signal, and the time of the measurement t determines the distance $z = tv_g/2$ at which the light pulse was backscattered.

Figure 26 presents a sample of the return signal measured by the OTDR. Since the light is attenuated in accordance with an exponential law, the backscattered power P measured by the detector is calculated as (8)

$$P = P_0(1 - \eta)\eta RD \exp(-2 \int \alpha(z) dz) \quad (57)$$

where α is an attenuation coefficient, P_0 the initial pulse power, D the length of the pulse, R the backscattering reflection coefficient per unit length, and η the coupling ratio in the directional coupler. The slope of the logarithm of the detected power at constant reflection R is proportional to the attenuation:

$$\frac{d}{dt} \left(\log \frac{P}{P_0} \right) = -\alpha(z)v_g \quad (58)$$

Thus those parts of the fiber with higher losses are recognized as regions where the detected characteristic has a larger slope,

Figure 26. Sample of the detected signal from a distributed fiber-optic sensor.

and those parts with higher backscattering are recognized as regions where there is a higher value of detected power. Any discontinuities (e.g., splices or a fiber end) produce high reflections and jumps in the characteristic of the detected signal.

The OTDR sensors detect the changes of the backscattered reflections R or changes of the losses α induced by the measured quantity. The Rayleigh scattering coefficient depends on temperature, and it can be applied in a temperature sensor (58). Measuring the losses in OTDRs with specially prepared fibers makes it possible to detect the temperature, pressure, liquid leakage, displacements, and other mechanical and chemical measurands. Another possibility is measuring the state of polarization of the backscattered light. Such polarization OTDRs measure changes in birefringence of the fiber, which is sensitive to strain, pressure, magnetic field, electric field, and temperature (59).

Besides the elastic Rayleigh scattering, the inelastic processes of Raman and Brillouin scattering occur in optical fibers. Raman scattering is caused by the molecular vibrations, while Brillouin scattering results from bulk vibrations. Brillouin OTDRs (60,61) and Raman OTDRs have detectors analyzing the spectrum of backscattered light. The ratio of the Stokes and anti-Stokes peaks and the frequency shift in the spectrum can be a source for determining the temperature or strain.

The OTDR allows measurement of changes in the measurand with a spatial resolution approximately equal to 1 m. Another technique, optical-frequency domain reflectometry (OFDR), offers better resolution. It is based on a chirped radio-frequency-modulated light source and on determining the position of light backscattering via the measured frequency.

FIBER-OPTIC SENSOR SYSTEMS

In a simple one-sensor, one-fiber arrangement of a discrete fiber-optic sensor, the optical fiber is largely underutilized as a transmission medium, mostly because the capacity of one information channel is much greater than the information generated by a typical sensor output. Important gains can therefore be made by multiplexing the fiber link by tapping several sensing devices into one passive fiber highway to increase the maximal number of sensors and to establish data telemetry channels. Such a configuration will obviously decrease the installation costs per sensor and at the same time increase the attractiveness of fiber-optic sensing technology for many potential users. Furthermore, industry has a need to install increasing numbers of sensors in surveillance and automation systems in factories, chemical plants, mines, off-shore platforms, aircraft, and spacecraft. Another driving force behind development of multiplexed fiber-optic sensor systems is their close relation to fiber-based LANs; the fact that they utilize the same or similar components will keep their prices low even if the market for industrial fiber-optic sensor systems is only in the early stages of emergence.

Basic Multiplexing Concepts

There are two principal multiplexing concepts that can be applied in designing a sensor system: In one class, a given number of sensors, having only one and the same property modulated by the external measurand field, can be incorporated into a single passive highway loop. Then some kind of multiplexing, addressing, and decoding is added to the system to allow mon-

Figure 27. Generalized fiber-optic sensor network.

itoring, detection, and interpretation of a returning output signal from a given sensor at a particular location. A second class involves the so-called orthogonal modulation scheme, where one measurand modulates different optical properties of the sensor. Such a system is capable of simultaneously performing measurements of several different physical parameters.

With the variety of optical fiber sensors currently under development, it does not seem possible yet to characterize the multiplexed system most likely to emerge as the standard, although its topology and parameters will obviously depend upon the type of sensor used, and in almost any multiplexed system at least four basic functions will have to be performed: powering the system at a level adequate for the predesigned power budget of the network, addressing and interrogating (identifying) a sensing device at a chosen discrete location, detecting the measurand-modulated signal of a given sensor, and eventually evaluating and calibrating the acquired individual sensor signals. The topological arrangement of a network, the generalized form of which is shown in Fig. 27, will largely depend on the scheme chosen for sensor addressing and demodulation.

Some of the best-known and most basic network topologies are linear array, ring, reflective/transmissive star, and ladder network. Both passive and active elements such as fiber links, splices, connectors, couplers, polarization controllers, light sources/detectors, modulators, multiplexers/demultiplexers, and sensors are themselves used to implement physical interconnections and components of a multiplexed optical fiber sensor network.

Examples of Discrete Sensor Multiplexing Techniques

Although many different multiplexing schemes and branching network concepts, often very sophisticated and costly, have been extensively investigated and reported (see for instance Refs. 62, 63, 64), industrial applications are usually looking for simpler, lower-key, and cheaper ideas. This short overview of multiplexing techniques starts with such an idea of a simple multiplexing configuration.

Space-Division Multiplexing. Space-division multiplexing (SDM), utilizing separate fiber paths and separate detector-source arrangements for individual sensors, is the easiest method to use and has been already implemented (65). Although it was initially dismissed as a low-key and inelegant

Figure 28. Wavelength-division-multiplexed fiber-optic sensor system.

approach, the rapidly decreasing prices of optoelectronic components (primarily laser sources and detectors) are imposing a reevaluation of the prospects for practical implementation of this method. The power budget of such a system is excellent, crosstalk is nonexistent, and the failure of one channel can usually be tolerated. The method can also be easily combined with a TDM or a WDM scheme (see the two following sub-sub-subsections) at the source–detector terminal unit. Several possible topologies of the SDM method involve common light source with multiple detector array, multiple sources with common detector, single source and single detector with one-to- N and N -to-one switching, and synchronous switching.

Wavelength-Division Multiplexing. The advantage of applying a wavelength-division multiplexing (WDM) scheme (see Fig. 28) for sensor arrays is that it still permits an excellent power budget for the system, as in the case of SDM, while affording savings in the form of a smaller number of necessary fiber links and connections. The light signal sent to each sensor is directed through the appropriate WDM coupling components, which are broadly similar to those designed for fiber communication systems. The most important problem related to this method is obtaining sufficient selectivity of the utilized wavelength division filters; to achieve this, several techniques can be employed, including the very promising spectral splicing technique with a broadband source and narrowband filters such as diffraction or holographic gratings. To further increase the number of multiplexable devices, the technique may obviously be used not only with single-, but also with dual- or multiple-fiber optical links.

An industrial differential-pressure transducer with wavelength-multiplexed power and data channels has been developed (66). It utilizes a resonant element optically excited at one wavelength of 850 nm, the pressure-modulated frequency of which is read out at another wavelength of 633 nm using the same two-wavelength single-fiber link.

Another example of a WDM system involves a digital rotary- and absolute-angular-position sensor utilizing a reflective code plate with ten channels, providing a resolution of 0.35° (67). Two light-emitting diodes with overlapping spectra and a single micro-optic multiplexer–demultiplexer composed of a GRIN rod

lens and a miniature grating are used to disperse the spectrum and recombine the spectral components from each channel after reflection by the code plate. This idea has been proposed for a fly-by-light control of the angular position of a throttle or a fuel control valve on an aircraft.

Time-Division Multiplexing. Time-division-multiplexed (TDM) systems usually require fast and costly electronics and because of this are less attractive for many industrial applications where the cost of installed hardware becomes a dominating factor. In a TDM system, each individual sensor signal can be identified and decoded at the detection end of the setup by arranging different propagation delays for the light signals returning from sensors at different locations. This method can also be coupled with the WDM technique in multiwavelength monitoring systems, with one wavelength affected by the measurand and another used for the reference (68). The method has several important advantages, including the large number of channels, the one-source, one-detector configuration, and equal applicability to both coherent and noncoherent systems. However, usually small optical path differences between the sensors require nontrivial processing. To this end, many complex topologies have already been proposed and reviewed (69). One possible form is a TDM optical passive sensor highway incorporating a commercially available electromechanical switch. Such a system has practically no crosstalk, but a stringent requirement to contain the time-sharing switching sequence within a very short period must be satisfied.

Frequency-Division Multiplexing. The general approach to frequency division multiplexing (FDM) of fiber-optic sensors is to send an amplitude- or frequency-modulated output signal from every sensor in a given network through an assigned frequency channel. The method consists of modulating several light sources by signals of different frequency, or modulating one light source with several frequencies (63) and then combining and separating signals at the detection end of the system employing a multichannel phase-sensitive (usually lock-in-based) detection scheme. One solution is a so-called matrix array method of FD multiplexing of intensity sensors, similar to the one developed by Młodzianowski et al. (70) in a three-sensor configuration. It has much simpler and slower electronics than typical TDM systems, and has a good potential for industrial intensity-modulated sensor multiplexing.

Coherence Multiplexing. Theoretical analysis (71) indicates that numerous WLI sensors with different optical path differences might be interrogated in a serial system by scanning the receiving interferometer. To date, however, a practical realization of only a four-sensor system has been reported (72). There are several factors limiting the number of multiplexed sensors, such as the power budget, the degradation of the contrast of white-light interference (WLI) patterns with increasing number of multiplexed sensors, and the difficulties in proper choice and precise control of optical group imbalances of all sensors in the system in order to assure separation of the signal and noise interference patterns. Furthermore, in many practical applications all multiplexed sensors need to be temperature-compensated. A typical temperature-compensated sensor consists of two equal lengths of highly birefringent (HB) fiber spliced with the polarization axes rotated by 90° , so that its

total group imbalance is close to nil (50). The requirement of temperature compensation conflicts with the principle of coherence multiplexing, which requires significantly different group imbalances between all multiplexed sensors.

Recently an interesting way of overcoming all these difficulties has been reported for sensors based on HB fibers (72). Such sensors are easy to manufacture, especially in that their group imbalances may be controlled simply by measuring the lengths of the fiber components. A system of four serially multiplexed sensors including two temperature-compensated pressure sensors and two temperature sensors has successfully been developed and tested. A modified concept of the temperature-compensated sensor has been adopted for hydrostatic-pressure measurements in order to simultaneously achieve the temperature desensitization of each pressure sensor while maintaining the possibility of individual addressing. The modified pressure sensor consists of three different fiber elements: sensing, compensating, and addressing fibers of lengths L_S , L_C , L_A , respectively. The sensor elements can be made of different types of HB fiber, but their lengths have to satisfy the following condition:

$$K_S^T L_S - K_A^T L_A - K_C^T L_C = 0 \quad (59)$$

where K_S^T , K_A^T and K_C^T are corresponding temperature sensitivities. By choosing the proper lengths and types of fiber for the particular sensor elements it is possible to fulfill the condition of Eq. (59) while setting the total group imbalance ΔR of the sensor at the desired value. In order to avoid overlapping of the noise and the signal interference patterns, the total group imbalance of every additional sensor connected to the serial system has to satisfy the following condition:

$$\Delta R_N = \sum_{i=1}^{N-1} (\Delta R_i + Q_i) \quad (60)$$

where ΔR_i and Q_i are the group imbalance and the operation range of the i th sensor, and the summation is carried out over all sensors already existing in the system.

Examples of Industrial Sensor Systems

As examples of practical implementations, we have selected several application-specific industrial sensor systems reported to have been recently installed in different environments. More information can be found in recent books (7,8) and conference proceedings (see for instance Refs. 54, 68).

Fiber-Optic Stress Monitoring. The fiber-optic stress cell (FOSC) has been developed as a safe and reliable method for embedding and interfacing the FOS (of pressure, load, or stress) in concrete, rock, or soil materials under harsh environmental conditions (73). This simple and practical method combines fiber optics with elements of traditional hydraulic measurement technology based on a compensation method in which stress in the material surrounding the pressure cell is compensated by automatically adjusted pneumatic or hydraulic pressure within it. The assembly of the fiber-optic stress cell is composed of a pressure pad connected to a fiber-optic pressure sensor. The pressure cell is optimized for stress measurements by adjusting the plate surface/thickness ratio to minimize both the measurement error and the influence of the

different modulus of elasticity between the cell and the surrounding material. The cell is attached to a housing containing a fiber-optic polarimetric pressure sensor in a temperature-compensated configuration and equipped with two specially designed pressure leadthroughs to input and output the leading fibers. The connectorized optical leading cables are protected by resistant plastic tubes to withstand the effects of the grouting process during bore-hole installation. Thus, internal pressure induced inside the FOSC, dependent on the stress in the surrounding material, can be directly read out by the fiber-optic pressure sensor and relayed to the remote digital demodulation and measurement unit via long optical cables. A prototype of this device has been successfully installed for load monitoring in a salt mine near Braunschweig, Germany, which is now being used as a nuclear waste disposal site.

Fiber-Optic Thermal Monitoring. An eight-channel fiber-optic sensor network has been installed for thermal monitoring of the stator of a 900 MW turbogenerator (65) by the Bertin Company in France. The system is based on white-light interferometry and uses optical phase demodulation provided by a dual-wavelength passive scheme in a polarimetric configuration (74). The temperature sensor itself is a miniature calcite probe aligned between two polarizers. The eight-channel system is achieved through space-division multiplexing using one LED source at 830 nm per sensor and a common optical and electronic demodulation unit. This unit sequentially interrogates the sensors at a rate of 13 Hz via an 80 m eight-fiber bundle cable and reconstructs the temperatures from the demodulated signals. The accuracy of the system is reported as 0.5°C in the operating range of 20°C to 120°C with accidental rises up to 200°C. The installation is located in the EDF nuclear power plant of Trickastin 1 and is proving successful for high-accuracy temperature monitoring in a harsh environment (high temperature, humidity 93% at 70°C, vibrations at 10 Hz to 100 Hz, and accelerations of 2g).

Fiber-Optic Combustion Monitoring. Real-time pressure measurements on internal combustion engines can provide information for optimum control of engine speed, throttle, air/fuel ratio, and exhaust gas recirculation. Optrand Inc. (USA) is now marketing an intensity-modulated fiber-optic diaphragm sensor integrated within a spark plug, where cylinder pressure flexes the diaphragm and modulates the light reflected from it and coupled back into the input fiber (75). This fiber is metal-coated and temperature-resistant, allowing it to be integrated with the sensor housing and providing a necessary hermetic seal. The sensor is powered from a LED source through a fiber-optic coupler, and the diaphragm is laser-welded to the sensor body. The operating range of this sensor is up to about 7 MPa (1000 psi) with overpressure up to 21 MPa. The range of temperatures is -40° to 550°C, and the frequency range is 0.1 kHz to 15 kHz. The overall accuracy of this system is reported to be better than 5%.

Fiber-Optic Damage Detection Monitoring. Fiber-optic submarine communication cables are exposed to a variety of damage risks from anchoring or fishing equipment. Early detection of such incipient damage can significantly improve the reliability of undersea transmission installations. To satisfy this requirement, a prototype 66 kV XLPE fiber-optic communication cable containing an integrated fiber-optic mechanical damage

detection sensor has been developed in Japan and is now used in real installations (76). The detection part contains four single-mode fibers placed in shallow grooves in the outside part of the cable every 90°. When lateral force is applied to the cable, some of the monitoring fibers become laterally compressed and their transmission losses greatly increase. Monitoring of these losses by the OTDR system means that the increasing risk of damage to the cable can be detected long before any degradation of the actual optical transmission becomes visible, and corrective action can be undertaken in time to save the cable. The system is able to detect cable deformation rates from 10%, whereas the deterioration of communications is normally noticed only at 40% cable deformation.

Fiber-Optic Traffic Monitoring. A fiber-optic airport ground traffic surveillance system has been installed in the Braunschweig airport in Germany to detect and identify vehicles or aircraft movement via monitoring of structural vibrations (77). The system is based on a fiber-optic extrinsic Fabry–Perot microinterferometer cantilever-beam-type vibration sensor. The Fabry–Perot cavity is formed by the air gap between the end of the sensing fiber and a low-reflectivity mirror, and its length depends on the vibrations. The sensing element is powered from a low-coherence SLD at $\lambda = 1300$ nm via a bidirectional coupler. The reflected modulated signal returns through the same coupler and is split into two components before entering a two-wavelength passive quadrature demodulation unit, which converts the two phase-shifted interference signals into output voltages. The sensors are located at taxiway intersections with runways and cemented at the edge of the taxiways without damaging the pavement. Each sensor is connected to the system via one of eight connectorized single-mode optical fibers inside a common optical cable about 1 km long running to the control unit. The reported system has now been in continuous operation for more than two years and has proven successful under all weather conditions.

Fiber-Optic Navigation Monitoring. The fiber-optic gyro (FOG), discussed earlier, is an open-loop ring interferometric rotation sensor and is the first mass-produced FOS for applications in vehicle, missile, or aircraft navigational systems (78). The system is manufactured by Hitachi and is currently installed, among other applications, in luxury automobiles. The sensor is entirely composed of polarization-maintaining fiber, uses an SLD source, and has a CMOS-integrated high-precision signal-processing system based on DSPs. The accuracy of rotation measurement can be as high as 0.01°/h and is stable within a temperature range from –30° to 80°C. The system is mass-produced at a maximum rate of 5,000 units per month and can be used for automotive navigation in planned intelligent transportation systems to overcome heavy traffic congestion or in other applications such as attitude control systems or direction measuring systems.

Fiber-Optic Displacement Monitoring. A WLI system of fiber-optic displacement sensors for monitoring the integrity of civil structures (SOFO) has been developed and implemented in Switzerland (79). It is based on a double all-fiber reflective Michelson interferometer in tandem configuration (80), with the sensing fiber pretensioned and coupled to the measured structure and with a free temperature-compensation fiber. The system is powered by an SLD at 1300 nm, and one arm of the

analyzing Michelson interferometer is terminated by a mobile mirror. The sensor length may vary from 20 cm to 50 m, and the resolution is 2 μ m; the dynamic range for measuring elongation is 1%. The sensors can be connected serially in chains by coherence multiplexing. It has been recently reported that this system has already been installed on four bridges and in several tunnels and dams, with a total of 600 sensors being installed since 1993 (79).

Fiber-Optic Current Monitoring. Commercial optical current transformers based on Faraday rotation in Bi-substituted rare earth iron garnet (BiRIG) materials have been developed by Panasonic in Japan (81) for metering in electric power systems. The optical magnetic field sensor head itself can take the form of a confocal sensor or a miniature fiber-integrated sensor. The polarizer, analyzer, and leading fibers are integrated together within the sensor head, and the intensity-modulated signal is acquired in a polarimetric configuration. It has been reported that the appropriate combination of garnet composition and optical design can yield 1% of sensor accuracy within a temperature range from –20°C to 80°C, with an ac linearity of 1% for input current up to 300 A.

FUTURE OF FIBER-OPTIC SENSORS

During the last 15 years, extensive research has been done on every imaginable fiber-optic sensing mechanism (3), making it rather difficult to come up with an entirely novel and exciting sensing idea. Many of the ideas studied, however, remain mere ideas, with no chance of practical implementation in a real environment. A promising trend is now developing in that more and more research groups are taking approaches that are application-oriented, and consequently such implementation issues as packaging, interconnecting, and above all reliability and multiplexing of fiber-optic sensors and systems are becoming the focus of attention. Research on FOS technology for industrial applications is still, however, in the early stages of development.

Three important aspects have to be addressed simultaneously in the near future for wider successful commercialization of these systems in direct competition with traditional sensing systems. These aspects are: (1) developing accurate, reliable, and cost-effective sensor systems; (2) safe packaging and interfacing of sensors with their working environment; (3) optical multiplexing, signal processing, and remote data telemetering for the installed sensor arrays. Research in these directions will certainly continue to increase, since the technology remains genuinely attractive in many application areas.

ULTRAVIOLET DETECTORS

The detection of ultraviolet (UV) radiation is of importance in many applications in science, industry, and medicine, such as flame and spark detection, communications, UV dosimetry of industrial processes such as UV-initiated photopolymerization reactions, and sterilization of equipment and water. The UV light spectrum is generally considered to comprise wavelengths from 10 nm to 400 nm. These wavelengths are traditionally subdivided into several ranges, given in Table 1. Photodetection of ultraviolet light within these ranges poses specific challenges in terms of the fabrication and engineering of photodetector devices and the development of appropriate materials. An excellent review (1) of all types of photodetectors, including ultraviolet-sensitive photodetectors, has been published

Table 1. Ultraviolet Light Nomenclature

UV Region	Wavelength Range (nm)
Near UV	400–300
Mid UV	300–200
Far UV	200–100
Extreme UV	100–10
UVA	400–320
UVB	320–280
UVC	280–100
Deep UV	350–190
Actinic UV	315–200
Vacuum UV	200–10

recently. A detailed review (2) of ultraviolet- and X-ray-sensitive detectors that addresses both imaging and nonimaging systems has also been recently published. This article discusses the current commercially available technologies for nonimaging UV photodetection applications. In addition, in view of the fact that UV photodetection is an active and important field of research, emerging technologies are also briefly discussed. The article is divided into two sections, the first addressing UV detection with semiconductor photodiodes and the second covering UV detection with photoemissive phototubes.

SEMICONDUCTOR ULTRAVIOLET PHOTODETECTORS

Semiconductor detectors, used in either the photoconductive or photovoltaic modes, are widely used photoelectric detectors of ultraviolet light. Razeghi and Rogalski (3) have recently published a comprehensive review of ultraviolet-sensitive semiconductor detectors that describes in detail the theory and operation of each different type of detector. Semiconductor detectors are attractive due to their small size, simple operation, and relative low cost, and, for many applications, provide stable, linear detection of ultraviolet light over a wide dynamic range of incident powers. Silicon traditionally has been the most widely used semiconductor material for the fabrication of ultraviolet-sensitive photodetectors; however, its use is limited by radiation-induced aging effects, problems arising from the strong absorption of UV light, and an inability to operate at elevated temperatures. Si photodetectors are also much more sensitive to visible and near-IR light than to UV light. However, silicon wafer processing technology is quite advanced and Si photodetectors have been engineered with features designed to enhance the ultraviolet light sensitivity. The most widely used UV enhanced device structures are junction photodetectors, including, for example, shallow diffused p - n junctions and Schottky barriers. In this section we will discuss the characteristics and relative merits of shallow diffused p - n junction and Schottky barrier photodiodes, fabricated using a number of materials, including silicon and several wider-band-gap materials such as silicon carbide (SiC), III-V nitrides (GaN, AlGaN) and III-V phosphides (GaAsP, GaP). Wide-band-gap materials are better suited in many ways than Si for UV photodetection. For example, wide-band-gap photodetectors exhibit improved radiation hardness, better resistance to temperature and harsh chemicals, and improved wavelength selectivity (visible blind operation). Consequently, the development of wide-band-gap materials and their application in photodetection is an active area of research.

Silicon p - n Junction Photodiode

Photodiodes fabricated using p - n junctions in silicon have been the most widely used photovoltaic detectors for ultraviolet photodetection. Silicon photodiodes exhibit good responsivity, on the order of 0.1 to 1 A/W, over the entire visible and near-IR spectrum. Although the UV response in a standard p - n photodiode is significantly lower than the peak response in the near-IR region, photodiodes are manufactured that exhibit enhanced blue and UV response. Due to the broad spectral response, if visible blind operation is desired, the incident light must be spectrally filtered to remove the visible and near-IR wavelengths. The typical spectral response for a Si p - n junction is shown in Fig. 1, exhibiting a peak at ~ 900 nm and a

Figure 1. Spectral response of a standard p - n junction Si photodiode.

broad long-wavelength cutoff extending beyond 1100 nm, due to the indirect nature of the Si band gap. The response in the UV region is essentially zero for wavelengths shorter than ~ 300 nm. The construction of a typical silicon p - n junction photodiode is shown in Fig. 2. In this example, a single-crystal, high-purity, n -type silicon substrate is doped with a material, such as boron, to form a thin p layer on one surface. The p layer may be formed by thermal diffusion or ion implantation of the boron to depths of ~ 1 μm or less. The interface between the p -doped Si and the n -doped Si comprises the p - n junction. p - n junction photodiodes operate by the absorption of light in the bulk of the semiconductor. In the figure, light is incident on the surface with the diffused p layer. Since Si has a high absorption coefficient, particularly for blue and UV wavelengths, the p layer at this surface must be thin enough to permit good interaction of the light with the bulk semiconductor near the p - n junction. The absorption of light creates electron-hole pairs that are subsequently separated by the electric field of the p - n junction. The electrons move toward the n layer and holes move toward the p layer. The notation p^+ and n^+ designate heavily doped p and n layers, respectively. Such layers have high conductivity and are used to ensure good electrical contact between the semiconductor and the metal conductor. The open-circuit voltage generated by the photoinduced charge is extremely linear with respect to the intensity of the light. If

Figure 2. Schematic of a typical p - n junction Si photodiode.

the anode and cathode of the photodiode are connected across a resistive load, this internal charge migration is measured externally as a photocurrent that is similarly found to be linear with the light intensity over a wide dynamic range. The operation of p - n junction photodiodes in this zero-bias photovoltaic mode is used for applications requiring the greatest sensitivity; however, increased speed and linearity can be attained by applying a reverse bias (the photocurrent remains the same). The reverse bias reduces the capacitance of the device, thereby decreasing the RC time constant and improving the temporal response of the photodiode. However, the bias also increases the dark current, resulting in an overall reduction in sensitivity. There is therefore a trade-off between sensitivity and speed in an ordinary p - n junction photodiode.

For the specific application of ultraviolet light detection the p - n junction photodiode must be optimized in a number of ways to enhance the quantum efficiency of the device to UV light and to avoid the loss of carriers to nonradiative recombination processes, particularly at surfaces and interfaces. The quantum efficiency is defined as the number of electron-hole pairs per incident photon that are generated and which are subsequently separated by the electric field of the p - n junction before recombination occurs. High quantum efficiency requires that the incident light be able to penetrate into the bulk of the semiconductor material to generate carriers near the junction. Due to the high absorptivity of Si the penetration depth of light is very small and standard Si photodiodes are fabricated with a relatively thin layer, $\sim 1\ \mu\text{m}$ or less, of doped material on the surface upon which the light is incident. Figure 3 shows the absorption coefficient of Si as a function of wavelength (4). For the wavelength range from 10 nm to 400 nm the absorption length is everywhere less than 100 nm and reaches a minimum value of 3 nm at a wavelength of ~ 300 nm. Thus, the quantum efficiency in the UV region is reduced, even for submicrometer-thick layers, because of the exceptionally strong absorptivity at these wavelengths. Obviously, the thickness of the doped layer must be kept as thin as possible to enhance the UV response. It follows that the shallow p - n junction lies very near the surface of the photodiode. Because of the high doping levels typically used and the close proximity of the charge carriers with the surface, nonradiative recombination of carriers can cause a significant loss of quantum efficiency. In order to minimize the probability of carrier recombination the surface can be passivated with a thin coating of a material such as silicon dioxide. This oxide coating is also intended to protect the photodiode surface from moisture, chemicals, and scratches and serves as

Figure 3. Absorption coefficient of Si as a function of wavelength for UV, visible, and near-infrared wavelengths.

an antireflection coating to reduce incident light losses. Control of the thickness and quality of the oxide coating is important for optimizing the UV response. The quality of this coating and the nature of the interaction at the interface between the coating and the semiconductor are largely responsible for aging effects that have been observed in the UV response of Si photodiodes. This has been a significant problem for Si photodiodes, with extended UV exposure, even at low power, capable of causing substantial degradation in the response (5–7). The quantum efficiency of a Si photodiode decreased (5) from an initial value of 27% to less than 8% when illuminated with 10^{10} photons/(s · mm²) at 124 eV for less than 30 min. UV-enhanced Si photodiodes having superior stability as well as high quantum efficiency (8,9) were manufactured by diffusing arsenic or phosphorus in a thin, highly doped layer on p -type Si. The superior characteristics of the photodiodes were attributed to the n on p construction and careful control of the quality and thickness of the oxide coating. These photodiodes have been further improved more recently (10,11) by nitriding the oxide layer to yield an oxynitride layer that possesses significantly improved radiation hardness and resistance to moisture. Because of the ruggedness of the 60 Å thick oxynitride layer and the virtual absence of nonradiative recombination at the oxynitride/silicon interface, the photodiodes possess high quantum efficiency with exceptional long-term stability. The same photodiodes, with the responsivity calibrated as a function of wavelength in the vacuum UV, are available from the National Institute of Standards and Technology (NIST) as transfer standard detectors. A schematic of the photodiode is shown in Fig. 4 and the wavelength dependence of the responsivity is shown in Fig. 5.

To summarize, UV-enhanced Si photodiodes are widely used for UV photodetection because they can be manufactured using well-established wafer-scale processing methods and they are relatively inexpensive. They are commercially available from a number of manufacturers (12). However, their response in the UV region is much smaller than their response in the visible and near-IR regions so that if solar blind operation is required, then optical filters, such as colored glass filters and dielectric coated band-pass filters, must be used with the photodiode to block the longer wavelengths. In addition, the quantum efficiency in the UV region can vary significantly with wavelength due to the rapidly varying absorption coefficient

Figure 4. Schematic of a state-of-the-art UV-enhanced Si photodiode. (Courtesy of the Physics Laboratory, National Institute of Standards and Technology.)

of Si at UV wavelengths, the related problem of nonradiative recombination losses close to the surface due to the short absorption lengths and because of the finite probability of creating more than one electron-hole pair per UV photon. Finally, when choosing a Si photodiode, the stability of the UV response with age and with accumulated UV exposure is an important consideration.

GaP and GaAsP Schottky Photodiodes

The second semiconductor photodiode architecture that is well suited for UV photodetection applications is the Schottky photodiode. In the diffusion-type p - n junction photodiode, discussed above, the depletion layer is formed between the p -doped and n -doped layers of the semiconductor while in a Schottky photodiode the depletion layer is formed at the interface between the semiconductor and a thin layer of metal, such as gold or platinum. Since the photosensitive region is located nearer to the surface, the Schottky barrier photodiode is capable of superior short-wavelength detection than the p - n junction if the material is highly absorbing. A schematic of a Schottky barrier photodiode is shown in Fig. 6. In this figure a thin layer of gold is deposited on an n -type substrate. The gold layer is thin enough, typically about 10 nm, to permit ultraviolet light to penetrate into the semiconductor layer. Photogenerated electron-hole pairs are collected in the depletion layer near the metal/semiconductor interface and are separated by the depletion layer field, giving rise to an external photocurrent, just as in the case for the p - n junction photodiode. Schottky barrier photodiodes are relatively simple to fabricate compared to diffused junction photodiodes, since the junction is formed by the deposition of a single thin layer of metal on the semiconductor surface. The spectral response of the resulting photodiode depends on the response of the semiconductor. Ultraviolet sen-

Figure 6. Schematic of a typical Schottky barrier photodiode.

Figure 7. Spectral response of a GaP Schottky barrier photodiode. (Courtesy of Hamamatsu Corporation.)

sitive Schottky photodiodes have been fabricated using Si, however, it was found that the quantum efficiency degraded with exposure in a manner essentially identical to that observed for p - n junction Si photodiodes (5). Commercially available (13) alternatives to Si photodiodes include GaP and GaAsP Schottky-type photodiodes. These photodiodes are manufactured using a thin layer of gold on an n -type semiconductor substrate. The stability of GaP and GaAsP Schottky photodiodes is superior to that of Si photodiodes, and it has been shown that (5) the quantum efficiencies of the GaP and GaAsP Schottky photodiodes remain constant over time with UV irradiation. Both GaP and GaAsP photodiodes have good sensitivity throughout the entire UV region and are more resistant to radiation damage than Si photodiodes. The spectral responsivity of a GaP Schottky photodiode is shown in Fig. 7. Since GaP and GaAsP are wider-band-gap materials than Si, they offer greater selectivity in the wavelength response. GaAsP photodiodes exhibit a peak response at ~ 600 nm and a relatively sharp cutoff at ~ 680 nm, while the peak of the response for GaP is ~ 450 nm, with a cutoff at ~ 550 nm. Although the quantum efficiencies of the GaP and GaAsP photodiodes are lower than the quantum efficiency for Si photodiodes, the spectral responsivities of GaP and GaAsP in the ultraviolet region are smoothly varying functions of wavelength. This is in contrast to the responsivity of Si, which exhibits abrupt excursions throughout the UV region due to multiple photon ionization. The rise time of the temporal response of the GaP and GaAsP Schottky photodiodes is significantly longer than that of a p - n junction photodiode, ranging from $5 \mu\text{s}$ to $50 \mu\text{s}$ for photodiodes having active areas that range from $1 \text{ mm} \times 1 \text{ mm}$ to $10 \text{ mm} \times 10 \text{ mm}$, respectively. This is because the capacitance of the Schottky barrier photodiodes are significantly larger as a result of the extremely thin depletion layer. The surface barrier structure also leads to higher dark currents in the GaP and GaAsP photodiodes compared to Si photodiodes.

Wide-Band-Gap Materials

The semiconductor photodetectors discussed thus far have differed with respect to the substrate material and the nature of the barrier that separates the photogenerated carriers. In all cases the responsivity of the photodiode was greater in the

visible and near-IR regions than in the ultraviolet region. For many applications it is desirable for a photodetector to exhibit high responsivity to ultraviolet wavelengths and negligible responsivity to visible and near-IR wavelengths (greater than 400 nm). This kind of operation is often referred to as visible-blind detection. Solar-blind detection is a class of visible-blind operation having even more stringent wavelength requirements, exhibiting high responsivity to only those wavelengths less than 290 nm. Solar blind operation is impossible to achieve using Si photodetectors without the use of filters such as UV-transmitting-visible-blocking colored-glass filters usually in combination with dielectric-coated band-pass filters. The use of these spectral filtering techniques, however, imposes certain restrictions on the operation of the resulting photodiode-filter assembly. Most band-pass filters are made by combining dielectric stack interference filters with additional colored-glass or metal-film blocking filters. While these band-pass filters offer some flexibility in the specification of the center wavelength (or edge wavelength) and the width of the band, the overall transmission off-band cannot be reduced to a value less than 10^{-4} without seriously degrading the transmission within the band. In addition, the transmission characteristics of interference-type filters are extremely angle dependent and often can accept only a small field of view. Colored-glass filters by themselves are not capable of rejecting both visible and near-IR wavelengths and their transmission in the ultraviolet degrades as the glass ages. For these reasons the field of solar-blind photodetection is an active area of research and development. In particular, the development of photodetectors manufactured using wide-band-gap materials (direct and indirect) offers the potential for developing true solar-blind detectors that have negligible visible and near-IR response. In addition to superior spectral selectivity, wide-band-gap materials exhibit superior physical properties compared to Si, such as higher thermal conductivity, better radiation hardness and durability, and greater resistance to dielectric breakdown. These properties permit the use of wide-band-gap photodetectors in environmentally demanding applications that require resistance, for example, to high temperature, high voltage, or high incident power. The wide-band-gap materials that have received the greatest scrutiny for UV photodetector applications are silicon carbide (SiC), III-V nitrides, such as gallium nitride (GaN), and diamond. Silicon carbide and the III-V nitrides are discussed later. Diamond is potentially an ideal solar-blind detector because of its wide band gap (5.5 eV), low electrical conductivity, and chemical inertness. Natural diamond has been used previously, with significant restrictions and limitations, as a photoconductive detector for ultraviolet and ionizing radiation. More recently, the growth of polycrystalline diamond films by chemical vapor deposition methods has raised significant anticipation for the development of diamond-based UV detectors. However, high-quality undoped and *n*-doped diamond films have proven difficult to prepare. Structural defects in the polycrystalline films are responsible for defect states that can generate an unwanted subgap photoresponse. Diamond UV detectors will not be discussed in detail and the interested reader is referred to the literature (14–17) for the latest developments in diamond materials research and diamond UV detector device development.

Silicon Carbide. Hexagonal, crystalline silicon carbide (6H-SiC) is a wide-band-gap (2.9 eV at 300 K) semiconduc-

Figure 8. Schematic of a typical 6H-SiC photodiode. [Courtesy of Cree Research, Inc. Reprinted with permission from *Phys. Status Solidi A*, **162**, 481, 1997. Copyright 1997 Wiley-VCH Verlag.]

tor that absorbs UV light, but is essentially transparent to IR and visible light. The strength of the Si-C bond (bond energy ~ 5 eV) provides the material with superior resistance to high temperatures, chemicals, and mechanical shock. The width of the band gap results in low dark currents, even at elevated temperatures, thereby permitting sensitive photodetection under widely varying environmental conditions. While the device fabrication techniques for SiC materials are not as mature as those for Si fabrication, recent progress has yielded good-quality, bulk 6H-SiC single crystals that are used as substrates for the subsequent deposition of epitaxially grown *p*-type and *n*-type layers (18). Both *p-n* junction and Schottky barrier SiC photodiodes have been reported (19–23). High-quality *p-n* junction SiC photodiodes are commercially available as a chip (18,21) or packaged within a fixture (24,25). A schematic of the photodiode is shown in Fig. 8. A wafer of *p*-type 6H-SiC is used as the substrate and an epitaxial junction is fabricated by first growing an aluminum doped *p*-type layer followed by a nitrogen-doped *n*-type layer. The responsivity of the photodiode depends on the degree of doping and the thickness of these layers. A mesa is patterned and etched using reactive ion etching. The typical size of the mesa varies from 0.09 mm² to 9 mm². A 50-nm-thick silicon dioxide layer is used to passivate the surface. A cross-shaped Al contact covers less than 2% of the area of the mesa. A scanning electron microscope (SEM) micrograph of the SiC photodiode is shown in Fig. 9. Although the absorption length of UV light in SiC is greater than it is in Si, the responsivity of the SiC photodiode is improved by limiting the thickness of the *n*⁺ layer to ~ 0.1 μ m. The responsivity and quantum efficiency of the SiC photodiode are shown in Fig. 10 as a function of wavelength at several temperatures. The spectral response curves are smoothly varying functions of UV wavelength from 200 nm to 400 nm, exhibiting peaks at ~ 275 nm to ~ 300 nm, with corresponding maximum quantum efficiencies ranging from 80% to 100%. The response curves shift to lower energy with temperature due to the shift in the band gap with temperature from ~ 3.03 eV at 223 K to ~ 2.88 eV at 623 K. The dark current, as expected, is quite low in these photodiodes. Figure 11 shows the reverse-bias dark-current density versus voltage as a function of temperature for a SiC photodiode having an active area of 0.04 cm². At a typical operating bias of -1.0 V, the dark current at 473 K is $\sim 10^{-11}$ A/cm². Extrapolated to room temperature, this corresponds to an extremely low dark-current density of $\sim 2 \times 10^{-17}$ A/cm² at a reverse bias of -1.0 V. Comparing the performance of the SiC photodiode to a

Figure 9. SEM micrograph of a typical 6H-SiC photodiode. [Courtesy of Cree Research, Inc. Reprinted with permission from *Phys. Status Solidi A*, **162**, 481, 1997. Copyright 1997 Wiley-VCH Verlag.]

UV-enhanced Si photodiode, we find the SiC possesses a number of advantages. First, the response of SiC peaks near 300 nm and falls dramatically after 400 nm, while that of Si peaks near 900 nm and extends to ~ 1200 nm. Therefore, for many applications, blocking filters are not required to eliminate unwanted visible and near-IR wavelengths in SiC while they are critical in Si. The responsivity of the SiC photodiodes is ~ 0.2 A/W to ~ 0.25 A/W near 300 nm, about the same or even greater than that of UV-enhanced Si photodiodes at the same wavelength. SiC photodiodes can operate with low noise at significantly higher temperatures than Si photodiodes and provide greater

long-term radiation resistance and stability than do Si photodiodes. (The ability to operate at high temperatures depends also on the limitations of the package that houses the semiconductor material and provides for electrical connections.) Recently, a thin-film photodetector utilizing amorphous SiC was reported (26). The photodetector was a $p-i-n$ structure made of hydrogenated amorphous Si and SiC in a sandwich configuration on a glass substrate. A schematic of the photodetector is shown in Fig. 12. Photogeneration of carriers due to UV light absorption occurred only in the α -SiC:H p layer, so the device exhibited good wavelength selectivity in rejecting visible and near-IR light. The primary advantage of this technology is the potential for fabricating low-cost, large-area arrays of photodiodes on a wide variety of substrates.

III-V Nitrides. Wide-band-gap materials that have been intensively studied in recent years are the III-V nitrides, including, in particular, gallium nitride (GaN), aluminum nitride

Figure 12. Schematic of thin film SiC photodetector fabricated using amorphous SiC and amorphous Si on a glass substrate. TCO = transparent conductive oxide film. [Reprinted with permission from *IEEE Trans. Electron Devices*, **43**, 1351, 1996. © 1996 IEEE.]

(AlN), and alloys of the two, $\text{Al}_x\text{Ga}_{1-x}\text{N}$ ($0 \leq x \leq 1$). GaN and AlN are direct-gap materials with band gaps of 3.4 eV and 6.2 eV, respectively, at 300 K. The band gaps of AlGaN alloys are also direct and can cover the range from 3.4 eV to 6.2 eV continuously, depending on the relative concentrations of Al and Ga. Therefore, optical devices developed using these materials will have cutoff wavelengths ranging from 365 nm to 200 nm. Devices of interest include light-emitting diodes and laser diodes in addition to UV photodetectors. The electronic properties of GaN provide for superior solar-blind wavelength selectivity, high dielectric breakdown thresholds, high thermal conductivity, and excellent mechanical hardness. These features offer the potential for operation of solar-blind GaN UV photodetectors without using long-wavelength cutoff filters. Also, these photodiodes may be operated under extreme environmental conditions such as high temperature and high humidity. The realization of such devices has been impeded because of the difficulty of fabricating high-quality intrinsic and *p*-doped materials. For this reason GaN manufacturing technology is still considered an art and is much less mature than that for Si or SiC. Since there is no suitable material that will lattice match it, GaN films are usually grown at high temperature on sapphire substrates. Metal-organic chemical vapor deposition and molecular beam epitaxy techniques can yield high-quality films on sapphire substrates. These have been used to demonstrate exceptionally good solar-blind UV photodetection. The first demonstration of UV photodetection using single-crystal GaN films was reported by Khan and coworkers (27). A photoconductive detector using interdigitated electrodes (due to the extremely high resistivity of GaN) exhibited excellent responsivity for wavelengths shorter than 365 nm and very little responsivity for wavelengths longer than 365 nm, with an extremely sharp cut-off due to the direct gap. This device had a very high photoconductive gain (responsivity > 1000 A/W), but had a long response time (order of ms). It has been found that both the responsivity and temporal response of photoconductive GaN detectors are functions of the incident power (28). This is the result of a competition between distinct recombination processes that involve deep traps within the GaN. More recently, a vertical geometry, transparent GaN Schottky barrier detector that uses front illumination has been described (29). A schematic of the detector is shown in Fig. 13. The vertical geometry of this detector resulted in efficient photocarrier collection and in a substantially improved response time (118 ns for a 50 Ω load). The spectral response of the Schottky photodiode for a -5 V bias is shown in Fig. 14. The response is relatively constant, ~ 0.15 A/W to

0.18 A/W, from 250 nm to the band edge at 365 nm. Although GaN photodetectors are available commercially (30) the fabrication of GaN epitaxial films and the development of photovoltaic and photoconductive detectors is still a topic of intense current research (31–36).

PHOTOEMISSIVE ULTRAVIOLET PHOTODETECTORS

In a semiconductor photodetector ultraviolet light is absorbed within the semiconductor, producing electron-hole pairs that are then separated by an electric field, giving rise to the photoconductive and photovoltaic effects. In a photoemissive photodetector, however, ultraviolet light ejects photoelectrons from the surface of a photocathode, generating a photoelectron current when the photoelectrons are collected by an anode at a positive bias with respect to the cathode. The photoelectron current is proportional to the intensity of the incident ultraviolet light. The spectral response of the detector depends largely on the work function of the photocathode material. Vacuum photodiodes are relatively simple photoemissive detectors that can have subnanosecond time resolution. They are well suited for applications that require the measurement of relatively intense, fast UV light signals (37). A schematic of a windowless aluminum oxide photoemissive photodiode (38) is shown in Fig. 15. The photocathode is manufactured by evaporating a thin film of aluminum onto a quartz disk and oxidizing the surface to yield a thin layer (~ 15 nm) of aluminum oxide. The anode is a stainless-steel ring that is assembled with the photocathode in a Teflon body. The response of this photodetector is quite solar blind, exhibiting a peak at ~ 70 nm and falling to essentially zero beyond 150 nm. The response at the peak is 0.16 electrons/photon, reflecting the fact that while these photodetectors can have high quantum efficiency there is no internal gain.

Photomultiplier Tubes

The primary photoelectrons produced by incident photons at the photocathode can be multiplied to provide a photoemissive detector with high gain. Photomultiplier tubes (PMTs) are photoemissive detectors with very high gain that provide the most

Figure 15. Schematic of windowless aluminum oxide photoemissive photodiode. [Courtesy of the Physics Laboratory, National Institute of Standards and Technology.]

sensitive method for measuring low light levels (39). The principle elements of a PMT are shown schematically in Fig. 16 and include a photocathode, an electron multiplier, and an anode, all of which are contained in a vacuum envelope. A photon impinges upon the photocathode of a PMT, causing a photoelectron to be ejected and accelerated toward the electron multiplier or dynode chain. The initial photoelectron impacts the surface of the first dynode, causing the emission of several secondary electrons, which in turn cascade through the dynode chain resulting in gains of 10^5 to 10^6 secondary electrons per photoelectron. The resulting electron current is detected at the anode. Depending on the rate at which the incident photons arrive, the output of the PMT may appear as short bursts of voltage pulses for low light levels or as a dc current for higher light levels. The most sensitive method for the measurement of low light levels ($N < 10^8$ photons/s) is single photon counting. This method counts the number of photoelectron-generated pulses that arrive at the anode during a preselected time interval. A voltage discriminator is used to discriminate between voltage pulses that originate from the photocathode (signal) and voltage pulses that originate from within the dynode chain (noise). For higher light levels, current measurement methods are used. There are a variety of types of electron multipliers that are used in PMTs including several types of dynode chains, wire mesh dynodes, and microchannel plates. Specific dynode structures are chosen for particular applications, for example, a linear focused dynode chain provides fast response times and

Figure 16. Schematic of a typical photomultiplier tube.

is particularly useful for pulsed measurements, while a box and grid type dynode chain provides excellent photon collection efficiency (40). Wire mesh and microchannel plate electron multiplier structures may be used for position-sensitive detection applications. These types of electron multipliers are particularly insensitive to external magnetic fields, and can be used in environments that are not suitable for most other PMTs. For the specific application of UV light detection, the wavelength response of a PMT is dependent on a number of factors including the window material used to seal the vacuum tube and the composition of the photocathode material. Windows composed of MgF_2 provide transmission down to 105 nm. Other UV-transmitting window materials include LiF, sapphire, and synthetic fused silica, with minimum transmission wavelengths of 115 nm, 145 nm, and 160 nm, respectively. Commercially available solar-blind, UV-sensitive PMTs utilize photocathode materials such as CsI, CsTe, KBr, and RbTe. The spectral response for a photomultiplier manufactured using a CsI photocathode and a magnesium fluoride window (13) extends from 115 nm to 195 nm, with the peak of the response occurring at ~ 120 nm. The spectral response for a photomultiplier manufactured using a CsTe photocathode and a synthetic silica window (13) extends from 160 nm to 320 nm, with the peak of the response occurring at ~ 200 nm. The short-wavelength cutoff for these photomultiplier tubes is determined by the absorption coefficient of the window material, while the long-wavelength limit is determined by the work function of the photocathode material. These UV-sensitive photocathodes are particularly useful for solar-blind detection applications as they are practically unresponsive to visible light wavelengths and can often be used without filters to block background light. Solar-blind PMTs are commercially available from a number of suppliers (12). Other photocathode materials are available with good UV sensitivity, such as bi-alkali, S-20, and S-11 photocathodes, but these are not visible-blind photocathodes, and appropriate wavelength discrimination using filters or monochromators is required to exclude visible light. Generally, although PMTs do not have the high quantum yield of semiconductor detectors, their large gain and low noise are necessary for very-low-light-level applications. Traditionally, the expense, mechanical fragility, susceptibility to magnetic fields, and high-voltage power requirements of PMTs have been important considerations in determining their use. Advances in PMT technology are challenging these traditional considerations as miniaturized PMTs, and PMT modules provide exceptional performance in small, rugged packages (13).

Gas-Filled Phototubes

The gas-filled phototube is another type of photoemissive photodetector that is used for solar-blind ultraviolet light detection applications. In these detectors a dc gas discharge is maintained by a small discharge current from a metal photocathode to a wire anode. When the gas discharge is illuminated with very low levels of ultraviolet light, gas breakdown occurs leading to an increase in the discharge current. The bias current is set near the breakdown condition and the response is nonlinear, exhibiting saturation at relatively low (nanowatt) power. Commercially available gas-filled phototubes (41) have a solar-blind spectral response (185 nm to 260 nm) and are used in flame detectors and fire alarms. Improved gas-filled phototubes have been described more recently (42) that operate without

gas breakdown and are significantly more sensitive than the gas-discharge tubes. These phototubes operate in the prebreakdown regime and detect light by an excited-state photoionization mechanism rather than glow discharge. The responsivity in the ultraviolet region is quite high, 6 A/W at 200 nm using molybdenum electrodes and argon gas, due to the internal gain. The response of these phototubes ranges from 190 nm to 270 nm.

CHEMICAL SENSORS

Chemical sensors are devices that allow for the detection and measurement of individual chemical components, usually from a complex mixture. In practice, the sensor is always part of a larger system designed for the purpose of providing process or product information. This information might be needed for a control loop or quality assurance procedure. The mixture is typically a liquid or gas, but may also be a solid or semisolid

substrate. For example, the pH of aqueous solutions in the presence of dissolved salts can be monitored by an electrochemical device called a glass pH electrode or pH sensor. This chemical sensor responds specifically to hydrogen ions over a concentration range spanning approximately 10 or more decades. The pH reading can then be used to regulate the pH level by the addition of acid or base to the process stream. As another example, gas sensors are available that use optical properties to track oxygen concentration over a wide range of temperatures and pressures. In automobile engines, this might be employed to adjust the fuel–air mixture for better engine performance. Many other examples can be cited since there are potentially as many different types of chemical sensors as there are different molecules. However, a few common sensing strategies and operating principles can be formulated that tie them neatly together. It is logical, therefore, to focus on these strategies and use a few well-developed chemical sensors to illustrate the approaches.

IDEAL CHEMICAL SENSORS

It is convenient to define an ideal chemical sensor as one that operates in an instantaneous, reversible, and absolutely selective fashion without disturbing the composition or other properties of the sensing fluid. In the end, it provides an electrical signal that is precisely calibrated to the composition information. In practice, few of these characteristics are actually achieved; nevertheless, commercial chemical sensors are available with 1994 worldwide market values approximating \$500 million (1). A similar market exists for biosensors (see Biomedical sensors), which we distinguish here from the term *chemical* sensors simply by the method in which the sensing is carried out. If no biological components are used to carry out the sensing, it will be called a chemical sensor regardless of its intended use. The relative importance of the various attributes found in an ideal sensor are dependent on the application in which the sensor will function. Unfortunately, this also tends to cloud the picture of what is meant by a sensor. Two simple examples are given to better highlight the definition.

First, consider a simple device that monitors pH (a measure of the acidity) of a sample using a paper “test strip,” also called pH paper. The person carrying out the measurement would wet the paper by immersing it in a sample of fluid and then examine the color of the strip after a short time period, usually by placing it next to a calibrated color scale supplied with the container that held the test strip. The device gives the pH with a certain degree of accuracy, but it is not a chemical sensor since it lacks features that are important for its utility in a process or product monitoring environment. Its biggest failing is that the sensor provides no direct signal in the absence of the operator. It also has a single-use feature that is not reversible, and it would be more appropriately called a pH measurement device. Therefore, a better definition should include the point that chemical sensors are measuring devices that provide signal output in a continuous or nearly continuous fashion.

In a second example, consider a fluid where we extract a sample and pass it to a sophisticated gas chromatograph (GC) coupled with a mass spectrometer (MS). The gas chromatograph, for our illustrative purpose here, is capable of exquisite chemical separation, and the mass spectrometer is capable of equally

exquisite identification of the separated components. The resulting signal could be used to provide detailed composition information of the fluid and can be subsequently coupled to a control system to better regulate the process being monitored; and, in fact, many chemical production facilities operate with GC/MS devices, as they are popularly known. This is also not what we intend to call a chemical sensor, however, since it is quite simply too “big.” More precisely, the need for sampling the fluid stream and then characterizing it using bench-top analytical instrumentation is usually an undesirable step for process control. The lag times introduced between sampling and subsequent control action, the cost of the equipment, and the inability to position an arbitrary number of such devices at or near the process line severely limit the utility of such otherwise sophisticated approaches. In fact, such steps are often considered for replacement whenever a more practical device, like a chemical sensor, is introduced. Therefore, we amend our definition again by saying that the sensor should provide rapid output of the signal to the process in a cost-effective manner.

A somewhat cumbersome, but inclusive, working definition can now be stated: a chemical sensor is a device that provides quantitative information on the composition of a fluid mixture in a reversible, minimally invasive, selective, rapid, continuous, and cost-effective manner.

In examining different examples of chemical sensors, we will see that many of the designs are refinements and adaptations of strategies that have been known to work effectively in the analytical laboratory. For example, a pH sensor could be developed by placing pH indicators, originally present in the pH paper just considered, on the end of an optical fiber integrated with a compact light source and detector arrangement to overcome the previously cited limitations. Additionally, gas separation steps employing membranes instead of chromatographic operations could be used together with selective electrochemical electrodes to eliminate the unfavorable attributes of the gas chromatograph setup. Nowadays, even miniaturized GC/MS devices operating on a millimeter-scale device (like an analytical lab on a chip) are being envisioned to function as future chemical sensors. The many advantages of microfabrication techniques are being increasingly exploited to produce sophisticated, reproducible, and inexpensive sensing systems. Some of these sensors have no equivalence to any laboratory protocol, and they function as truly unique devices.

GENERAL FEATURES OF CHEMICAL SENSORS

Three general features can be identified that make up a chemical sensor. These include a selective surface, a transducer, and a processor as depicted in Fig. 1, along with some examples of different materials and techniques that can be used for each component. The selective surface allows for a specific interaction with the target analyte, where analyte refers to the compound whose composition or presence is being sought. The surface can be modified by addition of ligands or catalysts that provide specific recognition features. The transducer tracks the association of the surface with the analyte. For example, the transducer may be a polymeric material that changes its electrical resistance with the incorporation of the analyte. Alternatively, the transducer may change color or modify the transmittance of light passing through it. Some signal detection, processing, and amplification are subsequently carried out to generate a

Figure 1. The basic features of a chemical sensor and its interaction with a process system. Representative examples of the three basic components found in any sensor are listed. The target analyte refers to the particular chemical species whose composition information is being sought.

practical output signal used by the process controller. The final signal coming from the sensor is invariably electronic so that it can be conveniently interfaced to standard controllers or data loggers.

The chief limitations of many chemical sensors are associated with the selectivity of the response to the target analyte compared with the response seen for potential background or contaminating compounds. In a constant background there is little need for selectivity, but in a more typical sensing situation the background concentration changes in unknown ways due to the presence of similar chemical components or "active" species as well as temperature and pressure fluctuations. A typical interferent in many gas-sensing situations is the background moisture or humidity level that is constantly undergoing variations.

The main types of chemical sensors developed to date rely primarily on electrical or optical transduction technologies. To a lesser degree, physical transduction processes such as displacement tracking, due primarily to pressure- or temperature-mediated effects, may also be used, but it is often the case that the operation of such devices rely, again, on electrical or optical signal modulation. Within the electrical transducers, it is convenient to divide them into amperometric, potentiometric, or conductimetric sensors depending on whether the measured

signal is the current, voltage, or conductance, respectively. Optical sensors include those that monitor the light absorption, refractive index, polarization, or fluorescence of a transducer, perhaps at many different wavelengths and using continuous or variable light input schemes. The class of electrochemical sensors dominates the worldwide chemical sensors market and, for example, accounted for 88% of the sales share in Japan for all chemical sensors in 1989 (2).

SENSOR TYPES

Electrochemical sensors include the familiar wired electrodes as well as metal oxide semiconducting devices, fuel cells, ion-selective field effect transistors (ISFETs), interdigitated electrodes, high-temperature solid-electrolyte systems, and chemiresistors. Optical sensors include so-called optodes and surface plasmon resonance systems that operate as fiber or planar structured devices. A current trend in many chemical sensors is toward miniaturization and microfabrication that can impart novel properties to sensors, thereby affecting their selectivity, sensitivity, and stability. This introduction does not explore all the latest research variations and innovations but focuses on devices that are commercial or near commercial. Recent research results can be found in specialized journals devoted to chemical sensing and analytical chemistry.

Electrochemical Sensors

Table 1 lists the three main types of electrochemical sensors. They are explored in separate sections below, with specific examples that illustrate the important features. Not all sensors can be exactly categorized in this way since they represent only limiting behaviors. Nevertheless, such distinctions are routinely used and widely adopted in the chemical sensor literature.

Amperometric Sensing. An amperometric chemical sensor is composed, at a minimum, of two metal electrodes maintained at a constant potential (voltage) difference. The current flowing in a closed circuit (which is established and monitored by suitable electronics) through the two electrodes is measured and indicates the presence of "electroactive" species. The relationship between the moles, N , of electroactive species reacted (either oxidized or reduced) and the charge passed through the sensor, Q , is known as Faraday's law:

$$N = Q/nF \quad (1)$$

where n is the number of electrons transferred per mole and

Table 1. Electrochemical Sensor Transduction Mechanisms

Transducer	Mechanism	Signal	Example Sensors
Amperometric	Electron charge transfer reaction (Faraday's law)	Current; due to production or consumption of electroactive species	Oxygen (Clark electrode), some hydrocarbons, hydrogen peroxide, fuel cells, high-temperature limiting-current sensors
Potentiometric	Multiphase equilibrium (Nernst equation)	Potential; due to distribution of ionic species across phases	Glass pH electrode, ion selective electrodes, gas sensors (Severinghaus CO ₂ electrode), some high-temperature solid-state sensors
Conductimetric	Variation of resistance with composition	Conductance or resistance; due to changes in resistive elements with absorption-adsorption events	Metal-oxide-semiconductor gas and humidity sensors, tin oxide gas sensors, conducting polymer humidity and gas sensors, broad specificity sensors

F is the Faraday constant ($F = 96487 \text{ C/mol}$). By monitoring the charge over time, which is the current, the amount of electroactive compounds can be deduced. To operate as a true sensor, however, some selectivity is required, and this can be achieved by the choice of a suitable electrical potential, by the introduction of a catalytic reaction step, and/or through permselective membranes. For example, a common method for the detection of dissolved oxygen in liquids is through the use of a so-called polarographic or Clark electrode. In this chemical sensor, the reduction of oxygen is followed at constant potential by monitoring the current passing between a working Pt (platinum) electrode and a Ag/AgCl (silver/silver chloride) reference electrode. At steady state, the current is proportional to the dissolved oxygen concentration. This is often reported as an equivalent partial pressure corresponding to the oxygen concentration in a gas phase that would be in equilibrium with the actual liquid-phase concentration.

Polarographic Sensors. In order to see how this chemical sensor functions and to draw analogies with many other equivalent systems, we examine the individual components of the device in greater detail. Figure 2 shows the salient features of a Clark electrode. First, in order to achieve some specificity to oxygen, a catalytic reaction is carried out at the cathode. The cathode is typically made of platinum, coated onto a wire or some other underlying support, that catalyzes the following electrochemical reaction,

where E^0 is the standard electrode potential at 25°C for the reaction as written measured against the standard hydrogen electrode. The hydrogen electrode is further described in the next section on potentiometric sensing. The actual reference electrode often used in a Clark oxygen sensor, however, is not the hydrogen electrode, but rather a Ag/AgCl electrode at which

the matching reaction occurs:

The net effect is the reduction of oxygen accompanied by the transfer of electrons at a standard electrode potential difference of about 600 mV. Second, the cathode is separated from the sensing fluid by the presence of an oxygen permeable membrane, usually made of a thin silicone polymer. This allows for oxygen transfer, but it eliminates many other electroactive polar and nonlipophilic compounds that would interfere if they were to be reduced at the cathode surface. The membrane also protects the sensor from fouling due to nonreactive adsorption that can severely degrade its performance. Finally, the anode is maintained at fixed reference conditions by establishing a constant chloride ion concentration. In practice, this is achieved by immersing the reference anode in a fixed KCl salt solution that is separated from the sampling fluid. The actual potential created between the reference and platinum electrodes confers further selectivity to the sensor in that it favors the reduction of oxygen.

The cathode in this example is often called the working electrode and has a surface area much smaller than the anode, or reference (also called the auxiliary) electrode. This ensures that the working electrode limits the current flow in the circuit and, hence, that the current measurements will only reflect reaction steps at the cathode (i.e., reactions with oxygen). The actual working potential is often greater than 600 mV to drive the oxygen reduction as much as possible. If the voltage is too high, however, undesirable electrolysis and corrosion steps can also take place that interfere with the measurement and limit the life of the sensor. A usual choice for the polarographic oxygen sensor (Clark electrode) is around 600 mV to 900 mV, where the working Pt electrode is made negative with respect to the auxiliary electrode. The two electrodes are often housed in an integrated package that provides a compact arrangement of all the necessary parts and allows the electric circuit to be completed on the sensing side of the permeable membrane.

Variations on this strategy for oxygen sensing have been developed that illustrate some alternative detection and sensing schemes. For instance, if a third electrode is introduced, called a "counter electrode," the current measurement can be carried out through a low-impedance circuit path that avoids driving large currents through the high impedance reference electrode (3). This has the advantage of maintaining long-term sensor calibration as well as prolonging the life of the sensor by avoiding corrosion reactions. The typical electric configurations for working with two- and three-electrode designs are shown in Fig. 3.

Galvanic Sensors. Alternatively, the reference electrode can be replaced by a base metal such as lead or zinc. The reaction at the anode (in the case of a lead auxiliary electrode) is now summarized as

This oxidation reaction obviously consumes the electrode over time, but nevertheless maintains a fixed potential that is sufficient to drive the reduction of oxygen. Usually, a silver cathode is used in combination with the base metal anode. Some simplification is introduced since no external potential is required and a direct measurement of the current is proportional to the

Figure 2. Features of an amperometric sensor for detecting oxygen (Clark electrode). The reactions occurring at the two electrodes are separated from the bulk fluid by an oxygen-permeable, nonporous membrane.

Figure 3. Electrochemical sensor configuration for amperometric sensors in two-electrode (a) and three-electrode (b) designs.

oxygen consumed. Such a design is referred to as a galvanic oxygen sensor, and a two-electrode configuration is shown in Fig. 3. In general, polarographic chemical sensors impose a fixed potential between the reference and sensing electrodes while galvanic chemical sensors do not. In both cases, however, the current is measured, and they are collectively referred to as amperometric sensors.

Fuel Cell Sensors. Finally, a “fuel cell” oxygen sensor can be constructed that contains the lead and working electrodes immersed in a basic electrolyte. Here, the anode generates a potential due to the following reaction:

In combination with the cathodic reaction, a net overall stoichiometry can be written as

which does not involve any of the electrolyte species. This is one reason it is often called a fuel cell sensor even though the generation of electricity is used only to obtain an appropriate signal. Again, a direct measurement of the current can be calibrated with the oxygen concentration.

Diffusion-Limited Current. Referring back to the polarographic oxygen electrode, it is instructive to consider the limiting case where the cathodic reaction is sufficiently fast that the oxygen concentration at the cathode surface goes to zero. As depicted in Fig. 2, the membrane will now generally limit the transport of oxygen from the measurement fluid to the electrode surface. Sensors that function under such conditions exhibit the maximum possible signal, all other things being equal, and are said to operate under diffusion-limited conditions. Such an operating protocol also allows for less stringent control over the applied potential. In fact, the potential can be allowed to fluctuate over small ranges without any dramatic effects on the sensor response since the applied potential is already sufficient to reduce all the oxygen at the electrode surface.

The mass transfer through the membrane satisfies Fick’s second law:

$$\frac{\partial p}{\partial t} = D_{\text{O}_2} \frac{\partial^2 p}{\partial x^2} \quad (2)$$

where p is the (equivalent) oxygen partial pressure in the membrane and D_{O_2} is the oxygen diffusion coefficient in the membrane. If we consider a step change in the bulk oxygen concentration from 0 to a value p_{O_2} , the measured current at the cathode surface can be found by integrating the above equation. The solution is

$$i(t) = \frac{4FAP_m}{\Delta} p_{\text{O}_2} \left[1 + 2 \sum_{n=1}^{\infty} (-1)^n e^{-n^2 \pi^2 D_{\text{O}_2} t / \Delta^2} \right] \quad (3)$$

The factor 4 in Eq. (3) reflects the transfer of four electrons per mole of oxygen reduced and A is the cathode surface area, as shown in Fig. 2. The other parameters include the membrane permeability, $P_m = D_{\text{O}_2} S_m$, where S_m is the solubility of oxygen in the membrane. The membrane thickness is Δ and the oxygen diffusivity is D_{O_2} . At sufficiently long times, the current is seen to be directly proportional to the oxygen partial pressure. This is the reading that would be measured at steady state, and the linearity of the steady-state current response with the oxygen partial pressure is a direct consequence of the diffusion-limited nature of the sensor. Furthermore, the time constant for the sensor can be characterized by the dominant exponential term and is conveniently represented as

$$\tau = \frac{\Delta^2}{\pi^2 D_{\text{O}_2}} \quad (4)$$

For a 0.1 mm thick membrane with an oxygen diffusivity of $10^{-6} \text{ cm}^2/\text{s}$, the time constant will be approximately 10 s. Other factors such as poor mixing in the electrolyte solution as well as slow mixing in the external sensing fluid will cause the actual sensor response to be longer. If it is necessary to track oxygen concentration on a much shorter time scale, thinner and more permeable membranes would be needed, or mixing in the external as well as internal regions should be introduced.

Selectivity. Other species besides oxygen can also be detected by analogous procedures. In some cases, a preliminary reaction step is introduced that converts the target compound into oxygen or consumes oxygen at a rate proportional to the concentration of the intended analyte. This allows the sensor just described to be used directly. Many biosensors (see Biomedical sensors) have been developed with this strategy in mind where an enzymatic reaction generates or consumes oxygen. In other cases, appropriate selection of the electrode potential can provide some selectivity. For instance, an amperometric sensor for ethylene (C_2H_4) has been reported (4) that oxidizes ethylene on a gold working electrode (anode). In this case, the gold was deposited on a membrane in order to generate high surface areas, rather than using a membrane to cover a typical wire electrode. The electrochemical sensor configuration was operated with an $\text{Hg}/\text{Hg}_2\text{SO}_4$ reference electrode (cathode) as well as a gold counterelectrode, and a linear current was observed for gas-phase ethylene concentrations between 0 ppm and 500 ppm (1 ppm = 1 “part per million” = 1 molecule or mole per million molecules or moles of gas). However, this sensor exhibits some cross-sensitivity to other electroactive species as shown in Table 2. This indicates that the selectivity of the sensor is such that other compounds can simultaneously contribute to the amperometric response. In this case, the response is evaluated at 10 ppm (or higher) for a variety of gases and is normalized to the response seen for 10 ppm ethylene. Such a ratio is a convenient

Table 2. Selectivity Profile of Ethylene Sensor

Gas Measured (concentration is 10 ppm, unless indicated)	Relative Response (ethylene = 1; 10 ppm)
Acetaldehyde (100 ppm)	0
Acetylene	7.4
CO (100 ppm)	0
Ethanol (100 ppm)	0
NO	1.8
NO ₂	0.3
SO ₂	2.5

measure of the selectivity. The sensor was found to be more selective for some compounds when the response was compared with that seen for ethylene. This implies that it would, in fact, be a better sensor if the target compound had been chosen to be, in this case, acetylene or sulfur dioxide. The consequence of this on the usefulness of the sensor for ethylene detection, however, depends on the intended application. In general, selectivity considerations must always be considered from the point of view of known interferents and expected interferent levels. These factors are prone to change when the application environment changes, and sensors that function well in one situation may turn out to be completely unacceptable in other applications. If it is not likely that known interferents will be present in the sampling stream, the response to those components may be of little consequence.

Potentiometric Sensing. A potentiometric chemical sensor is composed of many of the same parts as an amperometric sensor, except that voltage is measured under conditions of a small, often negligible, current. The most important feature in a potentiometric measurement is that equilibrium conditions are established between electroactive species in solution and at the electrode. This is in contrast to the diffusion-limited condition just discussed for amperometric measurements and leads to relations between voltage and concentration that are logarithmic rather than linear.

Nernstian (Equilibrium) Behavior. The general way to describe the performance of an ideal potentiometric chemical sensor is to refer to it as Nernstian. The derivation of the Nernst equation can be found in many introductory chemistry texts, so we will only outline the important features here for a particular system (see Electrochemical Electrodes). In particular, consider the silver-(porous) silver chloride (Ag/AgCl) electrochemical reaction described previously, but now as a reversible “half-cell” reaction:

The equality of electrochemical potentials for all reactants and products defines the equilibrium state of the system. Under ideal conditions, the electrochemical potential, μ_A^* , of a particular species in solution at a concentration $[A]$ is found from the thermodynamic relation (5)

$$\mu_A^* = \mu_A^0 + RT \ln[A] + zF\phi_A \quad (5)$$

where the brackets denote concentrations, R is the gas constant, T is the absolute temperature, z is the electric charge associated with the ion A , and ϕ_A is the electrode potential.

For any phase consisting of only a pure component, such as the metallic silver wire or the porous silver chloride coating, the electrochemical potential will be a constant at a specified temperature. Thereby, the Ag/AgCl equilibria (referred to also as a “couple”) can be expressed in terms of the chemical and electrical potentials as

$$\mu_{\text{Ag}}^0 + (\mu_{\text{Cl}^-}^0 + RT \ln[\text{Cl}^-] - F\phi_{\text{Cl}^-}) = \mu_{\text{AgCl}}^0 + (\mu_{\text{e}^-} - F\phi_{\text{e}^-}) \quad (6)$$

If we rearrange this equation, collect all terms that are at most a function of the temperature, and introduce $\Delta\phi = \phi_{\text{Cl}^-} - \phi_{\text{e}^-} = \phi_{\text{S}} - \phi_{\text{M}}$ to emphasize that the potential is determined as the difference between the solution and the metal, we obtain

$$\Delta\phi = E^0 - \frac{RT}{F} \ln[\text{Cl}^-] \quad (7)$$

The standard electrode potential is tabulated in many reference books (6) and was used previously in discussing amperometric reactions. It is seen that the potential at a fixed temperature will be a function of only the chloride ion concentration. In a saturated solution containing salt crystals, this is easily maintained at a fixed value and explains why this type of electrode is often used as a reference. The generalization of this expression to any number of soluble species participating in a half-cell reaction can be done using the same sequence of steps. The reaction, of course, must be properly balanced with respect to the stoichiometry as well as the charge.

If an experiment is set up to actually measure the potential predicted by the above equation, it will always be necessary to introduce a second wire (electrode) into the solution to complete the measurement circuit. This second wire is problematic since it can now establish its own potential difference in the solution under investigation and it will generally be impossible to isolate the individual contributions. For this reason, the H^+/H_2 couple has been arbitrarily chosen as a particular half-cell reaction to have a potential of zero (at 25°C). As a result, all measurements comprising a closed circuit with this electrode, called the standard hydrogen electrode (SHE), can be assigned unique values of the standard electrode potential.

For any two electrodes, the net resulting electrical potential will be found from the differences in their half-cell potentials. A cell made of any two half-cells that is balanced with respect to the production and utilization of electrons is called a “formal” cell, and the net reaction is called the formal cell reaction. The production of PbO from metallic lead and oxygen in a fuel cell oxygen sensor is a formal cell reaction, although it is not at equilibrium. It is convenient to summarize the components as well as the physical arrangement of a formal cell by using the following type of cell diagram:

This indicates that the potential difference, for this example, between a mercury electrode (commonly called a calomel electrode) and the silver electrode will be measured. The single vertical bars indicate a different solid or liquid phase that participates in the equilibria. In this case, both electrodes share the same aqueous phase, but this is not usually possible when sensing is to be carried out—since we would already need to know the composition in order to predict the reference potential. For liquids, porous barriers are often introduced that allow

for ion migration, but otherwise limit the bulk flow of aqueous solutions.

From the equation developed previously, we can write the electrode potentials for each half-cell and simply sum them. This eliminates the solution potential from the equations and leads to the Nernst equation, which in general will be expressed as

$$\Delta\phi = \Delta E^0 + \frac{RT}{F} \ln \frac{\prod a_{R_i}^{v_i}}{\prod a_{P_j}^{v_j}} \quad (8)$$

Here we have also introduced the activities in place of the concentrations to make the result applicable to nonideal solutions as well. The exponents v_i and v_j are the stoichiometric coefficients (always positive numbers) for those reactants and products, respectively, that participate as solution- or gas-phase species. The activity, a_i , is related to the concentration by the so-called activity coefficient,

$$a_i = \gamma_i [i] \quad (9)$$

Correlations for the activity coefficient are expressed in terms of the Debye–Hückel limiting law or its extension (7). Components that participate in the reaction as pure phases (like solids) or in great excess (like water) do not explicitly show up on the right hand side of Eq. (8). Experimentally, the measurement of electric potential together with the Nernst equation is often used to determine the activity coefficients of salt solutions.

Glass Electrode and the pH Sensor. By clever choice of electrode reactions and salt solutions, it is possible to construct chemical sensors for various ions that operate on the principles just described. However, poor sensor selectivity often limits such devices to a few specialized situations where the background interferences are fixed. Membranes, however, can offer a means to impart selectivity to potentiometric sensors in much the same way they were used for constructing the Clark electrode. One of the most widely used potentiometric sensors is the glass electrode, or pH sensor, which incorporates a glass membrane to limit the response to being dependent only on the hydrogen ion concentration or, more exactly, on the hydrogen ion activity. Figure 4 shows the construction of a pH sensor. With a suitable reference electrode, say a calomel electrode, the components of the cell can be summarized as

In fact, both the silver/silver chloride and the calomel electrodes can be considered as reference electrodes, and the potential-determining reactions are all confined to the glass membrane. The equilibration of hydrogen ions on the external side (surface) of the glass membrane and the external solution (this is the solution whose pH is sought) is due to an ion exchange with sodium ions in the special sodium/calcium-silicate glasses used. The anionic binding sites are fixed, and at high concentration

Figure 4. The glass electrode (pH sensor). A combination electrode is shown. The glass membrane region is expanded at the bottom of the figure to highlight the notation used in the text.

of sodium ions this leads to the relation

$$\phi_e - \phi_{g,e} = -\frac{RT}{F} \ln \frac{H_e^+}{H_{g,e}^+} \quad (10)$$

where the notation $H_e^+ = a_{H^+}$ is used to indicate the (external) solution activity. The subscript g denotes activities evaluated at the glass surface. At the inside surface of the glass membrane, an exactly analogous relation holds,

$$\phi_i - \phi_{g,i} = -\frac{RT}{F} \ln \frac{H_i^+}{H_{g,i}^+} \quad (11)$$

and, by adding the equations and rearranging, one obtains

$$-\frac{RT}{F} \ln \frac{H_e^+}{H_i^+} = \left[\frac{RT}{F} \ln \frac{H_{g,e}^+}{H_{g,i}^+} + (\phi_{g,e} - \phi_{g,i}) \right] + (\phi_e - \phi_i) \quad (12)$$

The term in square brackets reflects equilibria occurring within the glass membrane but confined to a small region on each surface. It has been estimated that the exchange surface consists of a hydrated layer on the order of 0.1 μm to 1 μm thick, whereas the overall thickness of the glass is typically about 100 μm . Only sodium ions transport charge through the dry glass membrane (no hydrogen ions are transferred through the glass), and they also participate in the surface equilibria. Although not readily apparent, this leads to conditions such that the term in brackets is essentially constant.

The two reference electrodes monitor the internal and external potentials. The last step in developing a sensor is to maintain a constant internal hydrogen ion concentration. This is easily done by filling the inside of the glass bulb shown in Fig. 4 with a solution of, say, 0.1 M HCl since neither hydrogen ions nor chloride ions permeate the glass. Collecting all the

constant terms as ϕ' and using activities, we obtain

$$(\phi_e - \phi_i) + \phi' = -\frac{RT}{F} \ln a_{H^+} = \frac{2.303 RT}{F} \text{pH} \quad (13)$$

The standard definition of the pH has been used:

$$\text{pH} \equiv -\log_{10} a_{H^+} \quad (14)$$

At 25°C, the equation above shows that for every unit change in pH the recorded potential should change by 59 mV ($R = 8.313 \text{ J/K mol}$, $T = 293 \text{ K}$). The selectivity, measured at equal concentrations, of the ion-exchange reaction is always greatly in favor of the hydrogen ion over other competing cations. At low pH and high sodium concentrations, however, the nature of the cation exchange mechanism shows that it will also be a function of the external sodium ion concentration. This usually limits pH sensors to values less than pH = 11. Special "high-pH" glass made of Li_2O (in place of $\text{Na}_2\text{O}/\text{SiO}_2$) can extend the range a few units higher, however.

In practice, the pH sensor is often designed as a "combination electrode" in which the calomel electrode is placed around the internal Ag/AgCl electrode as shown in Fig. 4. The calomel electrode must be exposed to a constant (usually saturated) chloride ion concentration, but it must also have continuous ionic contact with the analyte solution in order to allow for a complete electric circuit. A small porous plug or capillary channel, referred to as a liquid junction and indicated in a cell diagram by a vertical double bar, is used with a very small leakage flow rate to accomplish this. Furthermore, by choosing KCl as the salt, the anion and cation molar conductivities are such that very little additional potential is generated at the liquid junction.

A commercial pH meter includes the glass electrode, a high-impedance voltmeter, and some form of temperature compensation and calibration functions. Temperature compensation is usually built-in according to the predictions of the Nernst equation, and calibration protocols with buffers of known pH are established to account for asymmetry potentials in the glass membrane, reference electrode drift, and nonzero liquid junction potentials. The asymmetry potential arises from surface defects and strain due to production or aging of the glass bulb as well as surface adsorption phenomena. With proper care and operation, a pH meter is almost unmatched among all chemical sensors in its sensitivity, selectivity, dynamic range, and ease of operation.

Gas Sensors. The extension of this sensor to other chemical species or ions can be accomplished in two ways. On the one hand, a reversible reaction can be introduced that selectively generates or consumes hydrogen ions in proportion to the target analyte. On the other hand, membranes with selective permeability to other ions can be used. For the former situation, gas-sensing electrodes have been fabricated that rely on establishing an acid-base equilibrium in a solution exposed to the gas and also contacting a pH-sensing electrode. For example, if CO_2 is allowed to equilibrate in an aqueous solution, the following equilibria will be established:

This leads to the relation

$$p\text{CO}_2 = K a_{H^+} a_{\text{HCO}_3^-} \approx \kappa a_{H^+} \quad (15)$$

where the second equality depends on a constant concentration (activity) of HCO_3^- ion. This is readily achieved by using a 10 mM solution of sodium bicarbonate (NaHCO_3) in the aqueous phase. In practice, the bicarbonate ion is often integrated into the reference electrode that further communicates with the external solution through a gas-permeable membrane. It is also possible to wrap the membrane around the bulb of regular combination pH electrode so that the space between the membrane and the electrode sequesters a carbonate buffer solution. A combination pH electrode is often used in either of these situations since the entire sensing circuit can be placed behind the membrane. Levels as low as 10^{-5} M CO_2 can be detected. One of the most popular uses of this type of electrode is in biomedical applications to monitor arterial blood gases, and in such situations it is often referred to as a Severinghaus electrode.

The gas-sensing principle can be readily adapted to other gases such as ammonia (NH_3). In this case, a 0.1 M solution of ammonium chloride (NH_4Cl) is used in place of the bicarbonate salt. Through a series of equilibrium reactions, the ammonia gas solubility is directly related to the solution pH, and levels of NH_3 down to $1 \mu\text{M}$ can be detected. Table 3 lists some additional gas-sensing strategies for other species that can be coupled to the pH electrode. Other ion electrodes, mentioned below, have

Table 3. Gas Sensors Based on pH Electrodes

Gas Analyte	Equilibria, ($\text{p}K_a$; 25°C)	Lower Limit (μM)	Reference Solution, Sample Condition
Ammonia, NH_3	$\text{NH}_4^+ \leftrightarrow \text{NH}_3 + \text{H}^+$ (9.40)	1	0.01 M NH_4Cl , pH > 11
Acetate, HOAc (Ac = $\text{CH}_3\text{CO}-$)	$\text{HOAc} \leftrightarrow \text{H}^+ + \text{OAc}^-$ (4.76)	1000	0.1 M NaOAc, pH < 2
Carbon dioxide, CO_2	$\text{CO}_2 + \text{H}_2\text{O} \leftrightarrow \text{H}^+ + \text{HCO}_3^-$ (6.38; using $(\text{CO}_2 + \text{H}_2\text{CO}_3)$ in denominator)	10	0.01 M NaHCO_3 , pH < 4
Chlorine, Cl_2	$\text{Cl}_2 + \text{H}_2\text{O} \leftrightarrow 2\text{H}^+ + \text{ClO}^- + \text{Cl}^-$ (multiple equilibria)	5000	H_2SO_4 , pH < 2
Ethanol amine, Et_2NH (ET = $\text{CH}_3\text{CH}_2\text{O}$)	$\text{Et}_2\text{NH}_2^+ \leftrightarrow \text{Et}_2\text{NH} + \text{H}^+$ (9.01)	1	0.01 M $\text{Et}_2\text{NH}_2\text{Cl}$, pH > 11
Nitrogen dioxide, NO_2	$2\text{NO}_2 + \text{H}_2\text{O} \leftrightarrow \text{NO}_3^- + \text{NO}_2^- + 2\text{H}^+$ (1.4–3.2; multiple equilibria)	0.5	Citrate buffer, no SO_2
Sulfur dioxide, SO_2	$\text{SO}_2 + \text{H}_2\text{O} \leftrightarrow \text{H}^+ + \text{HSO}_3^-$ (1.89; includes dehydration)	1	0.01 M NaHSO_3

also been coupled to gas sensing in analogous fashion. Many enzyme electrodes work by further coupling enzymatic reaction steps in the membrane to eventual production or depletion of hydrogen ion, carbon dioxide, or ammonia. This allows for the detection of species that are not directly amenable to potentiometric analysis.

Ion-Selective Electrodes. As mentioned above, the alternative strategy for extending the concept of the glass electrode to other species is to develop membranes that are selective to the species of interest. Glasses have been developed for cations other than hydrogen, although the selectivity is generally much poorer. It is also possible to use (supported) liquid membranes or polymer films for ion sensing by incorporating ion-exchange sites that selectivity bind different target ions. Such ion-selective electrodes (ISEs) are widely used and commercially available. An instructive example is the sensing of potassium cations (K^+) carried out with a diphenylether film containing the ionophore valinomycin. Valinomycin is a cyclic peptide that binds to potassium with strength three to four orders of magnitude greater than that of competing cations such as sodium or ammonium. If the solution containing HCl in the pH sensor design is replaced by KCl and the glass membrane is replaced by the valinomycin membrane, the potential measured with a suitable reference electrode will be, again, 59 mV per decade change in the potassium ion activity. Such sensors have been used as potassium-selective microelectrodes to probe the ion concentration inside single living cells.

When the selective properties of the membrane are not sufficient to reject competing chemical species, the response often deviates from Nernstian behavior as shown in Fig. 5. At low target analyte concentrations, background ions can contribute to the signal through the generation of additional potentials. The exact analysis of such situations is complex and often approximated by the Nikolskij–Eisenman equation:

$$E = \Delta\phi = \phi_{\text{constant}} + \frac{2.303 RT}{z_x F} \log \left(a_x + \sum_i K_{x,i} a_i^{z_x/z_i} \right) \quad (16)$$

The selectivity coefficient, $K_{x,i}$, is defined to represent the contribution to the sensor response for each interfering ion and can be evaluated independently. Note that this equation shows the correct limiting behavior when the solution contains only a single ion, whether that ion is the target compound or an interfering one. Nonlinear calibrations can be used if the background is constant. Figure 5 also shows how the limit of detection is defined for ISEs.

Conductimetric Sensing. The electrical resistance change that accompanies the interaction of a target analyte with a conductive layer (typically a polymer or ceramic) held between two electrodes can also be used to construct a sensor. Such devices are generally known as conductimetric or resistive sensors. They are one of the simplest types of sensor to construct and have been widely used for the past 30 years, predominantly in gas-sensing applications. At the same time, however, they are among the least understood in terms of their selectivity properties. For this reason, many of the applications have been discovered by empirical modifications to various selective layers and to electrode physical design. The result is that conductimetric sensors often require detailed calibration with a variety of potential interferents in order to carefully define the

Figure 5. Deviation of ISEs from Nernstian behavior at low analyte concentrations. The deviation is due to presence of interfering ions. The IUPAC definition of the limit of detection (LOD) for ISEs is indicated by the intersection of the two straight-line extrapolations.

selectivity and be commercially useful. Nevertheless, these sensors are generally inexpensive, and the perceived disadvantages are easily outweighed.

The electrodes in a conductimetric sensing circuit contact the resistive element in such a way that direct-current (dc) or alternating-current (ac) measurements can be taken with the resistive layer exposed to the sensing fluid. Adsorption of the analyte occurs both at the surface and within the bulk of the material, which leads to changes in the electrical resistance. Such measurements can usually be done very accurately. Two particular types of materials have found the widest application in their use as selective layers: metal oxide semiconductors (MOSs) and conducting polymers (CPs).

Metal Oxide Semiconductors. At elevated temperatures (200°C to 600°C) in an oxygen atmosphere, oxygen ions (O^{2-}) are present on the surface of various metal oxides. These ions are formed by extraction of electrons from the oxide material. This electron depletion along with the surface morphology and microstructure will modulate the conductivity. If tin dioxide (SnO_2) is used, for example, the adsorbed oxygen ions will react with a variety of reducing gases to decrease the material resistance. The metal oxide functions as an *n*-type semiconductor in this case, and the underlying solid-state physics has been extensively investigated. The change in resistance can be quite dramatic, and linear responses have been observed over several decades of reducing gas concentration.

The requirement for high temperatures and oxygen (or other donor molecules such as water) leads to their predominance as gas sensors. The high temperature requirement could be met by the environment in which the sensor operates, but is often satisfied by integrating compact electrical heating elements into the design so they can function at room temperature conditions. The heating requirement necessitates a power consumption that is typically on the order of 10 mW. The tin oxide gas sensor (TGS) is the most popular MOS sensor and is produced by a variety of manufacturers. Some representative performance data are shown in Fig. 6 for Scimarec (Tokyo, Japan) gas sensors where the resistance is plotted as a function of gas concentration. Gases with resistance ratios much less than 1 will be easily sensed in a background of clean air.

Figure 6. MOS sensor resistance ratios for target gases and for clean air as a function of the target gas concentration. [From Scimarec Co., Ltd. (Tokyo, Japan) specifications sheet (AF-63 sensor), with permission.]

The range of concentrations from 1 ppm to 1000 ppm is typical of the performance of MOS sensors. It is also seen that different sensor types have differing selectivities. The mechanism for imparting selectivity to the sensor is often not understood at a level to allow for rational design. Nevertheless, selectivity is known to depend on the addition of dopants that promote catalytic reaction steps and affect the semiconductor charge layer. The fabrication method can also change the MOS film thickness as well as the grain boundary profile that results in variable resistance changes. The particular choice of metal oxide (SnO_2 , In_2O_3) or the use of mixed metal oxides ($\text{SnO}_2 + \text{Fe}_2\text{O}_3$) will change the selectivity. The heating cycle can also be adjusted in some cases to dynamically manipulate selectivity. In general, proprietary fabrication and processing

steps distinguish one manufacturer from another. A basic dc circuit diagram that shows how an ethanol MOS sensor (Scimarec AF63) can be integrated with signal processing steps is seen in Fig. 7. The absolute ethanol level is replaced by readings corresponding to ethanol ranges such as low, medium, and high. Some additional features include ready, reset, power, and low battery indicators that make for a practical device.

Conducting Polymers. The use of a conducting polymer in place of an MOS has been recently investigated for many liquid and gas phase applications. The CP films can be made of polymers formed from acetylene, thiophene, pyrrole, furan, phenylene, quinoline, and aniline monomers, as well as their substituted analogs. The key to producing usable sensors is to formulate conditions such that films are easy to process and manipulate. Polypyrrole, polythiophene, and polyaniline, as well as their derivatives, are generally easier to process into thin films than other CPs. Manipulation of polymer properties is done by addition of plasticizers and other constituents either before or after the polymerization process. The films are usually placed between two Pt or Au (gold) electrodes arranged as an interdigitated structure over an inert substrate such as silica. The sorption of vapors or liquid phase components causes swelling of the polymer films and/or modification of the charge-carrier complexes along the polymer backbone that results in either decreases or increases in the resistance. As with MOS devices, extensive calibrations are usually required.

The chemical specificity of CPs is manipulated to a certain extent through the additives used. It is also possible to covalently couple high-affinity ligands to the polymer, and this has been demonstrated with antibodies. Antibodies are biological molecules that have a strong affinity for other proteins, and specific antibodies can be generated for specific proteins. For small target molecules, antibodies are more difficult to obtain, but some success has been demonstrated. Some ultrasensitive applications have been reported (8) for the conducting polymer poly(3-hexylthiophene) when it was used to detect hydrazine

Figure 7. A circuit for utilizing an MOS sensor in the detection of gas-phase ethanol (alcohol).

vapor. This sensor, however, operated as an irreversible device and depended on the cumulative changes in resistance to measure hydrazine vapor concentrations. When operated in such a manner, these devices are often referred to as dosimeters.

Optical Sensors

Optical chemical sensors use interactions with light as the transducer component of the sensor. The current market for optical chemical sensors is smaller than the electrochemical sensor market, but it is a rapidly growing segment. Many of the optical measurements employed in the design of sensors have their basis in analytical spectroscopy and employ optical waveguides to transmit light to and from a suitable detection region. The availability of high-quality optical fiber (cylindrical) waveguides, high-power light sources at a variety of wavelengths, and sophisticated detectors, due primarily to advances in communications technology, has been a primary impetus for, and has greatly accelerated the use of, optical chemical sensors. It is also possible to use planar waveguides as components of optical sensors and these devices have, in fact, been among the first of the optical sensors to be commercialized. Applications that rely strictly on spectroscopic measurements without fiber or planar waveguides are also widespread, but they are not discussed in this overview. The general field of analytical spectroscopy for composition analysis of gases, liquids, and solids is covered in many other textbooks, handbooks, and encyclopedias that are devoted exclusively to the topic.

An optical waveguide is simply a medium through which light is transmitted in such a way that there are distinct light input and output regions. The transmission of light from the input to the output region is done with minimal loss, or the loss is designed to correspond to the sensing capabilities of the waveguide. In the case of a fiber configuration, the waveguide consists of a solid cylindrical “wire” (core) typically made of “clear” glass that is surrounded by a coating (clad) of another material with a different refractive index. Light is transmitted through the fiber by internal reflections as demonstrated in Fig. 8, where the core–clad interface is shown along with the position of a light source and detector. According to Snell’s law, the geometric relationship between refractive index and refraction angle (corresponding to a bend in the light path) is

$$n_1 \sin \Theta_1 = n_2 \sin \Theta_2 \quad (17)$$

Figure 8. Refraction of light at an optical waveguide interface and at the entrance of a fiber waveguide. Light entering (or exiting) the fiber within the acceptance cone will be totally internally reflected. Additional sensor components often include specific choices for a light source and detector, various lenses, gratings, and/or filters.

If $n_1 > n_2$, the refracted angle (measured for the light ray passing into the medium of lower refractive index) can go to 90° , and essentially all of the light will be reflected. Therefore, a critical angle exists that depends on the ratio of refractive indices above which the light will be totally internally reflected. For a borosilicate glass with a refractive index of 1.52 and a quartz clad of refractive index 1.46 [so-called hard-clad silica (HCS) fiber], the critical angle is

$$\Theta_{1,c} = \sin^{-1} \frac{n_2 \sin 90^\circ}{n_1} = 74^\circ \quad (18)$$

Fiber waveguides are made of different types of glasses or plastics, and the variety of possible core–clad combinations lead to different critical angles. Snell’s law can also be applied to the light entrance region of a fiber, and the maximum angle of light that can be directed into the fiber and still undergo total internal reflection can be found. This “acceptance” angle is summarized in terms of the numerical aperture of the fiber, NA:

$$NA = \sin \Theta_0 = \frac{\sqrt{n_1^2 - n_2^2}}{n_0} \quad (19)$$

The numerical aperture is a convenient number to summarize the light collection efficiency of optical fibers and varies between 0 and 1. An NA of 0.5, for instance, corresponds to a 30° angle, which in three dimensions defines an acceptance cone. At the input to a fiber, therefore, NA gives a measure of the light-collecting ability of the fiber, and high NA is preferred. At the output of a fiber, NA describes the cone of light exiting the fiber. Fibers with high NA, however, direct light less well and present problems for coupling to detectors or other fibers where collimated beams are usually desired. Therefore, a compromise may often be needed.

Absorption Sensors. The light passing through an optical waveguide can interact with chemical species present within the acceptance cone of the fiber through absorption phenomena. At different wavelengths, the light is attenuated due to interactions with the electronic, vibrational, and/or rotational energy levels of the molecules. In the visible region (400 nm to 800 nm), electronic interactions dominate while at higher wavelengths (lower energy), vibrational and rotational energy transitions cause light absorption. As light of intensity P passes through an absorbing medium, the rate at which the intensity changes with distance penetrated, l , is directly proportional to both the local light intensity (Lambert’s law) and to the concentration of the absorber, c (Beer’s law). This can be expressed as

$$\frac{dP}{dl} = -kcP \quad (20)$$

This expression is an approximation (despite the use of the word *law*) that becomes more exact for dilute solutions and in the absence of secondary reflection, refraction, or re-emission effects. For a uniform concentration distribution, the integrated form of this equation yields the expression

$$\frac{P}{P_0} = e^{-kcl} = 10^{-kcl/2.303} \quad (21)$$

where the initial (input) light intensity is denoted by P_0 . The ratio of light intensities is commonly called the transmittance (or percent transmittance when multiplied by 100) and the logarithm (base 10) of the transmittance is known as the absorbance, Abs. Thereby, an absorbance value of 2, for example, corresponds to absorption of 99% of the light entering the sample. From this, the Beer-Lambert relation can be found, which conveniently summarizes the absorption of light as

$$\text{Abs} = \epsilon cl \quad (22)$$

The parameter $\epsilon = k/2.303$ is known as the extinction coefficient or molar absorptivity. Different compounds will have characteristic absorption spectra due to the wavelength dependence of the molar absorptivity and this is used for identification as well as quantification. The linear dependence between the absorbance and the concentration can lead to simple quantitative assays for measuring the composition of unknown samples.

Sensor selectivity can be achieved, in principle, by using the inherent spectral features of the target molecule. In most cases, however, additional steps are needed since the spectral features are highly overlapping and it is impossible to account for unknown interferents. As with electrochemical sensors, target specific reactions and membranes have been developed.

pH Optodes. In particular, pH optical sensors (referred to also as pH optodes or pH optrodes) utilize an otherwise transparent membrane film that contains an entrapped pH indicator. In the simplest case, the absorbance properties of the film will then vary as a result of the acid-dissociation equilibrium taking place with the indicator molecules distributed throughout the film. The reaction scheme is

The absorption spectra of the protonated indicator, HI, is different from the absorption spectra of the unprotonated indicator, I^- . Since the equilibrium shifts with increasing or decreasing hydrogen ions, by monitoring the change in the spectra, a calibration can be developed between the absorbance at a particular wavelength and the local pH in the vicinity of the film. The range over which the pH is measured depends on the $\text{p}K_a (= -\log K_a)$ value of the indicator and is usually restricted to one pH unit above and below the $\text{p}K_a$ value. Therefore, the pH optode has a much more limited dynamic range than the glass electrode. Nevertheless, it is of interest in applications where small size and electromagnetic immunity are important.

As an example, consider the (aqueous solution phase) absorption spectra of the pH-sensitive dye 8-hydroxypyrene-1,3,6-trisulfonic acid (HPTS) which is shown in Fig. 9(a) as a function of different solution pH values. By tracking the absorbance at 450 nm, a calibration curve relating pH to absorbance can be easily developed, and this is demonstrated in Fig. 9(b). The absorbance values are conveniently normalized according to the relationship

$$\gamma = \frac{\text{Abs} - \text{Abs}_{\text{prot}}}{\text{Abs}_{\text{unprot}} - \text{Abs}_{\text{prot}}} = \frac{I^-}{I_{\text{tot}}} \quad (23)$$

where Abs is the experimentally measured absorbance at the appropriate wavelength. The subscripts refer to protonated and unprotonated species. An analytical expression can be derived from the definition of the acid dissociation equilibrium constant

Figure 9. (a) The change in absorption spectra of HPTS (aqueous solution) at different pH values. (From R. P. Haugland, *Handbook of Fluorescent Probes and Research Chemicals*, 6th ed., Eugene, OR: Molecular Probes, 1996, p. 557, with permission.) (b) The absorption maxima at 450 nm can be plotted as a function of the pH to generate a calibration curve. The overlap of different curves at 405 nm is seen to be independent of the pH and defines a useful calibration wavelength.

and a mass balance on the total indicator concentration, $I_{\text{tot}} = \text{HI} + \text{I}^-$:

$$(\alpha_{\text{H}^+})K_a^{-1} = \frac{1 - \gamma}{\gamma} \quad (24)$$

This equation can also be written as

$$-\text{pH} + \text{p}K_a = \log_{10} \frac{1 - \gamma}{\gamma} \quad (25)$$

and emphasizes that when $\alpha = 0.5$, $\text{pH} = \text{p}K_a$. A membrane containing the HPTS dye at the face of an optical fiber could function in this way as a suitable pH optode. However, its high water solubility and “blue” (low visible wavelength) absorption spectra make it less desirable for such applications than other dyes that better match the light output available from cheap light-emitting diode (LED) sources and matching detectors. Fortunately, many other dyes are known with a wide range of $\text{p}K_a$ values and absorption spectra. This allows for a broad range of optical as well as chemical characteristics to be designed into a pH sensor. The other feature in Fig. 9, which is seen for many indicators, is the so-called isosbestic point or pH-independent absorption wavelength at 405 nm. By ratioing measurements at 450 nm and 405 nm, a self-calibrating pH sensor can be

designed that accounts for fluctuations in light source intensity as well as degradation or loss of the dye from the membrane phase.

Ion-Sensitive Optodes. The pH optode can also be adapted to the measurement of other cations and anions. The mechanism by which this takes place has been summarized for a wide variety of ion-exchange mechanisms (9). Briefly, if a membrane is designed that contains a pH indicator as well as an adsorption site for other ions (mediated by the incorporation of an ionophore into the membrane), the requirement for electroneutrality causes charged species to move in pairs. If a positively charged cation is adsorbed on the surface, for instance, a proton is exchanged in the opposite direction to preserve electroneutrality. For anionic sensors, a negatively charged anion brings with it the positively charged proton to the surface. In either case, the affinity sites for the ions act together with the absorption spectra of the particular pH indicator to generate a color change. Such optical ion sensors will suffer from selectivity problems, however, in much the same way as the corresponding ion-selective electrochemical electrodes. The selectivity of the pH-sensitive dye for hydrogen ions is usually absolute, but the ionophores chosen for other ions are more flexible in their capacity to bind different chemical species. It is also necessary to independently monitor or fix the pH of the solution to ensure that the measured spectral changes are associated with ions other than hydrogen.

The selectivity for the sensor can be evaluated from a consideration of the following mechanism, which is an expansion of the simpler acid-dissociation scheme written earlier (see pH Optodes):

The subscript f denotes film-associated components, and S refers to the ionophore. This equation is written for an anion exchanger with a stoichiometric binding ratio of 1:1. The indicator, I_f , and the anionic binding site, S_f , are both confined to the film while the hydrogen ion and target anion, X_i^- , can freely exchange with the bulk solution. A similar equation exists for each anion, X_i^- . In this equation, the exchange coefficient, K_{X_i} , plays the same role as the previously described acid dissociation constant to summarize the reaction equilibrium. We also consider only an anion with a single charge of valence = -1 for illustrative purposes. Using an electroneutrality balance together with mass balances on the indicator and ionophore, the relation equivalent to Eq. (24) is

$$(a_{X_i^-})(a_{H^+})K_{X_i} = \frac{1 - \gamma}{\gamma} \frac{\omega_i}{\gamma\beta} \quad (26)$$

where the a_i are the activities and β is the (molar) ratio of indicator to ionophore loaded into the membrane. The fraction of ionophore that is complexed with the target anion is ω_i and $\Sigma \omega_i = 1 - \alpha\beta$.

For a solution containing only an individual anion ($i = 1$), a calibration curve can be developed from these equations and, in particular, the exchange coefficient can be found. A single-ion response function is then defined by

$$a_{X_1}^0 = \frac{1}{K_{X_1} a_{H^+}} \frac{1 - \gamma}{\gamma} \frac{1 - \gamma\beta}{\gamma\beta} \equiv f_1(\gamma) \quad (27)$$

where the superscript on the anion activity is used to emphasize that the response function is measured in the absence of interferents. If the equations are now expanded to consider a solution of competing (interfering) anions with activities a_{X_j} , the result can be compactly expressed as

$$a_{X_1} = f_1(\gamma) - \sum K_{1j} a_{X_j} \quad (28)$$

The selectivity coefficient $K_{1j} = K_{X_1}/K_{X_j}$ is found from experiments with pure component data. This relation is the optical analogue to the Nikolskij-Eisenman equation, Eq. (16), introduced previously for ISEs. It summarizes how the presence of interferents will lead to an overprediction of the target ion concentration if the single-ion response function is blindly used. Similar equations can be developed for solutions of ions with mixed valences as well as for the analogous cation sensor (9).

Gas-Sensing Optodes. It is also apparent that pH optodes can be used for the measurement of gases such as CO_2 and NH_3 in a manner exactly analogous to that described for gas-sensing electrodes. Many patents have been issued, and several commercial designs of optical sensors have been put forward that detail exactly how the light from a fiber waveguide will pass through the measuring sample.

Evanescent Sensors. Light passing through an optical fiber can also interact with the surrounding medium at the core-cladding interface through the so-called evanescent field. This electromagnetic field extends from the interface into the medium surrounding the fiber (or any reflection surface) only a short distance—typically 0.1 μm . Nevertheless, this makes it possible to carry out optical measurements using a fiber in a “closed-loop” configuration. It also allows for the use of membranes that impart selective advantages toward different target analytes while at the same time function as an integral part of the optical waveguide. The light intensity penetrating into the evanescent field is much lower than the intensity found in the acceptance cone region. This is compensated for by using long pathlengths, which are introduced by exposing correspondingly long sections of the fiber to the analyte fluid.

In environmental sensing applications that deal with the measurement of volatile organic compounds in water, hydrophobic membranes can effectively separate and concentrate target analytes from the dilute aqueous background. In fact, the plastic-clad (silicon) silica fibers that are readily available from many commercial sources have been demonstrated to function quite well as “evanescent fiber-optic chemical sensors” (EFOCS) for the analysis of chlorinated hydrocarbons in water (10). Organic species absorbed into the silicon clad interact with the evanescent light field leading to wavelength-dependent light absorption that is characteristic of the composition of the surrounding solution. Figure 10 shows a comparison of the absorbance spectra measured with an EFOCS and with a conventional spectrometer for toluene, trichloroethylene, and trichloroethane. It is seen that long lengths of fiber are needed to generate even small absorbances (note also the $10\times$ scale change) compared with conventional transmission spectroscopy. The spectra are plotted as a function of the wavenumber, ν , which is related to the wavelength, λ :

$$\nu (\text{cm}^{-1}) = \frac{10^7}{\lambda (\text{nm})} \quad (29)$$

Figure 10. Equilibrium EFOCS responses at specified analyte concentration (magnified $\times 10$) and transmission spectroscopy spectra of the pure components measured in a conventional instrument. (From Ref. 10, with permission. Copyright 1997 American Chemical Society.)

Fluorescence Sensors. Absorption of light can also lead to re-emission at lower energies (longer wavelengths). This can take place from an excited, singlet state to the ground level and leads to what is referred to as fluorescence. Applications of fluorescence to chemical sensing using optical waveguides are very similar in terms of the target compounds and mode of operation to those seen for absorbance sensors. One important additional feature, however, distinguishes this type of spectroscopy: The detection of emitted light often takes place against a zero (dark) background. As a result, fluorescence measurements are often done at a high signal-to-noise ratio. In combination with pulsed light sources and phase-resolved signal analysis, very accurate measurements can be taken of very small numbers of molecules. In this way, small changes can be monitored, and fluorescence assays are usually many orders of magnitude more sensitive than competing absorbance-based assays. The previously cited HPTS molecule, for example, emits light via fluorescence when excited at the absorbance wavelengths shown in Fig. 9. Such molecules are referred to as fluorophores and display a separate emission spectrum for each absorbance wavelength. The membrane-based design described earlier can now be used in a fluorescence-sensing mode by separating the incident excitation light from the emitted light using optical filters, gratings, and/or tunable light sources. In fact, by alternately exciting at 405 nm and at 450 nm, a ratioing scheme can also be devised for this type of fluorescence sensor that allows for internal calibration. Fluorescent optical sensors have found widespread application in many biosensing schemes where coupling of enzymatic reactions with fluorescence detection leads to extraordinary selectivity and sensitivity combinations.

Fluorescence quenching is another phenomenon that leads to reduction of the emitted light due to the presence of so-called quenching molecules. Optical sensors have also been designed around quenching effects, and oxygen, in particular, is a well-known quencher molecule. The relation between fluorescence intensity and oxygen concentration, for a constant excitation intensity, is often summarized by the Stern–Volmer equation:

$$\frac{F_0}{F} = 1 + K_{SV}[\text{O}_2] \quad (30)$$

This equation predicts a linear relation between the inverse of the fluorescence intensity, F , and the oxygen concentration, $[\text{O}_2]$. Such quantitative behavior is often seen in practice, but sensors are also empirically adapted to a modified form of the Stern–Volmer equation in order to generate useful calibration functions. The temperature dependence of the Stern–Volmer constant, K_{SV} , is significant, and simultaneous temperature measurement or temperature control is often needed in interpreting results. This is true of any fluorescence-based chemical sensor, and the fluorescence is typically decreasing with increasing temperature. In contrast, the absorbance-based detection schemes are more immune to temperature fluctuations.

As with absorbance-based sensors, evanescent interactions can also be exploited and many of the designs proposed for fluorescence-based assays utilize fluorophores that are immobilized on a short segment of optical fiber at the core–clad interface. The fibers are often tapered to allow for better interaction of the fluorophore with the excitation light and better capture of the fluorescence emission. The thin interfaces that are used in evanescent detection can also lead to faster response times for the sensor compared with situations observed for thick clads.

Refractive-Index Sensors. Optical chemical sensors have been developed that are based on measurements related directly or indirectly to changes in the refractive index. The cladding can be used as a selective adsorbent (typically a polymer) which changes its bulk refractive index due to absorption of target molecules (11). Such a sensor functions as a refractometer, although absolute values of the refractive index are rarely obtained. Measurements of changes in the light intensity are related to the changes in the critical angle for total internal reflection described previously. Light can essentially “leak” from the fiber if the refractive index of the clad increases from its nominal level. The refractive index of the clad also affects the NA value of the fiber that can be observed in the exit light intensity measured for a fixed solid spherical angle. Such refractive index sensors, for example, have been introduced for monitoring aromatic hydrocarbons in groundwater.

Absolute refractive index changes can also be monitored through so-called surface plasmon resonance (SPR) effects.

Surface plasmon resonance occurs when polarized light is reflected off a thin metal film covering a high refractive index material, such as glass, at particular incidence angle and wavelength combinations. Gold is often used to produce the thin film. The resonance effect is observed by rapid attenuation of the light intensity when either the angle or the wavelength of light is scanned across critical values. The critical values will change with the local refractive index at the interface; thus, molecules that adsorb to the gold surface and modulate the refractive index can be detected. A refractive index SPR sensor is most often fabricated on planar (flat) waveguides, but it has also been demonstrated on an optical fiber. Selectivity can be achieved by modification of the surface with specific affinity ligands for the target compound of interest. For example, in biosensing applications, antibodies have often been used for this purpose. One company, Biacore International AB (Uppsala, Sweden), markets instruments based on SPR technology for a variety of biosensor applications. Other designs have also been introduced (12) that utilize compact, integrated electrooptic features.

Sensor Arrays

Selectivity is one of the most important parameters in developing useful sensors (see Fig. 1). This is true for electrochemical as well as optical designs, and much effort has been devoted to fabrication and discovery of specialized surfaces. An alternative approach is to forgo absolute specificity and rely, instead, on simultaneous measurements over many incrementally selective surfaces. These sensor arrays can provide for versatile operation without highly specific interactions taking place. In the detection of volatile compounds and in odor-sensing applications, they are often referred to as "electronic noses." They have been used in analysis of food processing operations, perfumes and cosmetic production, environmental sensing and a variety of other application areas where odor is a recognizable quality indicator. Some companies that produce electronic noses commercially include Alpha M.O.S. America (Belle Mead, NJ), AromaScan (Hollis, NH), and Neotronics Scientific (Essex, UK).

Sensor arrays have been most often developed with conductimetric sensors such as MOS and CP devices. They can also include chemical sensors based on surface acoustic wave (SAW) transduction schemes [see Surface acoustic wave devices], and often a mixture of sensing elements is used to impart the greatest degree of flexibility. The interpretation of signals from such arrays requires extensive calibrations with pure components and/or known mixtures. The signal analysis often uses statistical methods, including principal component and partial least-squares analysis, or artificial neural networks to recover compositional information on unknown samples. Many times, it is sufficient to categorize the mixture in terms of "good" or "bad" or other loosely defined quality descriptors.

For example, a 14-element CP array has been developed that was shown to be capable of discriminating 8 different solvents (13). The CP array was fabricated from the conducting polymer poly(pyrrole), which was blended with 12 different plasticizers and two different combinations of oxidant. The polymers were dip-coated onto interdigitated electrodes, and resistance measurements were simultaneously performed on all elements of the array after exposing the array to an air-vapor gas phase

of fixed composition. The data were analyzed for each array element by a simple binary criteria related to whether an individual sensor element was responding within a given range or not. The (saturated) pure components in air could be distinguished from each other and, with arrays of 19 elements, individual saturation levels as well as binary mixtures in air could also be quantified. The presentation of the data is often done with respect to the principal components, and in this case it was found that three components were sufficient in this particular experiment.

Arrayed sensors represent a rapidly emerging area of chemical sensor development. New coatings and structures as well as new methods for signal analysis greatly expand the role for chemical sensors into applications that were once deemed too complex. The ability to multiplex diverse sensors will continually expand their application to new areas of use. Together with miniaturization and efficient fabrication techniques, it is expected that chemical sensors will, in the near future, become pervasive in industry, medicine, the environment, and indeed everyday use.

INTELLIGENT BIOSENSORS

BACKGROUND

In the past decade, there have been a number of reports on self-assemblies of molecules as “advanced materials” or “smart sensors”. Without question, the inspiration for this exciting development comes from the biological world, where, for example, the lipid bilayer of cell membranes is among the foremost self-assembling system. Although the first reports on self-assembled bilayer lipid membranes (BLMs and liposomes) appeared in the 1960s (1), experimental scientists have been dealing with BLM-type interfacial adsorption phenomena since Robert Hooke’s time (see Table 1). BLMs (planar lipid bilayers) have been used in a number of investigations ranging from basic membrane biophysics to the conversion of solar energy via water photolysis, and to biosensor development using supported bilayer lipid membranes (s-BLMs). A cogent reason that self-assembled BLMs and liposomes are of sustained scientific and practical interest is due to the fact that most physiological activities involve some kind of lipid bilayer-based ligand-receptor contact interactions. For instance, by embedding a receptor or a host of specific entities in a supported BLM, it is possible to create a sensor that will interact with its environmental counterpart. In the accompanying figure (Fig. 1), an overview is presented. From the top of Fig. 1, soap bubbles were among the first ultrathin films quantitatively characterized, from which the origin of the lipid bilayer concept of cell membranes and its experimental realization, as we know it today, can be traced (1). This is shown in the center of Fig. 1. In this connection, electrical activities of the nerve and photoelectric effects in photosynthesis have been elucidated with the aid of experimental planar BLMs and liposomes. In nerves, translocation of ions across protein channels embedded in the lipid bilayer play the pivotal role. In photosynthesis, light absorption by pigments, confined in the lipid bilayer, initiates electronic charge generation and separation, leading eventually to redox reactions on opposite sides of the membrane. Presently, electron and charge transfer processes through the lipid bilayer are being actively investigated, from both theoretical and biotechnological viewpoints. The crucial role played by the lipid bilayer may be summarized as follows. Living organisms are made of cells bound by their membranes. As we know them, living beings are self-assembling entities, each is organizing a particular combination of phospholipids in the form of a bilayer with other constituents (e.g., proteins) embedded in it. This lipid bilayer, existing in all biomembranes, is most unique

BLM = Bilayer Lipid Membrane

Figure 1. Ultrathin films, biomembranes, and applications (an overview).

in that it serves not merely as a physical barrier but functions as a two-dimensional matrix for surface reactions, as well as for transmembrane processes. The lipid bilayer acts as a conduit for ion transport, as a framework for antigen-antibody binding; as a bipolar electrode for redox reactions; as a reactor for energy conversion (e.g., light to electrical and/or to chemical). Further, a modified lipid bilayer performs as a transducer for signal transduction (e.g., molecular sensing), as well as numerous other functions (1–6). All these myriad activities require the ultrathin (~5 nm) lipid bilayer which is the focus of our research. Many attempts have been made to develop biosensors and molecular devices based on planar BLMs; the task has been a daunting one until a few years ago (7,8), since a 5 nm thick BLM is an extremely labile structure with limited lifetime. Planar BLMs can now be formed on various substrates with long-term stability, thereby opening the way for basic research and development work. Before explaining the lower portion of Fig. 1, mention should be made concerning the self-assembly. Nature uses self-assembly as a strategy to

create complex, functional structures such as viral protein coatings, and DNA, besides the above-mentioned *lipid bilayer* of cell membranes. Supported BLMs, formed on metallic wires, conducting SnO₂ glass, and hydrogel substrates, as well as on microchips, possess properties resembling biomembranes. These self-assembled, supported BLMs, have opened research opportunities in studying hitherto unapproachable phenomena at interfaces. Some recent findings demonstrate potential for investigating processes at solid-liquid interfaces (1–6,8). Possible applications include catalysis, corrosion, electrochemistry, lithography, and membrane biophysics (9–15). In the lower portion of Fig. 1, the focus is on *Integrated Lipid Bilayer System*, from which research endeavor is divided into three related areas, namely, membrane biophysics, biosensors, and microelectronics. These are delineated below under separate headings.

Membrane Biophysics. In connection to information processing of the brain, i.e., “How does the brain work?” This is based on the fact that living beings possess excellent mechanisms for recognition, learning, memory, and inference. Understanding the mechanisms will bring about a novel architecture for information processing that is quite different from current computing systems. Experimentally, we have studied the olfactory system of an animal (e.g., frog) whose system is oscillatory neural network, with which highly parallel and distributed information such as odors are processed (1). Concurrently, we would like to carry out molecular simulations using a modified planar lipid bilayer to gain insight at the molecular level (9,14–17). Here, perhaps the concept of force measurement on the nanometer scale, and the method developed to evaluate them would provide a quantitative logic to ponder about the new ways in which molecules behave at nanometer distances.

Biosensors. The research is based on the lipid bilayer from which system sensor concepts can now be advanced. The lipid bilayer provides an environment for receptors similar to the biomembrane (such as immune receptors, growth factor receptors, cytokine receptors, etc). For example, currently most microbiological tests are centralized in stationary laboratories because complex instrumentation and highly qualified technical staff are required. Traditional methods for the detection of bacteria involve at least four basic steps (2–4,18,19). Hence, a complex series of tests is often required before any identification can be confirmed. These methods are often slow (up to 72 h), and may vary in time since the development of a colony containing 10⁶ organisms will take 18–24 h. With the availability of s-BLM probes coupled with microelectronics techniques, an entire new approach is ripe for molecular sensing. The plan is to decentralize the above mentioned procedures using s-BLMs, so that they can be performed virtually anywhere and under field conditions. The long-term goal is to develop a novel type of an electrochemical biosensor for label-free detection of bacteria in real-time (<10 minutes) for medical and environmental application with immediate on-the-spot interpretation of the results. The goal is to achieve extremely high selectivity and sensitivity (5–20 bacteria per sample). Concurrently, working closely with our colleagues in microelectronics, a small analytical device for on-site monitoring of different kinds of pathogenic bacteria in air and water will be studied. Previous results have demonstrated the suitability of the electrochemical approach for the label-free measurements of specific bimolecular interactions. The biosensor will exploit the phenomena of the trans-

membrane ion-current modulation of biospecific interactions in the solid-state surface layer (1–4). Detection of channel opening or closure will be realized directly by monitoring a transient change. Nonspecific binding at a biospecific membrane does not interfere with the ion flux through ion channels. Theoretically, the sensitivity of such a device can approach one molecule. This principle could be also applied as a strategy for sensor design using BLM-doped receptors or ligands.

Microelectronics. The use of a strip thin-film microsystem, based on the silicon diaphragm or glass substrate, is progress. Experiences with thin-film heater and planar interdigital array of electrodes have been reported (20–22). The thin-film and silicon micromachining techniques are compatible with microelectronics IC technologies that allow a further development toward smart sensors, based on the supported s-BLMs. Ideally, one would like to develop a metal/BLM/liquid integrated system that functions as a transducer-actuator. A suitably modified BLM-bifacial can receive appropriate information, act upon it, and initiate a response. In physicochemical terms, a ligand interacts, with a lipid bilayer-bound receptor, resulting in a signal. This signal is transduced from the contact interaction into an electrical output, which in turn actuates a chemical or a physical process. The stimulus for interactions might be electrical, mechanical, light, or chemical, with the electrical perturbation most elegant and easy to control and manipulate. The electric field across the BLM/bifacial is very sensitive to bifacial tension and BLM thickness, which are in turn susceptible to the embedded compounds. Externally applied electric fields act on the BLM/bifacial by inducing surface charge and by creating transient pores, although the exact process is still obscure and remains to be studied (10,13). In this connection, according to solid-state physics, when electrons are confined in a narrow space (i.e., a lipid bilayer) comparable to an electron wavelength, the electrons are subject to interrelated quantum effects, size quantization and resonance. The former causes the continuum of energy levels that usually exists in the conduction band of a solid to become articulated into discrete energy quanta or states. A planar lipid bilayer, a self-assembled supramolecular structure is microscopic in thickness (~5 nm). Such a structure is in a liquid-crystalline state, and inherently dynamic. Upon modification with compounds (e.g., fullerene C₆₀), non-linear electronic behavior and photoelectric phenomena may be examined for unusual quantum-size effects. Thus, a supported BLM is a research area of many exciting possibilities, since it is the dynamic lipid bilayer surface that enable our senses to contact with the environment (1). For our senses, lipid bilayer-bound receptors are involved. These are rod and cone receptors for vision, olfactory bulbs for smelling, tectorial cells for hearing, taste buds for tasting, and nerves for touching. From environment to the brain, signal transduction and information processing must be transmitted in a language that the brain can understand. Insofar as can be ascertained, this language is electrical, for most part based on the translocation of ions and electrons. Protein-channels and electron transfer chains, embedded in the lipid bilayer, are the keys to our understanding (1).

It is worth pointing out that, with all other systems, the entity of interest is immobilized in a rigid, solid-like structure (e.g., polymers, L-B films), whereas in the BLM it is embedded. By embedding is meant that the entity of interest (i.e., membrane modifiers such as polypeptides, proteins, electron acceptors, donors, tissues or whole cells) in the lipid bilayer

is relatively free to adapt to its surroundings. The functions of lipid bilayers are mediated via specific modifiers, which assume their active conformations only in a hydrophobic lipid environment (11,13,14,23,24). Further, the presence of the lipid bilayer greatly reduces the background noise (interference) and effectively excludes hydrophilic electroactive compounds from reaching the detecting surface, thereby causing undesired reactions. The development of conventional BLMs (planar lipid bilayers) and later s-BLMs and sb-BLMs, have made it possible for the first time to study, directly, electrical properties and transport phenomena across a 5 nm ultrathin structure separating two phases, in particular as models of biomembranes. As a result of extensive studies over the past four decades, biomembranes have now been recognized as the basic structure of Nature's sensors and molecular devices. To impart relevant functions in BLMs, a variety of compounds such as ionophores, enzymes, receptors, pigments, tissues, and so on have been embedded. Some of these incorporated compounds cause the BLMs to exhibit non-linear phenomena and photoelectric effects (25–29). The self-assembled lipid bilayer, the most crucial component of all biomembranes, is in a liquid-crystalline and dynamic state. A functional cell membrane system, based on self-assembled lipid bilayers, proteins, carbohydrates and their complexes, should be considered in molecular and electronic terms; it is capable of supporting ion and/or electron transport, and is the site of cellular activities in that it functions as a "device" for either energy conversion or signal transduction. Such a system, as we know intuitively, must act as some sort of a transducer capable of gathering information, processing it, and then delivering a response based on this information. Today, planar lipid bilayer research is a matured field of endeavor, as a result of applications of many disciplines and techniques including interfacial chemistry, electrochemistry, patch-clamp techniques, spectroscopy, microelectronics, and others. In membrane reconstitution experiments, for example, the evidence is that intracellular signal transduction begins at membrane receptors. The research area covered in this paper is highly interdisciplinary. Emphasis has been placed on basic research. The past work has been benefited by a cross-fertilization of ideas among various branches of sciences. The biomimetic approach to practical applications is unique and full of exciting possibilities. We can glean the design principles from Nature's successful products and apply them to our research and development, from which molecular medicine and advanced biosensors may ultimately depend. It should be stated that manipulating and controlling conduction processes of an integrated lipid bilayer system at the nanometer dimension remains a challenge for both experimentalists and theoreticians. From specificity, selectivity, and design points of view, a supported planar lipid bilayer is an ideal natural milieu for embedding a host of materials of interest. For example, mention should be made concerning a most unique group of compounds, namely fullerenes that are of interest in materials science. Fullerene C_{60} , for instance, is an excellent electron mediator and behaves as n-type semiconductor. It is strongly hydrophobic. Hence, a BLM is an ideal environment for the compound (12,17,24,30–45). We, along with others, have investigated electron transfer across an s-BLM containing C_{60} , which can act both as an electron carrier and a photosensitizer. In this connection, fullerenes are expected to play an important role in photodynamic therapy and device development in the coming years. Finally, it should be stated that manipulating and controlling conduction

processes of an integrated lipid bilayer system at nanometer dimension, a system of choice remains a challenge for both experimentalists and theoreticians.

OVERVIEW OF A BIOSENSOR

The interaction of biophysics with cell physiology and molecular biology has given rise to an exciting area of research termed membrane biophysics, which integrates up-to-date findings on molecules and processes involved in inter- and intracellular recognition and communication. Knowledge of the ideas and findings resulting from such interdisciplinary research are now being used for practical applications in analytical chemistry, immunology, photobiology, chemical/biological sensors and transducers, and molecular electronics.

What is a Biosensor?

A biosensor is an analytical device incorporating biological and chemical sensing elements either intimately connected to, or integrated with, a suitable transducer, enabling the conversion of concentrations of a specific species into digital electronic signals. A majority of the biosensors developed thus far have incorporated an enzyme as a biological recognition component. For example, all types of enzyme sensors are based on the classic idea which measures glucose by detecting the reduction in oxygen when the oxidation of glucose is catalyzed by the enzyme. To date, there are many substrates that have been studied by the use of oxidoreductases, and the majority of the enzyme biosensors have been designed specifically for the determination of a large number of "cardiac" enzymes in blood.

Tissue materials from plant and mammalian sources have been successfully employed for the construction of biosensors as well (46). This class of biocatalytic materials simply maintains the enzyme of interest in its natural environment (e.g., lipid bilayer), which results in a considerable stabilization of the desired enzymatic activity.

The microbial sensors are composed of immobilized microorganisms and an electrochemical device and are suitable for the on-line control of biochemical processes. These sensors involve the assimilation of organic compounds by the microorganisms, change in respiration activity, or production of electroactive metabolites. These changes have been monitored directly by an electrochemical device.

The sensitivity of electrical measurements developed for the electrochemical biosensors, coupled with the specificity of antigen–antibody reactions, provides a useful tool for immunology. However, more recently, the optical sensors for immunoassays have been receiving considerable attention in research laboratories and also *in vivo* applications. Among different types of optical biosensors, two types appear to be especially promising. One is based on a surface plasmon resonance phenomenon, and the second one is a fluorescence capillary fill device. Surface plasmon resonance in a thin metal film deposited on a wave guide can be induced by an electromagnetic wave generated when the light is reflected within the wave guide, and it is highly sensitive to variations in the refractive index of the immediate surrounding medium. This phenomenon is monitored by a reduction in the intensity of the reflected light (47).

Biosensors: Diversity and Development

Generally, the biological components used in a biosensor construction can be divided into two categories: (a) those where the primary sensing event results from catalysis (such as whole microorganisms, tissue slices, organelles, and enzymes) and (b) those which depend on an essentially long-term binding of the target molecule (i.e., cell receptors, nucleic acids, and antibodies). The essential element, however, in making a successful biosensor is to provide a suitable immobilization procedure for biological compounds. Five main approaches to enzyme immobilization have been employed: (1) physical adsorption at a solid surface, (2) entrapment in polymeric gel or within microcapsules, (3) cross-linking by means of bifunctional reagents, often in combination with (1) and (2), (4) covalent binding to a reactive insoluble support, and (5) embedding in a lipid bilayer. This last-mentioned approach is unique in that embedding means that the compound(s) (membrane modifiers such as electron acceptors, donors, mediators, polypeptides, proteins, etc.) of interest in the lipid bilayer is relatively free to adapt to its surroundings. The functions of biomembranes are mediated by specific modifiers, which assume their active conformations *only* in the lipid bilayer environment. Furthermore, the presence of the lipid bilayer greatly reduces the background noise (interference). It also effectively excludes hydrophilic electroactive compounds from reaching the detecting surface that may cause undesired reactions. From the specificity, selectivity, speed of response, and design points of view, a supported planar bilayer lipid membrane (s-BLM) is an ideal natural environment for embedding a host of materials of interest. Hence, the s-BLM system offers a wider opportunity for the biosensor development (48). In the following we shall be mainly concerned with the electrochemical biosensors based on supported BLMs using electrical detection methods.

In practice, researchers continue to search for ideal combinations of biocatalysts—enzymes, antibodies—antigens, bacteria, plant slices isolated receptors, and even whole cells. In this context, genetic engineering technology will have a role in improving the biological component of enzyme-based and whole cell biosensors. Materials science and chemical engineering are instrumental in finding solutions for such problems as suitable immobilization procedures, transducers, and the effective coupling of the biological component to the transducer and the subsequent amplification system. The main types of transducers used in biosensor construction are listed in Table 2.

Table 2. Types of Transducers and Measurements Used in Biosensor Technology

Transducers	Measurement
Oxygen electrode	Electrochemical
Ion-selective electrode	Potentiometry
Modified metal electrode	Amperometry
Field-effect transistor	Conductimetry
Conductometry	Impedometry
Spectrophotometry	Photometric
Laser light scattering	
Optical fibers combine with absorption and fluorescence	
Surface plasmon resonance	
Thermistors	Thermometric
Piezoelectric crystal	Acoustic
Surface acoustic wave device	

Although in recent years a variety of different biological components have been used (46), it is by no means certain that all possible combinations of sensing elements and transducers have been explored.

The main challenge to the scientist in biosensor technology is to find an effective coupling of the biological component to the transducer. This is particularly important in the development of amperometric biosensors, since conventional “clean” metal electrodes are generally very poor voltammetric electrodes for the direct oxidation or reduction of biological components. A host of approaches to the modification of electrodes have been developed and investigated. All those methods, however, can be divided into two groups: (a) the modification of the electrode surface by depositing a monolayer, which is based upon either the adsorption of species at the electrode surface or a covalent attachment of redox mediators to the electrode, and (b) the modification by a multilayer, which is most frequently achieved by the use of polymeric modification of the electrode or sometimes by a vapor-phase deposition. The use of mediators in conjunction with oxidoreductases is not a recent innovation. Molecules such as quinones, organic and inorganic ions, and redox dyes have all been used. More recently, a novel electrode based on highly conducting metals and polymeric electron transfer mediators has been used. A practical mediator, however, should fulfill certain criteria. One of the most successful classes of electron mediators have been highly conjugated compounds such as ferrocene (bis-cyclopentadienyl iron), tetracyanoquinodimethane (TCNQ), tetrathiafulvalene (TTF), and their derivatives. However, very recently, avidin biotin coupling arose as a promising method for preparing enzyme-based biosensors (46,49).

Recent success in the interdisciplinary research in biology combined with electronics has led to exciting new developments based on enzymology and transducer techniques. They are known as enzyme electrodes, enzyme thermistor, CHEM-FET/ENFET devices, and immunosensor or enzyme transistor. Collectively, they are called “biosensors or biochips” (50). A common feature of all these devices is a close connection between the enzyme and the transducing system, which is used to follow the enzymatic reaction. The essential principle of the devices, broadly speaking, is predicated on the ligand–receptor contact interactions (51). Application of such developments in the fields of medicine, pharmaceuticals, biochemistry, environmental settings, robotics, and the food industry are obvious. For example, enzyme thermistors make use of the heat which is liberated during an enzymatic reaction. Their usual sensitivity is around 0.01°C. A recent modification of enzyme thermistor is the “TELISA” electrode, which achieves a sensitivity of about 10^{-13} M using an immunoabsorbent. It is expected that this measuring technique will find a broad application in continuous measurements of the release of hormones and/or antigens–antibodies in blood circulation. The quick attainment of a new steady state in the reaction occurring at an enzyme electrode after a random perturbation makes the latter ideally suited to monitor an industrial process (e.g., the production of antibodies). Classic calorimetric methods require much more time than an enzyme thermistor assay to perform a quantitative analysis. Two other interesting developments are ellipsometry and piezoelectric crystals. In ellipsometry, a close connection between the enzyme and the transducing device is not required. The method relies on the change in the angle of polarization of incident light which is reflected by a layer of

biomolecules bound to a solid surface. A change in the thickness and conformation of this layer, under the influence of other macromolecules interaction with the layer, can be easily monitored. This principle is now used in the fermentation industry. Piezoelectric crystals can be used in the analysis of the traces of certain compounds, mainly anesthetics. The frequency of the crystal depends strongly on the absence or presence of adsorbed molecules on the surface of the crystal (52). The selectivity of crystals toward a given compound may be increased by a coating process (e.g., with hydrophobic substances such as oils and fats).

Another exciting new research area is the combination of semiconductor technology with enzymes and other biological macromolecules. Here, mostly field-effect transistors (FETs) are used. If sensitivity of a FET toward certain chemicals or ions can be achieved, the prototype of an "ISFET" is born. A common feature of all these devices is the use of metal oxide semiconductor (MOS) structure. In combination with a thin layer of palladium, a high sensitivity toward gaseous hydrogen can be achieved. In this case, the membrane separates the gaseous from the liquid phase. Addition of traces of certain metals (e.g., Ir) to the Pd-MOS device also increased its sensitivity toward ammonia. It has been shown that such a device is capable of monitoring reliably the production of hydrogen by microorganisms (e.g., *Clostridium acetobutylicum*).

Lipid-Bilayer-Based Biosensors

The basic unit of all living organisms is the cell. Each cell is bound by a limiting plasma membrane, the fundamental structure of which is a lipid bilayer modified with proteins and carbohydrates. This is so because of the unique property of the lipid molecule: One end of the molecule is hydrophilic with a strong affinity toward a medium of high dielectric constant, while the other end of the molecule is hydrophobic, which is sequestered away from the aqueous solution. We now know that the remarkable stability of a lipid bilayer is due to the combination of hydrophilic and hydrophobic forces, which makes the lipid bilayer a thermodynamically favored structure (53).

The living cells undertake intercellular communication, which take place across as well as between cell membranes. The intercellular communication is mediated by the signal-transducing system, which is undertaken by various sensitive biomolecules (or sensor molecules) such as enzymes, ion channels, receptors, and carriers. These sensors *in vivo* serve as communicators to send, receive, transfer, and decode signal to adapt the cell to the changed environment. This ability of living cells is so-called biosensitivity. These signals are generally electrical and chemical in nature, predicated upon the presence of membrane. From the viewpoint of membrane biophysics and physiology, biological membranes are essentially the supporting matrix of the nature's sensors and devices (48,49), and the cell membrane plays a crucial role in signal transduction, energy conversion, and information processing. This is due to the fact that most physiological activities involve some kind of lipid bilayer-based ligand-receptor contact interactions. Outstanding examples among these are ion sensing, antigen-antibody binding, light conversion and detection, and gated channels, to name a few. For example, the thylakoid membrane of green plants functions as an energy transducer converting sunlight into electrical/chemical energy, the photoreceptor membrane

of a rod's outer segment detects photons as the initial step in visual perception, and the plasma membrane of cells and organelles possess the ability for ion sensing—for instance, differentiating Na^+ and K^+ with a great specificity. Furthermore, the plasma membrane provides sites for a host of ligand-receptor contact interactions such as antigen-antibody formation (47–49).

These outstanding characteristics have contributed to the discoveries of two artificial bilayer lipid membrane systems—namely, planar BLMs (7) and spherical liposomes (54)—in 1960s. The seminal work on the self-assembly of planar, bilayer or "black" lipid membranes (BLMs) was carried out by Rudin and his associates in 1959 to 1963. The idea started while one of the authors was reading a paperback edition of *Soap Bubbles* by C. V. Boys (55). These early researchers realized that a soap film in air in its final stage of thinning has a structure which may be depicted as two monolayers sandwiching an aqueous surfactant solution. Rudin and co-workers showed that an under water "soap bubble" (i.e., a BLM formed from brain extracts) was self-sealing and resistant to puncture and had many physical and chemical properties similar to those of biomembranes (7,47). Since then, techniques have been developed to incorporate a wide variety of compounds into BLMs to endow them with desired properties. As a result of the efforts of many investigators (56–59), biologically relevant phenomena such as ion selectivity, excitability, antibody-antigen reactions, active ion transport, and photoelectric effects have all been demonstrated.

In recent years, numerous attempts have been made to exploit the BLM system's potential in practical applications in sensor (46). Advances in microelectronics and interest in ultrathin organic films, including the BLM, especially the newly developed self-assembled bilayer lipid membrane (s-BLM) on a nascent metallic surface (60), have resulted in a unique fusion of ideas towards the development of intelligent biosensor and transducer. Furthermore, recent trends in interdisciplinary studies in chemistry, electronics, and biology have led to a new field of scientific-technological endeavor which is a part of a more general approach toward the development of a new, post-semiconductor electronic technology, namely, molecular electronics with a long-term goal of molecular computers (61).

SELF-ASSEMBLED LIPID BILAYER: TECHNOLOGY AND MEASUREMENT

Techniques of Planar BLMs and s-BLMs

The history of the BLM system and its development as a model for biomembranes has been recounted elsewhere (7). It should be mentioned that there is one major difference between Langmuir-Blodgett (L-B) film layers on rigid substrates and the BLMs. Apart from its bimolecular thickness, a BLM is a liquid-like, dynamic structure in a metastable state from a self-assembling point of view; it is envisioned that for long-term stability, a BLM separating two aqueous solutions requires the presence of a Plateau-Gibbs border. For biosensor development, it is our opinion that a fluid bilayer is of crucial importance. The aim of this section is to describe in sufficient detail how to set up a simple BLM system using the self-assembling techniques (see Table 1).

Conventional Planar BLMs. An experimental BLM, composed of either a mixture of 1% phosphatidylcholine and cholesterol in *n*-decane or oxidized cholesterol (ox. chol.) in *n*-octane, is formed in an aperture (diameter from 0.1 mm to 2 mm depending on the experimental requirement) punched in the side of a 10 ml Teflon cup which sits in an outer chamber of 20 ml volume. Before the introduction of the lipid solution, both chambers are filled with 0.1 M KCl. The lipid solution is then injected over the orifice of the Teflon cup in the bathing solution with a micro-syringe. The lipid solution should cover the opening over the entire orifice. One should see the light reflected from the thinning lipid film with iridescent color patterns. These colors gradually disappear as the membrane thins, and the membrane appears "black" when a BLM is finally formed. That is because such an ultrathin planar BLM possesses two interfaces and its thickness is less than 7 nm compared to the wavelength of visible light, and the membrane appears "black" because the light reflected from the front interface undergoes a half wavelength phase shift and interferes destructively with the light reflected from the back interface, which experiences essentially no phase shift. The BLM formation is monitored by the increase in membrane capacitance via a pair of Ag/AgCl electrodes. Electrical parameters of the BLM are measured with a high gain electrometer and a picoammeter. A number of simple setups for the BLM study have been published (7,62), and several comprehensive reviews on the subject are available (56–59).

Supported Bilayer Lipid Membranes (s-BLMs): The New BLM System. Since BLM's inception in 1960, many modifications have been made to the original BLM technique, with one notable exception to be described below, but the essential principle has remained the same. A BLM formed in the conventional manner (as described in the last section) is an extremely fragile structure with a limited lifetime. For long-term basic studies as well as for technological applications, the common concern has been the mechanical stability of the BLM. Although a number of improvements have been made to prolong the lifetime of the BLM, they rarely last longer than a few hours. For protracted studies and practical applications such as in biosensors and molecular electronic devices development, a long-lived BLM is a prerequisite. For this reason, it is both desirable and imperative that a method be found so that long-lasting BLMs can be generated. In 1989, a simple and novel method was reported for the formation of self-assembled BLMs on solid substrates, which possessed the desired dynamic properties and the requisite mechanical stability (51,60).

The principle and potentialities of the original method of the s-BLM probe construction are as follows. The two-step procedure consists of the adsorption of lipids from a BLM-forming solution on a nascent metal surface followed by the immersion of the lipid-coated tip into an aqueous solution for a BLM to self-assemble (60). This method is very simple, and it rivals the much more complicated and widely used Langmuir–Blodgett (L-B) film technique for certain biosensor fabrication (Table 1). Experimentally, s-BLMs on solid support have been formed by a number of methods, and the two-consecutive steps technique is carried out in the following manner: (1) Place a Teflon-coated metal wire [e.g., platinum (Pt) or stainless steel (ss)] and cut the tip of the wire with a sharp blade, while it is in contact with a BLM-forming solution. (2) Immerse the lipid layer that has adsorbed onto the metal wire tip into an aqueous solution for

5 min to 10 min for a BLM to self-assemble [see Fig. 2(a)]. For best cutting of the metal wire a miniature guillotine has been used, in which the sharp knife is moved vertically onto the wire placed on a flat surface and immersed in a lipid solution (60). Typically we used either an 1% glycerol dioleate in squalene or 5% phospholipid (PC or lecithin) in *n*-decane. For the probe construction we used Teflon-coated ss wire (0.05 cm diameter). Assuming the molecular area of PC to be $50 \text{ \AA}^2$, about 2×10^{14} molecules are needed to cover 1 cm^2 of metal surface with a BLM.

Alternatively, an s-BLM can also be formed at the end of a Teflon tubing filled with a hydrogel in KCl as a salt bridge used in electrochemistry. The formation procedure consists of three steps. In the first step, a chlorided Ag wire (Ag/AgCl) is inserted into the Teflon tubing which has been previously filled with a mixture of agar (or agarose) and KCl solution saturated with AgCl (0.3 g agar in 15 ml of 3 M KCl). The AgCl electrode and the filled Teflon tubing are glued together with wax at the point of insertion. In this way an Ag/AgCl–Teflon salt bridge is constructed. In the second step, the tip of the other end of the Teflon salt bridge is cut *in situ* while immersed in a BLM-forming solution with a scalpel. In the third and the last step, the Ag/AgCl–Teflon salt bridge with the freshly lipid solution coated tip is immersed in 0.1 M KCl solution of the cell chamber. The second step described above may be carried out in air and then the freshly cut end of the salt bridge is immediately immersed in the lipid solution for a few minutes. In either case, the cell chamber fills with an appropriate aqueous solution (e.g., 0.1 M KCl) containing an Ag/AgCl reference electrode and an Ag/AgCl–Teflon salt bridge with a self-assembled BLM at its end. The lead wires of the two electrodes are connected to the measuring instrumentation (see Fig. 3).

The precise arrangement and degree of ordering of the lipid molecules in the final structure is not known for certain. However, it seems highly probable that the bilayer nature of the assembly is a consequence of the thermodynamics of free-energy changes at the metal–lipid and lipid–aqueous solution interfaces.

Instrumentation. A number of methods that study the properties of BLMs such as optical, electrical, mechanical, transport, and permeability have been developed over the years (47,56,57,63). Of these methods, we shall describe only the electrical methods. In the last decade, many new electrochemical methods have been developed and applied to membrane research (64). Among these, the cyclic voltammetry (CV) turns out to be a very powerful method. The basics of CV consist of cycling the potential of a working electrode in an unstirred solution and measuring the resulting current. The potential of the working electrode is controlled relative to a reference electrode which is provided by a triangular potential waveform generator. The instrumentation used with BLMs can be much simpler than that used in the conventional CV, owing to the fact that the high resistance of BLMs can be studied with a two-electrode setup. Thus, a picoammeter together with a voltage waveform generator is all that is required. If a computer or an X–Y displaying device is available, the current–voltage (*I*–*V*) curves may be obtained, which are known as voltammograms. From such voltammograms, information about thermodynamic and kinetic parameters of the BLM system may be

Figure 2. Schematic representations of (a) a metal-supported s-BLM probe, (b) a hydrogel-supported sb-BLM probe (78,93), (c) an interdigitated structure used for supporting an s-BLM (20), (d) a microsystem on a glass substrate for supporting s-BLMs (20), (e) a cell for electrochemical measurements (75), and (f) an enlarged view of the supported BLM illustrating the receptor (R)–ligand (L) interaction. P–G denotes Plateau–Gibbs border (49).

obtained, thereby providing insights into the mechanism of the membrane process under investigation.

A block diagram of the setup for obtaining cyclic voltammograms of the s-BLM system is shown in Fig. 3. The supporting metallic wire serves as a working electrode in a one-cell chamber [Fig. 2(e)]. The reference electrode, usually a chlorided Ag wire (Ag/AgCl) electrode, is dipped in the 0.1 M KCl solution placed in another chamber, and a salt bridge spans over the two chambers. For a two-electrode system as is usually used in the measurement, the newly cut tip of the metallic wire, coated with adsorbed lipids, acts as the working electrode. The current through the s-BLM is measured in the auxiliary electrode (made of a coil of Pt wire) during the CV scanning. The setup is housed in a Faraday cage to minimize interference by the external noise and electrical transients. Despite shielding, the external noise may still be picked up by the switch box; therefore, for the critical measurements the switch box should be incorporated within the same Faraday shield

Figure 3. Block diagram of the setup for cyclic voltammetry on the s-BLM system.

as the cell. All cables used are shielded and the shields are grounded.

On-Line Measurement of BLMs from Voltammograms

Parameters Determination of Planar BLMs. The I - V response of an unmodified BLM has a form of parallelogram under the triangle sweeping wave. Figure 4(a) (top) is a typical voltammogram of conventional planar BLM system. A typical equivalent circuit of the planar BLM system is represented as illustrated in Fig. 4(a) (bottom) by a membrane resistance R_m in parallel with a membrane capacitance C_m . The parameters such as the capacitance, resistance, and membrane potential can be determined easily by analyzing these voltammograms. The triangular sweeping wave in the range of $\pm V_0$ with the scan rate A ($\text{mV}\cdot\text{s}^{-1}$) is the input from the circuit. The current in nanoamperes or picoamperes is measured. There are two components in the current through the membrane, namely the charging current i_c and resistance current i_r . The former is determined by the capacitance as follows:

$$i_c = C_m \frac{dV}{dt} = C_m A \quad (1)$$

It can be shown that the capacitance current i_c through the membrane capacitance is a constant. From Ohm's law, the latter component i_r of the membrane current is caused by the membrane resistance, that is,

$$i_r = \frac{V}{R_m} \quad (2)$$

So the net current passing through the BLM can be expressed as

$$i = i_r + i_c = \frac{V}{R_m} + C_m A \quad (3)$$

Equation 3 shows that the current through the resistor increases with increasing scan voltage. In the case of the constant

scan rate A , with fixed values of C_m and R_m , the current i has a linear relationship with the sweeping potential V . Thus the slope reflects the value of R_m , whereas C_m can be determined by measuring i_c according to the graph of the I - V response. i_c will jump to its negative values suddenly ($-i_c$) only at such points where the sweeping wave reaches its maximum and begins to reverse. The jump distance $2h$ equals $2i_c$, and thus C_m will be calculated by merely measuring h .

Parameters Determination of Supported BLMs. When the CV technique is applied to the solid-supported BLM, it has been found that the shape of I - V curve is quite different from that of a planar BLM (parallelogram). The typical voltammogram of an unmodified s-BLM shown in Fig. 4(b) (top) obviously has a different shape when compared with parallelograms obtained for the planar BLMs in Fig. 4(a) (top). The difference between them indicates that the equivalent circuit as well as the corresponding methods for the measurement of conventional BLM properties are no longer rigorously applicable to the s-BLM system. Measurement errors will have a great impact on the accuracy of the parameter determination unless the circuit is improved. Therefore it is necessary to improve the original equivalent circuit and to establish proper parameters relations using a set of differential equations so that the accurate determination of electrical properties of the s-BLM is assured (64,65).

A typical s-BLM system consists of a supported BLM as the working electrode, an electrolyte, and a reference electrode, which may be represented by a number of suitably connected resistors and capacitors such as R_m and C_m . According to the I - V response recorded on the real s-BLM in Fig. 4(b), the improved equivalent circuit for the s-BLM is developed in Fig. 4(b) (bottom), where the nonmembrane resistance R_n is introduced in series with the original circuit, and the parallel C_s is the distributing capacitance for the entire circuit. The membrane is characterized by a high resistance and a high capacitance. Their measured accuracies are far more affected by the proposed nonmembrane resistance R_n , whose composition and effect on the measurement error will be discussed in the following section.

From simulation we have obtained similar I - V responses by CV with the BLM simulator which contains relevant electrical circuit (see Fig. 3). The effect of R_n is achieved by a set of I - V responses generated by a BLM simulator with and without R_n as shown in Fig. 5, where the regular development of the CV waveforms are shown with varying values of R_m , C_m , R_n , and C_s . Figure 5(a) is a set of voltammograms in which C_m is varied while holding R_m constant and R_n at 0 Ω . From cycle 1 to 3, the intercept with the i axis rises gradually in correspondence with the increasing C_m . In Fig. 5(b) the slope drops down from curve 1 to curve 3 as R_m increases while keeping C_m constant.

Figure 5(c) is based on the improved equivalent circuit [see Fig. 3(b)], where both R_n and C_s are involved in the consideration. A detailed observation of the effect of R_n on the shape of the I - V cycle is carried out. In our experiment, R_n varies in a wide range from 10^0 to 10^9 Ω , while the other membrane properties are simulated by holding R_m at 10^9 Ω , C_m at 5 nF, both of which are still within the range of biomembrane. Curves 1 to 7 display the similarities of the I - V cycles which have the shape of parallelograms even if R_n reaches the value of 10^7 Ω . However,

Figure 5. Voltammograms of the BLM simulator: (a) Voltammograms with different values of C_m ($C_m^1 < C_m^2 < C_m^3$) while remaining R_m constant; (b) voltammograms with different R_m ($R_m^1 < R_m^2 < R_m^3$), while remaining C_m constant; (c) affection of R_n on voltammograms (cycles 1–7, $R_n \approx 0-0.01 \text{ G}\Omega$; cycle 8, $R_n \approx 0.1 \text{ G}\Omega$; cycle 9, $R_n \approx 1 \text{ G}\Omega$).

when R_n increases to $10^8 \Omega$ ($\approx 0.1 R_m$), it begins to be characterized by charging current (curve 8). The intercept with the current axis is also somewhat decreased. The most important feature is that, when R_n reaches the same order as R_m ($\approx R_m$), the voltammogram (curve 9) does not display the shape of a parallelogram any longer, and it is very similar to that observed for the s-BLM system [see Fig. 4(b)]. The intercept with the i axis drops down sharply. The slope decreases during the potential sweeping, and it is much lower than the slope in the case of the BLM simulator without R_n or with a low value of R_n (cycles 1 to 7). In this last case, the intercept can no longer reflect the membrane capacitance, and it is the same as the slope of membrane resistance.

Therefore, the measurement error would be greatly increased if one still considers the intercept with the i -axis as the

membrane capacitance and the slope as the resistance. What causes the large value of R_n is still being discussed. The previous report using the LAPS technique has studied the system by considering the solution impedance effect (62). However, the value is not so high that it approaches R_m . Based on our previous research the nonmembrane resistance was not found so high in conventional planar BLM, and the technique for forming self-organized s-BLMs is based conceptually on interactions between a nascent metallic surface and amphipathic lipid molecules. It is supposed that an additional factor is owing to the presence of the metal-lipid interface (interfacial resistance) of R_n . Other important details in R_n include the electrode, electrolyte and solution impedance, and any other components which greatly effect the measurement accuracy.

Here, we propose a new method for determining R_m , C_m , C_s , and R_n accurately from the on-line s-BLM cyclic voltammogram (65). To make clear the effect of R_n on the I - V response, the quantitative relationship of the membrane current with the sweep wave potential has been derived rigorously from the solution of coupled equations based on the equivalent circuit shown in Fig. 4(b). The set of differential equations is as follows:

$$\begin{aligned} i &= i_r + i_c + i_s \\ i_r R_m &= \frac{1}{C_m} \int_0^t i_c dt \\ V &= (i_r + i_c) R_n + \frac{1}{C_m} \int_0^t i_c dt \\ i_s &= C_s A \end{aligned} \quad (4)$$

where i is the total current recorded, i_s is defined as the current through C_s , and all other parameters are defined above.

The final (definite) solution $i = f(V)$ is presented, where R_n and C_s have been included:

$$\begin{aligned} i &= \frac{AR_m C_m}{R_m + R_n} \left[\frac{V}{AR_m C_m} + \frac{R_m}{R_m + R_n} - \frac{2R_m}{R_m + R_n} \right. \\ &\quad \left. \exp \left(-\frac{(R_m + R_n)(V + V_0)}{AR_n R_m C_m} \right) \right] + C_s \cdot A \end{aligned} \quad (5)$$

The initial condition for Eq. (5) is

$$V_{t=0} = -V_0 + A \cdot t_{t=0} = -V_0 \quad (6)$$

During the half-cycle sweep from $-V_0$ to $+V_0$, we can see from Eq. (5) that there are three components included in membrane current: (a) the time-linearly dependent term, which is the resistance current obeying Ohm's law; (b) the time-exponentially dependent term in which R_n , R_m and C_m should be taken into account; and (c) the constant term resulting from the distributing capacitance C_s for the entire circuit.

The traditional way for the parameter determination is to vary each of the parameter values while holding all other parameters constant and to select a fitting curve with a minimal deviation. However, the complexity of the calculation is the major impediment in finding a group of effective suitable values to fit the calculated curve. Despite the aid of a computer, the calculation still requires much more time, which cannot be applied in the on-line parameter determination. So it is necessary to derive a set of accurate expressions from the original solution of Eq. (5), by which one-step calculation for determination of R_m , C_m , R_n , and C_s can be conducted.

Figure 6 presents this method to determine R_m , C_m , R_n , and C_s . First of all, the constant term $C_s A$ in Eq. (5) will be negative at the very moment when the sweep potential reaches its maximum and begins to reverse. So, the height $2h$ in Fig. 6 corresponds to twice the value of the distribution capacitance C_s multiplied with A . So from on-line computer acquire and parameters determination, the height $2h$ can be read out, and C_s

Figure 6. Method for on-line calculation of membrane parameters from s-BLM voltammogram. Four parameters are needed to be acquired from the on-line voltammogram: (1) $1/D$, the slope of the tangent line CD at the half-cycle terminal b ($+V_0$); (2) y_1 , the intercept of tangent line CD with the current i -axis; (3) y_2 , the intercept of the voltammogram with current i -axis; (4) $2h$, the transient current change at the time where the sweeping voltage reaches the maximum, and begins to reverse. Following Eq. (12) in the text, the membrane parameters can be calculated right away after a one-cycle voltammogram is acquired.

is determined by

$$C_s = h/A \quad (7)$$

The differentiation of Eq. (5) is given by

$$\frac{di}{dV} = \frac{1}{R_m + R_n} + \frac{2R_m}{R_n(R_m + R_n)} \exp \left(-\frac{(R_m + R_n)(V + V_0)}{AR_n R_m C_m} \right) \quad (8)$$

The potential of the triangular sweep wave moves from $-V_0$ to $+V_0$ (from a to b in Fig. 6). At the half-cycle terminal b , the exponential term can be rationally omitted and the slope of the tangent line CD at the point b can be expressed as

$$\frac{1}{D} = \frac{1}{R_m + R_n} \quad (9)$$

The intercept of CD with the current i -axis is y_1 , which is expressed as

$$y_1 = \frac{AR_m^2 C_m}{(R_m + R_n)^2} \quad (10)$$

The intercept of the voltammogram with the current i -axis is y_2 ; therefore

$$\Delta y = y_1 - y_2 = 2y_1 \exp \left(-\frac{R_m V_0}{y_1 D R_n} \right) \quad (11)$$

Thus, without any time-wasted fitting procedures, all the membrane parameters can be calculated cycle by cycle from the on-line data acquire as follows:

$$\begin{aligned} R_m &= \frac{m}{m+1} D \\ C_m &= \frac{y_1}{A} \left(\frac{m+1}{m} \right)^2 \\ R_n &= \frac{1}{m+1} D \\ C_s &= \frac{h}{A} \\ m &= \ln \left(\frac{2y_1}{y_1 - y_2} \right) y_1 \frac{D}{V_0} \end{aligned} \quad (12)$$

where D , y_1 , y_2 , and $2h$ are acquired from on-line voltammetry.

In conclusion, the only parameters that need to be acquired directly for a recorded voltammogram of the s-BLM are D , y_1 , y_2 , and $2h$. From the relationship described in Eq. (56), it is now possible to calculate accurate values of the membrane electrical parameters for the s-BLM system. Here a novel method is proposed which can determine the properties accurately without any iteration (65). So the real-time measurement is realized to be suitable for the dynamic analysis.

Solid-Supported BLM Formation. Similar to the time-resolved spectrometry through which the transient molecular reaction can be observed optically, the dynamics of modified or unmodified BLMs, or reconstituted systems using the BLM, is studied electrically by the CV technique where the capacitance, resistance, membrane potential, and current peak are the fundamental parameters in determining the static or the dynamic change of the BLM system. Among these studies, the formation of the s-BLM is a valuable one in analyzing the BLM mechanics and its electrochemical reactions.

Here, the membrane capacitance and resistance are chosen as two principal parameters in monitoring the formation of unmodified s-BLMs. The time-resolved capacitance and resistance are measured following the model described above, based on the recorded s-BLM voltammogram. Table 3 gives the values of s-BLM electrical properties under different BLM-forming solutions. The unmodified s-BLMs were formed from various lipid solutions: 0.5% and 2% lecithin PC (PC = phosphatidylcholine) in *n*-decane. The triangle potential wave sweeps within ± 100 mV, at sweeping rate of 50 mV/s. The setup, materials preparation and techniques for the formation of s-BLM have been described in the above section.

Dynamics of s-BLM Formation. The dynamics of the s-BLM should be studied to establish the membrane parameters of the s-BLM in stable stage (65). Figure 7 presents the time-resolved membrane resistance (a) and capacitance (b) during the s-BLM formation. Several successive stages are featured as shown (c),

Figure 7. S-BLM formation dynamics: (a) Time-resolved membrane resistance during the formation process (curves 1, 2, and 3, continuous monitoring for 0.5%, 2%, and 10% lecithin solutions, respectively; “+” denotes point monitoring without CV potential effect); (b) Time-resolved membrane capacitance during the formation process (curves 1, 2, and 3, continuous monitoring for 0.5%, 2%, and 10% lecithin solutions, respectively; “+” denotes point monitoring without CV potential effect). (c) Characteristic stages of the s-BLM formation monitored by the membrane capacitance: (1) The tip of Teflon-coated platinum wire is cut off with a sharp blade while immersed in a lipid solution; (2) the newly cut surface of the wire attracts the polar groups of the lipid molecules, and thus a monolayer of lipid molecules is irreversibly adsorbed onto the tip of the wire, while the hydrophobic hydrocarbon chains are in contact with the lipid solution in air; (3) upon immersion of the wire into the aqueous solution, the lipid coating adhering to the metal surface will thin down spontaneously to a lipid bilayer, with the hydrocarbon chains of the two layers facing one another and the polar heads of the second layer of lipid molecules exposed to the water; (4) a self-assembled BLM adsorbed on a metal support has been formed.

according to the mechanics of s-BLM formation described in a previous report (65). In Fig. 7, the continuous curves

Table 3. Electrical Properties of Solid Supported BLM (Diameter: 0.1 mm)

BLM Solution	R_m (MΩ · cm ²)	C_m (μF cm ⁻²)	R_n (MΩ · cm ²)	C_s (pF)
Lecithin (0.5%) in <i>n</i> -decane	0.54	1.56	0.43	27
Lecithin (2%) in <i>n</i> -decane	1.74	0.63	0.40	31
Lecithin (10%) in <i>n</i> -decane	2.25	0.82	0.71	25

correspond to the forming solution of three different concentrations (curves 1, 2, and 3 for 0.5%, 2%, and 10% lecithin, respectively). The formation dynamics indicates that the higher membrane capacitance and resistance of static s-BLM (measured 600 s later) are obtained for the more concentrated solution. This phenomenon is in agreement with the fact that, as the concentration increases, the lipid molecules attached onto the unit area of solid surface (nascent surface of silver wire) become more dense (less solvent), and alter the dielectric constant and resistivity of the lipid bilayer.

Another important phenomenon is that the resistance as shown in Fig. 7(a) has the tendency shifting to the left with the increasing lipid concentration, while the capacitance [Fig. 7(b)] changes in the reverse direction (right shifting). With the denser packing, the lipid molecules quickly cover the freshly cut surface of the metallic wire, and less leak charge can go through the lipid-metal interface, as well as through the Plateau–Gibbs (P–G) border which is provided by the lipid solution between the Teflon coating and the metal wire. This causes the resistance rising in a shorter time for a more concentrated solution. But for the capacitance, though the denser lipid molecules block the current, their orderly parallel arrangement (perpendicular to the cut face of the metallic wire) becomes more difficult to reach the final state. This may be the reason for the capacitance “delay” in more concentrated lipid solutions.

The major principle of the CV technique is to impose an extra potential on the s-BLM in monitoring its dynamics. This influence is detected by the comparison of the “continuous” measurement and “point” measurement (also called nonimpact measurement). The point measurement is conducted through the single cyclic voltammogram recording at several predetermined time points while holding the s-BLM electrically isolated for a different period of time. In contrast, the continuous measurement is the cyclic recording without interruption during the entire formation. The result is reflected in Fig. 7(a, b) (cross-point curve 4) by the point monitoring for the 0.5% lecithin forming solution. The interval between two adjacent measurements is 60 s. The three continuous curves which have been described above are the result of continuous measurement. In Fig. 7(a) (compare curve 1 and the cross-point curve), little change is found regarding the effect of CV on the resistance, but the capacitance right shift in Fig. 7(b) (comparing curve 1 and the cross-point curve) is detected for point monitoring. The polar groups of lipid molecules are supposed to be charged for this behavior. In the initial stage of BLM formation, the lecithin PC polar molecules are in a random state. In the case where no CV potential is imposed on the BLM, the preferred self-organization is being completed only through the attraction between the highly hydrophilic nascent metal surface and the polar groups of the lipid molecules. However, the detecting cyclic potential wave arouses an additional alternative electrical field. The “in field” molecules are forced by the sweeping voltage to accelerate their orientation, which as a result shortens the time for the bilayer formation on the nascent metal surface.

According to the capacitance monitoring of the s-BLM formation (see Fig. 7), in general, there are about four characteristic stages that can be distinguished from the initial “cutting operation” to the final formation of the s-BLM. These stages are as follows:

1. At the beginning, the capacitance fluctuates at random for a few seconds because the tip of the Teflon-coated

metallic wire has just been cut off with a sharp blade while immersed in a lipid solution.

2. During the next few seconds, the capacitance is relatively low due to the droplet of the BLM forming solution on the newly cut surface of the metallic wire. Rapidly a monolayer of lipid molecules is irreversibly adsorbed onto it.
3. The capacitance tends to increase after upon immersion of the wire into the aqueous solution. The lipid droplet on the tip becomes thinner and leads spontaneously to form a lipid bilayer. Moreover, the potential of CV also tends to speed up the s-BLM formation.
4. As the s-BLM adsorbed on a metal support has been formed, the capacitance becomes stable, though sometimes it fluctuates slightly due to the transfer of the solvent and of the excess lipids to the aqueous phase as well as to the P–G border [see Fig. 2(f)]. In fact, all the capacitance values in Table 3 have been measured in this stage.

Self-Assembled Lipid-Bilayer-Based Biosensors. It should be pointed out that, first of all, unmodified lipid bilayers (i.e., BLMs formed from common phospholipids or oxidized cholesterol dissolved in *n*-octane) in 0.1 M KCl will typically have the following electrical properties: R_m greater than $10^8 \Omega \cdot \text{cm}^2$, C_m of about $0.4 \mu\text{F}/\text{cm}^2$, E_m about 0, V_b about $200 \pm 50 \text{ mV}$, and current–voltage (I – V) curves obeying Ohm’s law. However, the electrical properties of BLMs can be drastically altered by incorporating a host of materials such as pigments, dyes, polypeptides, membrane proteins, organic metals, and semiconductor particles (48,49).

Advances of Self-Assembled Lipid-Bilayer-Based Biosensors

There have been a number of reports on self-assembled molecules or structures described as advanced materials or smart materials. Without question, the inspiration for this exciting work comes from the biological world, where the lipid bilayer of cell membranes plays a pivotal role. Insofar as planar lipid bilayers are concerned, these are evidenced by self-assembled lipid bilayers, photoelectric effects in pigmented BLMs, and TCNQ-based BLM rectifiers, and they most recently supported BLMs on interdigitated structures as biosensors by microelectronics techniques (20,66). Our approach to materials science research is a biomimetic one and is centered on experimental BLMs in that the membranes can function in such important processes as electron transfer, signal transduction, and cellular environmental sensing (48,49). Specifically, the following experiments, some of which are in progress, are delineated below.

Incorporation of Ferrocene in s-BLMs. To test the versatility of s-BLMs as a “smart material,” an amperometric sensor was constructed for ferri-/ferrocyanide ions. The results have shown that (1) ferrocene can be very easily immobilized in the lipid bilayer on the tip of a metallic wire (s-BLM) system and (2) ferrocene in an s-BLM on a Pt support increases the sensitivity by about two orders of magnitude for potassium ferri-/ferrocyanide ions compared with that of a bare platinum electrode. This demonstrates that the s-BLM system offers a novel approach to the electrode modification by incorporation of compounds within a lipid bilayer (67–69).

Hydrogen Peroxide-Sensitive s-BLMs. The insertion of appropriate active molecules (modifiers) into the matrix of the lipid bilayer should be able to impart functional characteristics to s-BLMs. We chose TCNQ and dipyriddy-tetrathiafulvalene (DP-TTF) because of their properties as typical electron acceptor and donor molecules, respectively. It was found that DP-TTF not only improved the stability but also increased the range of s-BLM's sensitivity to hydrogen peroxide. In contrast, TCNQ-containing s-BLMs did not show much response to H_2O_2 (68).

Modified-BLMs as pH Sensors. The hydrated hydrogen ion (H_3O^+) is crucial to the functioning of cellular processes because it plays a leading role in enzyme catalysis and membrane transport. To test our concept, we incorporated a number of quinonoid compounds (chloranils) into s-BLMs and found that, indeed, s-BLMs containing either tetrachloro-*o*-benzoquinone (TC_oBQ) or tetrachloro-*p*-benzoquinone (TC_pBQ) responded to pH changes whose potential measurements exhibit a nearly theoretical slope (70,71). In this connection, mention should be made that s-BLMs formed from a glycerol dioleate (GDO) lipid solution containing polypyrrole have been found to be sensitive to pH with a Nernstian slope of 57 mV/decade hydrogen ion concentration as compared with unmodified s-BLMs (slope $\approx$ 20 mV). These new pH-sensitive s-BLMs offer prospects for a ligand-selective probe development using microelectronics technologies.

Modified s-BLMs as Ion Sensors. s-BLMs containing six different kinds of crown ethers were investigated using cyclic voltammetry. In particular, s-BLMs formed from a liquid crystalline aza-18-crown-6 ether and cholesterol-saturated *n*-heptane solution were found to be sensitive to K^+ in the concentration range 10^{-4} to 10^{-1} M with the theoretical Nernstian slope (72,73). The specificity for three alkali metal cations and NH_4^+ of these doped BLMs were also investigated. The order of specificity for most of these bis-crown ethers was found to follow hydrated radii of the cations, that is, $\text{NH}_4^+ > \text{K}^+ > \text{Na}^+ > \text{Li}^+$ (72). The results obtained with these s-BLMs compare favorably with conventional BLMs containing similar compounds, such as valinomycin and gramicidin (7). Concerning the gramicidin, it is well known that it forms ion channels. Cornell et al. (74) reported recently that a lipid-bilayer-based biosensor contains "sliding ion gates" made of gramicidin, and they claimed that a device can be designed for almost any analyte for which a receptor can be synthesized. The idea is again based on ligand-receptor interactions (48,49,69,75).

Recently we have investigated electron transfer across a BLM containing the so-called buckminsterfullerene C_{60} , which can act both as a mediator and a photosensitizer (see a later section on photoactive s-BLMs). Using the s-BLM, it is possible to construct a sensor probe sensitive to iodide ion and to investigate redox reactions across the lipid bilayer (76). The presence of C_{60} greatly strengthened the stability of the s-BLM and dramatically alters its electrical properties. Using the cyclic voltammetry technique, the results show that C_{60} embedded in the BLM acts as an excellent electron carrier/mediator and should be useful for electrochemical biosensor and molecular electronics device development. The cyclic voltammograms contain distinct redox peaks, which are not symmetrical. Further, the C_{60} in the lipid bilayer had the opposite effects on membrane resistance (R_m) and capacitance (C_m), respectively; it caused the R_m to decrease and C_m to increase. The presence of iodine

in conjunction with C_{60} in the s-BLMs further accentuated the effects. It is apparent that both C_{60} and iodine, when embedded in BLMs, facilitate electrical conduction, thereby lowering the R_m . Since the dielectric constant, ϵ , of a typical, unmodified BLM is about 2, the presence of C_{60} and iodine should exert a great influence on ϵ . Since C_m depends on a number of factors such as the surface charge of the BLM, the nature of hydrocarbon chains, and embedded modifiers, an increase in ϵ , and consequently in C_m , is therefore expected. The modified probe increased the detection limit for iodide ion by 100 times, with a linear response in the range from 10^{-8} M to 10^{-2} M. Thus, C_{60} facilitates the discharge of I_3^- at the metal surface, which demonstrates clearly that the embedded C_{60} is indeed an excellent electron mediator (76).

Modified s-BLM as Molecular Sensors. Many authors have reported sensors for the detection of glucose using glucose oxidase (77). Interestingly, using s-BLMs containing redox compounds and electron mediators but without the enzyme, glucose was detected in the buffered solution. The results are preliminary and further experiments are in progress. If a highly conjugated compound such as TCNQ is incorporated in the s-BLM forming solution, the resulting s-BLM was able to detect the presence of ascorbic acid, which is consistent with the findings obtained with conventional BLMs (78).

Molecular Recognition in an s-BLM. S-BLMs can be employed for embedding a number of compounds such as enzymes, antibodies, protein complexes (channels, receptors, membrane fragments or whole cells), ionophores, and redox species for the detection of their counterparts, respectively, such as substrates, antigens, hormones (or other ligands), ions, and electron donors or acceptors (7). The antigen-antibody reaction can be undertaken by using s-BLMs as the probe with electrical detection. The antigen, hepatitis B surface antigen (HBs-Ag) was incorporated into an s-BLM, which then interacted with its corresponding antibody (HBs-Ab or monoclonal antibody) in the bathing solution. This Ag-Ab interaction resulted in some dramatic changes in the electrical parameters (conductance, potential, and capacitance) of s-BLMs. The magnitude of these changes was directly related to the concentration of the antibody in the bathing solution (see Table 4). The linear response was very good from 1 to 50 ng ml^{-1} of antibody, demonstrating the potential use of such an Ag-Ab interaction via the s-BLM as a transducing device (79).

Electron Transfer Experiments in s-BLMs. Research in the field of electron transfer processes in BLMs was first conducted in

Table 4. Effect of Concentrations of HBs-Ab on the Resistance of s-BLMs

[HBs-Ab] (ng m^{-1})	$R_1(\times 10^8)$ ($\Omega \cdot \text{cm}^2$)	$R_2(\times 10^8)$ ($\Omega \cdot \text{cm}^2$)	$\log R_1/R_2$

10	6.30	51.2	1.09
1	6.50	162	0.604

the late 1960s to understand the primary step in natural photosynthesis (47,80). It was discovered that a light-driven electron transfer process between donor and acceptor species can occur across the thickness of a pigmented BLM. This finding has subsequently led to the view that the reaction center of natural photosynthesis functions similarly to that of a photovoltaic device of molecular dimensions (56). In the mid-1980s, electron transfer in the dark was seen in BLMs doped with either organic "metals" or semiconducting nanoparticles formed in situ (62). These phenomena were explained in terms of light-induced charge separation, field-driven charge transport, and subsequent redox reactions on opposite sides of the BLM. In the absence of light, the theory of electron tunneling was invoked (see above on TCNQ or TTF containing BLMs). When an s-BLM doped with Zn-phthalocyanine was excited by light, a voltage and a current were recorded, with the action spectra closely parallel to the absorption spectrum of the photon absorber (60). Thus we have shown that a pigmented s-BLM can function as a light transducer or photon-activated switch or detector (76,81).

S-BLMs Deposited on Piezoelectric Quartz Crystals. Smell and taste (olfaction and gustation) are among living organisms' two most vital sensing systems, the biophysics of which have been increasingly elucidated at the molecular level (52,66). Here again the crucial receptors are BLMs. In the preliminary experiments, several kinds of BLMs were successfully deposited on AT-cut quartz resonators (52,82). These were verified by observing frequency (f_m), potential (E_m), capacitance (C_m) and I - V curves. Frequency change (versus that in air) ranged from 9 kHz to 16 kHz, and in cyclic voltammetry experiments no redox peaks could be observed or the peaks were largely damped in the presence of $\text{Fe}(\text{CN})_6^{3-}$. E_m and C_m also showed characteristic values. But the exact values of these parameters were found to be related to the lipid solution, the pH of the bathing solution, and the scan time of voltammograms. If the BLM failed to form or was broken, obvious changes in these parameters were observed. In this case, f_m increased several kilohertz (to about 6 kHz, which corresponds to that induced only by pure viscous loading); C_m and E_m also increased and characteristic redox peaks were observed. Our findings show that BLMs can be formed on piezoelectric quartz crystals and that the piezoelectric techniques can be applied as a powerful tool to characterize the s-BLM system.

S-BLMs on Interdigitated Structures by Microelectronics Techniques. The fact that a lipid bilayer structure can be self-assembled on a solid substrate is intriguing. This novel manner of lipid bilayer formation overcomes two basic obstacles in the way of practical utilization of the BLM structure, namely: (a) its stability and (b) its compatibility with a standard microelectronics technology. As has been repeatedly demonstrated by us and others (20,83), the solid s-BLM system not only possesses the advantages of a conventional BLM structure, but gains new important properties, besides its long-term stability, such as (1) an anisotropic, highly ordered, yet very dynamic liquid-like structure and (2) two asymmetric interfaces, one of which is metallic. With this metallic connection, this type of probe solves the interfacing problem and is applicable to microelectronics technology. On this last-mentioned property, we have extended the experiment described above to the interdigitated structures (IDS). IDS are finger-like electrodes made by

microelectronics technologies and used in microchip applications (20). By forming s-BLMs on IDS made of platinum with a window of $0.5 \text{ mm} \times 0.5 \text{ mm}$, we obtained the following interesting results. First, when an IDS coated with a BLM was formed from asolectin, it responded to pH changes with only a $(15 \pm 2) \text{ mV/decade}$ slope. The conductance of s-BLMs on the IDS was about 50 times higher than the usual s-BLMs. Second, when an IDS coated with a BLM formed from asolectin was doped with either TCoOBQ or TCpBQ, the pH response was linear with a slope close to the theoretical value (68,70). This type of structure (i.e., s-BLM on interdigitated electrodes) can be used to investigate ligand-receptor contact interactions.

S-BLMs on an IDS can be manufactured using microelectronics technologies which already exist without the explicit need for special modification. This finding is viewed as a major "breakthrough" in the biosensor development. In this connection it should be mentioned that experiments on IDS chips modified with a BLM are based on a common basic aspiration—that is, to self-assemble a lipid bilayer containing membrane receptors, natural or synthetic, so that a host of physiological activities, such as ion-molecular recognition, can be investigated (20,52). At the molecular level, most of these activities may be termed collectively as the receptor-ligand contact interactions. The structures which are being reconstituted are inherently dynamic. Receptors and ligands in such close contact will normally vary as a function of time, frequently resulting in non-linear behavior. With an IDS chip modified with a BLM, we now have at last a most unique system for extensive experimentation which will be limited only by our imagination. Thus, insight gained from these studies will guide the preparation of functional BLMs on IDS support. Our aim is to take advantage of microelectronics techniques and apply them to the biochemical and neuroscience research.

Photoelectric Effects in Planar s-BLMs and sb-BLMs. Fullerenes (e.g., C_{60}) have been of great interest in materials science in the last decade. Our interest in fullerenes as a BLM modifier is owing to their most unique properties. Unmodified C_{60} , for example, is a water-insoluble and highly conjugated hydrophobic compound; it behaves as a good electron mediator and as an n -type semiconductor (bandgap = 1.6 eV). Hence, the lipid bilayer is an ideal environment for the compound to reside. The C_{60} -containing s-BLM, considered basically as a "molecular device," is a light-sensitive diode capable of photoinduced charge separation which undergoes redox reactions across the substrate-hydrophobic lipid bilayer-aqueous solution junctions.

Concerning photoactive compounds in BLMs, mention should be made about electron transfer processes in the membranes of photosynthesis and mitochondrial respiration, both of which have been reported in a number of BLM studies (47,53,56,59,80,84). In the 1980s, electron transfer was demonstrated in BLMs. The phenomena were explained in terms of the light-induced charge generation and separation, field-driven charge transport, and subsequent redox reactions on opposite sides of the BLM. In the absence of light, the theory of electron tunneling was invoked (56,64). When an s-BLM doped with Zn-phthalocyanine was excited by light, a voltage and a current were recorded, with the action spectrum paralleled closely to that of the absorption spectrum of the pigment (7,60). This provides direct evidence that the light-induced currents are indeed due to the photoactive compound embedded in the

BLM. Thus, a pigmented s-BLM can function as a light transducer or photon-activated switch or detector. In this connection, the experiments reported by Rolandi et al. (85), Yonezawa et al. (86), Lamrabte et al. (87), Yamaguchi and Nakanishi (88), Bi et al. (89), Ikematsu et al. (90), and more recently by Gruszecki et al. (91) should be of great interest.

Molecular Electronics and Lipid-Bilayer-Based Biosensors

Molecular electronics makes uses of materials at the molecular level in which the species retain their separate identities. As a result, the properties of such materials depend on the molecular arrangement, properties, and interactions. Theory seeks to guide the design and synthesis of effective molecular materials (57). It does so by analysis, interpretation, and prediction, leading to the development and evaluation of concepts, models, and techniques (66). The role of theory in treating molecular properties (mainly by molecular orbital methods) and arrangement (by electromagnetic or quantum-mechanical approaches) is of importance. When these factors are combined, the material properties can be treated more successfully in cases where the interactions are not essential for the existence—for example, in nonlinear optics as opposed to electronic transport properties (92).

The major advantage of molecular electronics with a lower limit on the order of micrometers is the further development of lithographic techniques. The changed physical properties in the submicroscopic region are the major obstacles to further miniaturization in the semiconductor technologies. The physical border for the silicon technologies is about 100 nm, because one cannot overcome the characteristic lengths such as diffusion, Debye, and tunnel lengths. With still smaller dimensions, we enter the realm of biological and molecular systems. Although biotransducers function much slower than silicon-based devices and are not very reliable, they are extremely efficient. Also, despite their disadvantages, nature's molecular devices function more generally and are superior to technical computers or sensors. In contrast to macromolecular biological systems, the main advantage of molecular devices, purportedly, is their relatively simple construction. In this sense, molecular devices may be readily constructed, and they are always easily accessible experimentally from a quantitative point of view (61).

The main elements of molecular electronics are molecular wire, conducting material, molecular-specific transducers of signals similar to the particles, and molecular switches, memories, emitters, detectors, and so on. The flux of information between the molecules can be released in many ways. One of the most important is the transfer of individual charges in terms of electrons, holes, or hydrogen ions, or of other shapes similar to the elements, like solitons, soliton waves, or excitons. Molecular switches may be optical, electrical, magnetic, or thermally reversible systems, such as photochroma-salicylidenanilin. Storage of information in a molecular system can be realized through a change in the electronic as well as geometric structures of the molecules in reversible thermal reactions—for example, conformational or configurational changes upon replacement of hydrogen or protons (66,92).

FUTURE PROSPECTS

In recent years, the development of biosensor configurations has been concentrated largely around the design of the trans-

ducer used. Further researcher's attention, however, should be focused on the mechanism of molecular recognition and catalysis. The fundamental properties of the device must be better understood in order to optimize critical factors such as response time, selectivity, and stability. Immobilization technologies and new membrane materials may basically change the present performance of biosensors.

The key advantage of molecular and biomolecular computing is specificity (92). The large number of variations that are possible with organic polymers such as poly (*N*-isopropylacrylamide as a "linking arm" in the protein ligand recognitions, and artificial photochrome and photorefractive material for future photon information storage and optical computer) allows for fine tuning of electronic motions to a much greater extent than is possible with organic materials. In biological molecules, certain configurational motions are comparable in significance to electronic motions. This is certainly the case in all conformation-based recognition processes. For example, the energy-loan model is applicable to many conformational switching processes based on the "lock-key"-type interactions of macromolecules. This could include self-assembly processes, protein folding, and various motions of biological macromolecules, which are generally attributed to fluctuation phenomena. The electronic instability in the energy-loan model may be thought of as a mechanism for amplifying the effects of fluctuations.

The switching process based on the energy-loan mechanism can mediate important forms of signal processing within biological cells. The enzymatic recognition is itself a basic form of information processing. When proteins and other macromolecules are combined into highly integrated complexes, they become possible for conformational switching processes to propagate over significant distances. The cytoskeleton is a good candidate for such a signal-processing network (92). One hypothesis is that conformational changes propagate through the cytoskeletal network by the energy-loan mechanism, with the conformation change of component macromolecules inducing the required lattice distortion in neighboring macromolecules. Such propagating conformation changes would play a role in transport processes in the cell, and it is likely that they would play a role in information processing as well.

One of the most delicate "molecular wires" is the so-called conjugated hydrocarbon chain, which is the best represented through the chain of carbon atoms in polymers. Most organic polymers are well-known insulators. However, polyacetylene (CH)_x, polydiacetylene, and polysulfinitride (SN)_x, with their conjugated double bonds, are semiconductors or superconductors. Such conjugated systems form the group of organic conductors and semiconductors. The most important organic electroactive polymer is polyacetylene. The foundation of the electron-hole pairs and the positive and negative charges are quite well known. In the outer electric field, the electron and the hole are accelerated in opposite directions. This properties can be used in optical switches for switching on and off the flux of information. Combining molecular "wire" and switchable molecules could lead to the construction of electronic systems based on molecules. Present research is oriented toward discovering peptides/proteins that can transduce electrical current or exist in two-electrical states. These could lead to future "biochips." Research on biochips could lead not only to a better understanding of higher nerve function, but also to the foundation of qualitative computer systems that could provide many of the activities currently performed only by the human brain.

Biochips can be considered, therefore, as highly sophisticated biosensors. The unique properties of biochips are their analog and digital computing potentials, self-perpetuating and potentially self-repairing. Biochips hold promise in a variety of applications such as bionic implants, memory-intensive systems, image processing and storage, artificial intelligence, language processing, and molecular computers. For instance, the analog capability of biochips could enable the creation of "artificial intelligence." As such, biochips are at a very early stage of research and development (66,92). As with biosensors, the current problem is our inability to produce uniform high-activity, stable biomolecular layers and their associated transduction systems. These problems notwithstanding, it seems likely that the initial application of biochips as advanced biosensors, based on the ligand-receptor contact interaction, may be in the clinical setting, where they could serve as automated control devices for drug delivery (61). It also appears probable that in order to extend the capabilities of present silicon-only systems, hybrid biochips and silicon-chip devices would be first produced for computing and memory-intensive systems. The key to the successful application of biochips will be to fill places that are not well-served by current silicon chip technology. Thus, the future development of biochips requires the successful technologies of stable biomolecule embedding and immobilization, biotransduction, and molecular lithography. Several urgent problems to be solved are biologically based amplification, molecular switching, electron transport, and memory function. In the coming decade, the answers to some of these problems will undoubtedly be found. In this connection, the development of lipid-bilayer-based sensors and biological electronic devices seems to be a logical first step. With the BLM systems, especially s-BLMs, we now have an experimental approach for testing some of the new ideas in the development of sensors for practical applications (8,20,46,74).

Addendum (Some Recent Experiments Using Conventional BLMs and Supported BLMs)

A number of pertinent publications using conventional BLMs and supported BLMs have appeared. The incorporation of these findings into the text is not feasible at the present time. Therefore, a bibliography (annotated Refs. (1,93–105)) is added in this survey volume, so that the literature is up to date. The interested reader may wish to visit our WebPages at:

SIGNAL CONDITIONING

INSTRUMENTATION AMPLIFIERS

BACKGROUND

The monolithic operational amplifier (op-amp) has, in recent years, surpassed the basic discrete transistor as an analog building block in almost all instrumentation applications. While there are still many application areas (particularly very high speed, high voltage, high current, and ultra low noise) in which the discrete transistor (or even the vacuum tube) predominates, the ease of application of the op-amp has vastly simplified analog design at the system level, at least at frequencies below 100 MHz or so. The origins of the op-amp are buried deep in early negative feedback techniques, but suffice it to say here that the term “operational amplifier” appears to have been coined in a paper by Ragazzini and his colleagues (1), although the term “computing amplifier” survived for a while. The op-amp consisted of a high-gain inverting amplifier that remained stable with 100% negative feedback. This enabled highly controlled closed-loop functions (particularly integrators) to be realized, which, in turn, formed the basis for many analog computing functions. Later op-amps included a noninverting input, modifying the transfer function to one of high gain appearing *differentially* between the two inputs.

Of course, differential amplifiers were not new; simple long-tailed-pair amplifiers with controlled gain date far back to the early days of electronics. But the op-amp was different in that the gain control came from purely external components (assuming high enough open-loop gain), potentially enabling precision gain control from purely passive components.

However, herein lies the dilemma: When feedback is applied around an op-amp, the inverting input becomes a low (ideally zero) impedance. The noninverting input, though, remains at high impedance. Many instrumentation (and other) systems require a precise differential amplifier with high (relative to signal source) impedance for *both* inputs, and this function is now known as an *instrumentation amplifier*. Obviously, simple op-amps require considerable modification to fulfill this function.

DEFINITION

An *instrumentation amplifier* is a precision amplifier with single-ended output and differential inputs and with precisely controlled gain for voltages appearing between its inputs. Ideally, voltages common to both inputs should not affect the output (this will lead to a discussion concerning common-mode rejection in due course). Additionally, both inputs are expected to have high impedance (relative to the source impedance), and this is normally expected to be symmetric, at least to a first order.

Unlike the op-amp, the origins of the term “instrumentation amplifier” are somewhat nebulous. Some early monolithic precision op-amps, notably the μ A725 from Fairchild Semiconductor (1969) and the OP-07 from Precision Monolithics (1975), were referred to as instrumentation operational amplifiers.

This was undoubtedly a marketing label intended to emphasize their precision input characteristics, necessary in many instrumentation applications; but they were still op-amps and not instrumentation amplifiers in the sense now generally accepted. The term “differential amplifier” has its origins lost to obscurity, but such terms as “high-accuracy differential amplifier” or “direct-coupled differential amplifier” appear regularly in texts prior to 1960, and these, of course, are terms that basically describe the quintessential instrumentation amplifier. In the mid-1960s the term *data amplifier* became commonplace to describe such amplifiers (2,3), and several companies were producing self-contained modular amplifiers at this time. The now commonly used term *instrumentation amplifier* was certainly in use by 1967 (4), and the two terms were concurrent for a while.

THE BASIC INSTRUMENTATION AMPLIFIER

Possibly the simplest way to achieve the instrumentation amplifier function is with a single op-amp configured for equal inverting and noninverting gains.

Referring to Fig. 1, the amplifier produces a gain between the inverting input (–IN) and the output, which can be derived from classical op-amp theory as follows:

$$G_{-} = -\frac{R_4}{R_3}$$

The gain from the noninverting input (+IN) to the output can be described by

$$G_{+} = \left(\frac{R_2}{R_1 + R_2} \right) \left(\frac{R_3 + R_4}{R_3} \right)$$

So if the ratio R_1/R_2 is made identical to the ratio R_3/R_4 , the resulting output gain is identical for both inputs but of opposite sign (assuming, for the moment, that A1 is ideal and neglecting any source impedance). This is tantamount to saying that the *common-mode* gain is zero. The absolute value of gain from either input to the output with respect to

Figure 1. Basic instrumentation amplifier.

the other input is still given by

$$G = \frac{R4}{R3}$$

and this is the *differential-mode* gain. For simplicity, the term “gain” when used without qualification, will subsequently be assumed to be the differential-mode value. This circuit thus performs the basic functions of an instrumentation amplifier.

Although this circuit is commonly used where economy is a major concern, as will be shown, it lacks many of the features demanded in modern instrumentation systems. It is, however, a good starting point to illustrate some of the problems encountered in the design of instrumentation amplifiers in general.

GAIN ERROR

Errors in gain for the simple instrumentation amplifier of Fig. 1 are essentially those of the resistors themselves, unless the gain is unusually high or the op-amp has poor open-loop gain or common-mode rejection ratio (CMRR). For such a simple circuit, the effects of resistor mismatch cause much greater problems by common-mode rejection than by gain error. Small gain errors can often be tolerated or calibrated out, whereas in the case of poor common-mode rejection spurious signals end up mixed with the desired signal and may be impossible to remove. This situation is exacerbated greatly if the common-mode signal is comparable to (or even greater than) the desired one, which unfortunately is often the case (this is the major reason why an instrumentation amplifier is usually needed).

COMMON-MODE REJECTION RATIO

As already mentioned, if the inverting and noninverting gains are perfectly matched, then input voltages common to both of these inputs theoretically never appear at the output. This is, of course, the ideal case. In the case of the simple circuit of Fig. 1, mismatch in the ratios $R2/R1$ and $R3/R4$ results in different gains from each input to the output (neglecting the sign difference, which is obviously intentional). This means that signals common to both inputs will appear at the output to some degree. The accepted standard measurement of the extent to which this will occur is the CMRR. There are various ways to define the CMRR, but the classic definition is simply the differential-mode gain divided by the common-mode gain. This is a rather large number, and for this reason it is almost always expressed in (voltage) decibels:

$$\text{CMRR(dB)} = 20 \log_{10} (\text{CMRR(ratio)})$$

The sign of CMRR can also be confusing. Frequently, CMRR is expressed as something like -70 dB. Strictly speaking, this would imply a common-mode gain greater than the differential-mode gain, but (although it is possible to design an amplifier that would accomplish this) such figures should be treated as common-mode *acceptance* (the inverse of CMRR) when dealing with realistic instrumentation amplifiers. The CMRR of a simple instrumentation amplifier as depicted in Fig. 1 is obviously dependent on the accuracy to which the resistors can be matched. Using the symbol Δ_R for resistor mismatch, and assuming no correlation in the matching, it can be shown that worst-case CMRR owing to this term alone

can be expressed by

$$\text{CMRR} = \frac{1 + G}{4\Delta_R}$$

where G is the selected gain.

For off-the-shelf 0.1% tolerance resistors and a gain equal to 10, the CMRR could be as poor as 2750 or about 69 dB. This would be regarded as extremely meager in most precision applications. Clearly, a fine trim on any of the four resistors can be used to improve this parameter, and that is why integrated circuit instrumentation amplifiers are so commonly used where automated resistor adjustments (by means of a laser or other techniques) can be cost-effectively employed in their manufacture. Using such techniques, the critical resistor *ratios* can be trimmed to a tolerance of 0.005% or so, resulting in a CMRR in the preceding example of over 100 dB.

Even when the resistors are perfectly matched, common-mode errors in the op-amp itself cannot be overlooked. Common-mode rejection in the op-amp shows up directly as a CMRR error in the output multiplied by the gain. Modern precision monolithic op-amps frequently boast CMRR specifications of 110 dB or more. When the instrumentation amplifier is used at low gains, such figures can be considered negligible compared to errors such as resistor mismatch. At high gains, however, this may not be the case. The open-loop gain of the op-amp, ideally infinite, can also upset the behavior of both CMRR and gain error.

An often more serious consideration is the CMRR behavior with frequency. Both CMRR and gain roll-off with increases in frequency are typical of operational amplifiers with dominant-pole (or alternate) methods of compensation designed to be operated with good closed-loop stability and high feedback factors (often 100%). This effect is exacerbated in many precision op-amps that use multiple stages of gain, which, in turn, demand high levels of internal frequency compensation or, to put it another way, tend to have poor ac characteristics.

The most commonly encountered frequency of interest for CMRR is the fundamental frequency of the power-supply grid, which is nominally 60 Hz in the United States and Canada and 50 Hz in much of the remainder of the world. Additional harmonics generated by power transformers, rectifiers, and thyristor control systems produce radiated frequencies that can be far more important than initially expected, given that capacitive coupling tends to increase with frequency whereas op-amp precision tends to decrease with frequency. The subject of RF (radio frequency) susceptibility with frequencies up to several GHz is obviously an extreme (but often important) consideration in the evaluation of CMRR in an instrumentation amplifier.

A full dynamic analysis of factors affecting CMRR (and other effects, such as ac gain error, ac power supply rejection ratio [PSRR], and settling time) is considered beyond the scope of the present discourse. Suffice it to say, however, that even at 50 Hz, many precision op-amps can produce CMRR errors far worse than simple dc analysis would predict.

ADVANTAGES OF THE BASIC INSTRUMENTATION AMPLIFIER

One advantage of the simple amplifier of Fig. 1 is that only one op-amp is used. This is, of course, good not only for economic reasons but also because only one op-amp contributes to the overall error budget. A less obvious advantage is that the input

voltage range is very high. Because of the attenuating effect of R_1 and R_2 , the common-mode input range can extend beyond the input voltage range of the op-amp itself. This is often useful where external signals approach or exceed the supply voltage available to the instrumentation amplifier.

SHORTCOMINGS OF THE BASIC INSTRUMENTATION AMPLIFIER

The most serious shortcoming of the configuration shown in Fig. 1 is that the input impedance is not very high (unless the resistors are made impractically large, with severe noise and bandwidth penalties). To make things worse, the analysis of the effects of the input impedance is highly dependent on the characteristics of the input signals.

The impedance at +IN is equal to $R_1 + R_2$, while at -IN it is equal to R_3 because the feedback action of A1 forces a low impedance at its inverting input. For the usual arrangement, where R_2 is equal to R_4 , and R_1 is equal to R_3 (to preserve symmetry at the op-amp inputs, for input bias current considerations among others), the input impedance is therefore considerably higher at +IN than at -IN. While this can be corrected by reducing the values of R_1 and R_2 (or better, by adding a resistor from +IN to ground), this is often a dangerous practice. For truly differential inputs with matched source impedances, the input impedance is not actually asymmetric (due to the fact that the inverting input of A1 follows part of the signal at +IN). Attempting to balance the absolute input impedances thus could cause severe CMRR errors when the inputs are driven differentially from well-matched source impedances. If the source impedances are not well matched (or at least not well defined), the usefulness of this configuration becomes highly questionable.

For the record, the common-mode input impedance turns out to be $\frac{1}{2}(R_1 + R_2)$ and the differential value is equal to $2(R_1)$. These equations only hold for balanced differential sources.

Another nuisance is that the gain cannot be varied without simultaneously changing two resistors, and again tight matching must always be preserved if CMRR is not to suffer. However, if R_2 and R_4 are each split into two resistors, then an additional resistor connected between the midpoints can be used to increase the gain with minimal effect on CMRR. Now, of course, six matched resistors are required to obtain good CMRR. Such shortcomings are the main reasons to look to alternative instrumentation amplifier topologies.

Despite the limitations, the basic configuration of Fig. 1 is useful enough that at least two companies (Analog Devices and Burr-Brown) are producing this circuit in (laser-trimmed) monolithic form at the time of writing.

THE CLASSIC THREE-OP-AMP INSTRUMENTATION AMPLIFIER

Adding buffer amplifiers to both inputs will clearly remedy the input impedance problem of the aforementioned configuration, but a little more elaboration can solve the gain-setting problem as well. This leads to the classic three-op-amp configuration of Fig. 2. Once more, a definitive reference has proven to be elusive, but at the very least it dates back to a 1966 George Philbrick publication (5).

Referring to Fig. 2, A3, in conjunction with R_1 – R_4 , forms a differential amplifier identical to the circuit of Fig. 1. If R_G is omitted, A1 and A2 act as unity-gain buffers, removing the input impedance problems described previously. In the presence of R_G , the differential gain between the inputs and outputs of A1 and A2 becomes

$$G_{\text{diff}} = 1 + \frac{(R_5 + R_6)}{R_G}$$

The common-mode gain, however, remains at unity. Thus, when R_1 – R_4 are carefully trimmed for optimum CMRR, the differential gain can be increased by reduction of R_G without affecting overall common-mode gain. Because of the way CMRR is defined (as the ratio of differential-mode gain to common-mode gain), the effective CMRR of the amplifier becomes proportional to G_{diff} . The overall gain of the amplifier will be the product of the gain of the second stage and G_{diff} or, (assuming $R_1/R_2 = R_3/R_4$),

$$G = \left(1 + \frac{(R_5 + R_6)}{R_G}\right) \left(\frac{R_4}{R_3}\right)$$

Thus the lower limit on gain is set by R_4/R_3 .

The best distribution of the gain between the first and second stages is the subject of considerable compromise. By using a gain below unity in the second stage ($R_4 < R_3$), the overall CMRR (for a given resistor mismatch) is increased, and the lower gain limit is extended. Unfortunately, this tends to put the gain burden on the op-amps A1 and A2, thus amplifying their input referred errors and reducing their bandwidth.

Figure 2. Three-op-amp instrumentation amplifier.

Conversely, taking gain from the second stage ($R4 > R3$) can improve the overall bandwidth at the expense of CMRR (and amplification of the input referred errors of A3) and increases the limit on the lowest achievable gain.

A more subtle (but extremely important) effect, however, is the limit imposed on the common-mode input range. With no differential input, the common-mode input range is limited either by the input voltage range or the output voltage swing (whichever happens first) of A1 and A2. With modern “rail-to-rail” op-amps, this restriction can often be minimal (though most high-precision and high-speed op-amps still require considerable headroom, often a couple of volts or so). Even so, the power supplies dictate a limit on the output swing.

With a differential input applied, the output of either A1 or A2 swings positive about the common-mode input voltage, while the other swings negative. Thus the entire differential output voltage of the first stage directly subtracts from the available common-mode input range. This effect also limits the output swing of the overall amplifier in the case where the second stage is operated at a gain below unity.

As an extreme example, consider the case in which the supply voltages are ± 15 V and all op-amps are limited in range only by these supplies. Also consider the case in which the second stage is operated at a gain of 0.1 ($R3/R4 = 10$). With the outputs of A1 and A2 at opposite supply rails, the output swing will be only 3 V, and even if a 1 V output swing is all that is required, the common-mode input range will be reduced by 10 V, barely making a ± 10 V common-mode input range with symmetric swings for the input amplifiers.

A more practical example might be the case in which the second stage gain is set to unity and ± 10 V swings are required at the output. This output swing can now be achieved, but again the common-mode input range is still barely ± 10 V, even with ideal amplifiers. For realistic op-amps requiring 2 V of headroom, the common-mode input range is at best ± 8 V with a full differential signal applied. If this range is unacceptable, then gain must be provided in the second stage.

The symmetric swing referred to previously actually occurs when $R5$ is equal to $R6$. This is highly desirable because it maintains as much symmetry as possible in the two input op-amps. Making $R5$ and $R6$ dissimilar can cause offset problems (due to the input bias currents of the op-amps flowing through unequal impedances) and ac CMRR problems (because the effective closed-loop gains of the amplifiers are different). Purposely making $R5$ and $R6$ different values can position the common-mode input range closer to one supply or the other, but this is usually a poor solution to the problem.

Suffice it to say that most commercial implementations of this architecture (and there are many) have used symmetric values for $R5$ and $R6$ and a second stage gain of unity (occasionally greater). Even with these limitations, this is one of the most powerful configurations available for instrumentation amplifier realization.

REFERENCE INPUT

Because the instrumentation amplifier has a differential input and single-ended output, it is necessary to refer the output voltage to some reference potential. So far, this has been represented by a symbol commonly referred to as ground, which is a somewhat universal reference point in most analog systems. Often, however, the integrity of a global ground connection is

highly questionable, particularly when high degrees of analog precision are sought. In some cases, it may be necessary to refer the output to some other potential; this is particularly true where only a single supply voltage is available and the so-called ground is actually one of the supplies (usually the negative one). In the circuit of Fig. 2 the ground connection is made via $R2$, but in fact this point can be used as a reference input since it has (close to) unity gain to the output. Most modern, commercially available instrumentation amplifiers therefore label this pin as reference rather than ground. In the interest of clarity, many of the figures in this article show the reference input as a ground symbol. For the purpose of this article, the ground symbol may be assumed to correspond to a reference input, which can be used to refer the output to a different point (or a precision Kelvin ground) inside the system.

SENSE INPUT

The overall feedback loop for an instrumentation amplifier is often completed externally to allow for Kelvin sensing of remote potentials where there exists the possibility of significant voltage drops along the connecting wires (due to finite loading of the amplifier output). Thus, some instrumentation amplifiers feature a sense input, which is almost always connected to the final amplifier output, either locally or remotely via force and sense wires.

Care must be used when taking advantage of this feature, however, since most instrumentation amplifiers can become unstable when presented with large amounts of capacitance at the output, a condition often created by long wires connected to the output (and sense) pins.

INPUT AND OUTPUT REFERRED ERRORS

This is a good point at which to introduce the concept of input and output referred errors. In virtually all variable-gain instrumentation amplifiers, most of the error terms actually have two components. One is called output referred, since it appears at the output independent of gain setting. Examples of this are the CMRR error caused by mismatch of resistors $R1$ – $R4$ in Fig. 2 and all errors caused by op-amp A3. The other component is called input referred, and it appears at the output multiplied by the overall gain of the amplifier. Examples of this are almost all errors attributable to the input op-amps A1 and A2. Most instrumentation amplifier data sheets specify these terms (such as input offset voltage and output offset voltage) separately. Since the sign is generally unpredictable, at any particular gain the terms are usually presumed to add at the output (except for noise, where an RSS [root sum of squares] summation technique is generally applied).

In passing, it should be noted that it is not so much the individual errors of A1 and A2 that appear as the input referred error (again, except for noise) but the difference between them, since any systematic errors appear as a common-mode signal to the second stage. For this reason, a matched monolithic dual op-amp is usually used for A1 and A2 in the configuration of Fig. 2.

THE TWO-OP-AMP INSTRUMENTATION AMPLIFIER

The simple circuit of Fig. 1 attempts to balance the inverting and noninverting gains of an op-amp operated in a closed-loop

Figure 3. Two-op-amp instrumentation amplifier.

configuration by attenuation of the signal at the noninverting input. Another alternative is to leave the noninverting input alone (thus maintaining its inherently high input impedance) and to use a second op-amp to balance the gains by amplifying the gain at the inverting input. Since the latter op-amp can be operated in a noninverting gain configuration, a high input impedance for both final instrumentation amplifier inputs can be preserved. The basic circuit is shown in Fig. 3. The op-amp A2 provides the differential function, while A1 amplifies the $-IN$ input to equalize the gains between the $+IN$ and $-IN$ inputs. The incremental transfer gain from $+IN$ to the output is given by

$$G_+ = 1 + \frac{R_4}{R_3}$$

whereas the incremental transfer gain from $-IN$ to the output is given by:

$$G_- = -\left(1 + \frac{R_2}{R_1}\right)\left(\frac{R_4}{R_3}\right)$$

To obtain good CMRR, the absolute value of these gains must again be equalized, and this is achieved by making the ratio of R_2/R_1 equal to R_3/R_4 , in which case the common-mode gain is theoretically zero and the differential gain is given by

$$G_{\text{diff}} = 1 + \frac{R_4}{R_3}$$

The resistor matching requirements for CMRR are very similar to the simple configuration of Fig. 1, except that the CMRR depends on $G/4\Delta R$ rather than $(1 + G)/4\Delta R$. Choosing R_2 equal to R_3 and R_4 equal to R_1 balances input bias current errors of the op-amps (but not their dynamic characteristics—more on this later). Of more importance, however, are the gain and common-mode input range limitations. The first thing to be noted is that unity gain (or anything less) is impossible, because under these conditions the value of R_2 must be infinite. Second, even at somewhat higher gains, it should be noted that A1 *always* amplifies the common-mode voltage, producing severe limitation of common-mode input range due to available swing at the output of A1. For this reason, it is rare to find this configuration used in an overall gain of less than five (the closed-loop gain of A1 asymptotically approaches unity as the overall gain is increased, progressively ameliorating this problem).

Another limitation concerns the ac characteristics. Like the circuit of Fig. 2, a matched dual monolithic op-amp used for

Figure 4. Modified two-op-amp instrumentation amplifier.

A1 and A2 can contribute greatly to the goal of good dc precision. Unlike the circuit of Fig. 2, however, the op-amps operate under very different individual closed-loop conditions. This causes problems when trying to maintain a good CMRR versus frequency, particularly since the entire phase shift of A1 appears in the inverting path but is totally absent in the noninverting one. Some phase compensation techniques can be applied to help this situation, but for the most part if good ac characteristics are required, this is unlikely to be the topology of choice.

A final note concerns the variable-gain characteristics of the circuit of Fig. 3. Like the circuit of Fig. 1, any gain change requires that the ratio matching of R_2/R_1 to R_3/R_4 be left unchanged if CMRR performance is not to be degraded. Bearing in mind that there is a practical minimum gain for this configuration, there is a way to increase the gain without severe CMRR penalty. Figure 4 shows the modification. The addition of R_G between the inverting inputs of A1 and A2 modifies the gain equation to

$$G = \left(1 + \frac{R_4}{R_3}\right) + \left(\frac{2R_4}{R_G}\right)$$

Using this technique, some commercial realizations of this configuration have had their usefulness greatly extended. Companies such as Linear Technology and Burr-Brown feature this configuration in their product portfolio (at the time of writing) in the form of monolithic integrated circuits.

AN ALTERNATIVE APPROACH USING THREE OP-AMPS

Another possibility using three op-amps is shown in Fig. 5 (6). Op-amp A2 does most of the work, with A1 (connected as a unity-gain buffer) restoring a high impedance to the inverting input ($-IN$). In this case, however, the inverting and noninverting gains of A2 are equalized by using a third op-amp (A3) to provide active attenuation of the common-mode signal appearing at $-IN$. This common-mode signal is impressed across R_1 and, by the action of A3, is injected as a nulling current back into the inverting input of A2. It can be shown that optimum CMRR is obtained when the ratio of R_3/R_1 is made equal to the ratio of R_2/R_{FB} . For symmetry, generally R_1 will be made equal to R_{FB} and R_2 will be made equal to R_3 . This topology has some interesting characteristics:

Figure 5. An interesting alternative three-op-amp configuration.

1. CMRR can be trimmed by a fine adjustment on any of R_1 , R_2 , or R_3 without affecting the gain of the amplifier.
2. The overall differential gain is simply R_{FB}/R_G . Thus gains from zero to any practical value are available by adjusting only one component (R_G). The CMRR (referred to output) is not affected by this gain adjustment.
3. The circuit is capable of a very wide common-mode input range. Op-amps A1 and A2 limit this range by their input/output swings in the usual fashion, of course, but the main limitation comes from the output swing of A3 since it amplifies the common-mode voltage by the factor $(1 + R_3/R_2)$. This limitation can be removed, however, by choosing the ratio of R_3/R_2 to be small enough that the other amplifiers become the limiting factor. The common-mode input range of the overall amplifier can thus approach the limits of the op-amps themselves.

This circuit (as might be anticipated) is not without drawbacks. The most significant of these is due to the fact that the errors of A3 are effectively amplified by the ratio R_{FB}/R_2 (this is an output referred error, not affected by gain setting). So attempts to maximize the common-mode input range in this manner tend to produce higher output offset voltages and noise. Also, A1 and A2 operate in very different closed-loop conditions, making it difficult to maintain good CMRR at high frequencies. Finally, the inverting input ($-IN$) is loaded by only one op-amp, whereas the noninverting input ($+IN$) is loaded by two op-amps, making the input characteristics somewhat asymmetric, especially in the case where the op-amps have significant input bias currents. Nevertheless, this configuration has been used (with some modification) to produce a monolithic instrumentation amplifier capable of operating from a single 5 V supply, where the common-mode input voltage range extends all the way to the negative supply rail (7).

VENTURING BEYOND OP-AMP DESIGN TECHNIQUES

The examples presented so far have relied on configurations formed from conventional op-amps and resistors. True, all of the aforementioned circuits have been integrated in monolithic form at some time or another; but they all could also be effectively produced using commercially available off-the-shelf components. In parallel with developments along these conventional lines, the monolithic integrated circuit industry has produced many topologies for the realization of the instrumentation amplifier function, most of which would be difficult, and certainly uneconomic, to produce outside the environment of a monolithic integrated circuit. The remainder of this article focuses on some of the more important techniques used to produce monolithic instrumentation amplifiers.

CURRENT-FEEDBACK TECHNIQUES

The traditional design approach of using conventional operational amplifiers with feedback consisting of resistive components is nowadays often referred to as *voltage feedback*. In the mid-1980s a new term started to appear in op-amp literature: *current feedback*. A current-feedback op-amp differs from a conventional one in that its inverting input is internally held at a low impedance; the displacement current in the compensation capacitor is ultimately derived from the current flowing in the feedback network (8). This enables such op-amps to have very high slew-rate characteristics. Also, to the extent that the inherent input impedance of the inverting input is less than that of the feedback network, such op-amps maintain a more constant bandwidth as the closed-loop gain is increased than their conventional counterparts (which tend to have a fixed gain-bandwidth product). The drawback here is that such op-amps have intrinsically imbalanced

Figure 6. Current-feedback version of Fig. 2.

input stages and cannot approach the precision of more conventional types, despite many ingenious schemes to balance them up. Actually, current-feedback is an offshoot of what used to be called *cathode feedback* in the vacuum-tube days and is not a fundamentally new technique from a circuit theory viewpoint.

Applying current feedback to an instrumentation amplifier is actually much easier than in the case of a general-purpose op-amp (although all configurations described so far can be implemented using current-feedback op-amps). This is because the instrumentation amplifier is an inherently dc balanced structure with well-defined feedback components.

Figure 6 shows a current-feedback approach to the configuration of Fig. 2 (9), now produced in integrated circuit form by several manufacturers. Essentially, this consists of the classic three-op-amp design preceded by a preamplifier consisting of $Q1$ and $Q2$ and their associated load resistors, $R5$ and $R6$. Feedback (via the resistors R_{FB}) is now returned directly to the emitters of the input pair rather than to inherently high-impedance op-amp inputs, as in previous examples. The bias currents for $Q1$ and $Q2$ are not set by current sources $I1$ and $I2$ (as might first be thought) but rather are provided from the outputs of $A1$ and $A2$, in a common-mode feedback loop controlled by V_{bias} . Since these currents must flow through the feedback resistors (R_{FB}), $I1$ and $I2$ are added in order to center the common-mode swing at the outputs of $A1$ and $A2$ (these current sources are sometimes omitted when the input stage currents are small enough to produce negligible voltage drops across the feedback resistors).

The gain equations for this arrangement are identical to that of the example presented in Fig. 2, at least under dc condi-

tions. However, to the extent that the dynamic impedance at the emitters of $Q1$ and $Q2$ is lower than the value for R_G , the latter component does not greatly attenuate the overall ac feedback, resulting in an approximately constant bandwidth (rather than a constant gain-bandwidth product typical of voltage-feedback configurations) as R_G is varied. The configuration does slow down at higher gains (as R_G becomes comparable to or less than the input transistors' dynamic emitter impedance), but it can still offer a considerable practical improvement in overall bandwidth and settling time.

Other advantages stem from the fact that only two transistors comprise the input stage, rather than the four necessary for two conventional op-amps. This leads to reduced input-referred errors (particularly noise). A minor disadvantage comes from the fact that the uncorrelated portion of the error currents in $I1$ and $I2$ (and the input transistors) has to flow through the feedback resistors and appears as an increase in output referred offset and noise. With careful design, however, this effect can be kept small. Similar current feedback configurations can be devised for the other voltage-feedback topologies presented previously.

ACTIVE FEEDBACK

In the sense used here, *active feedback* involves the use of an active voltage-to-current converter as a feedback element, instead of the resistor, which until now has been shown as the basic feedback component. Confusingly, the term *current feedback* has also been employed for this type of feedback, and there is no real accepted standardization in common usage (maybe

this article will encourage such a standard). At least I feel I have defined my own nomenclature (with some historical justification), but for the record I am one of the many whose past publications have (unintentionally) contributed to the present state of confusion.

CONCEPTUAL ACTIVE-FEEDBACK INSTRUMENTATION AMPLIFIERS

In the basic circuit of Fig. 7, two identical differential bipolar transistor pairs (they could be field-effect transistors in theory) are degenerated by R_{G1} and R_{G2} (assumed to be equal for now, as are the current sources $I1$ through $I4$). The degeneration resistors are large enough to ensure that any desired differential input voltage (impressed between $+IN$ and $-IN$) will retain some sensible current in both of the input transistors, $Q1$ and $Q2$. Both differential pairs are summed into differential loads consisting of $R1$ and $R2$, which are further sensed by op-amp $A1$.

A negative feedback loop is provided from the output of $A1$ to the second differential pair (note that the base of $Q3$ is grounded). When the loop is closed (frequency compensated by capacitor C_C), the output voltage will thus be closely equal to the differential input, independent of the common-mode input voltage (10). The nonlinearities of the two transistor pairs nominally cancel under this arrangement; thus the circuit forms a unity-gain amplifier with common-mode rejection limited only by second-order nonidealities in the transistors themselves. The most important nonideality (for CMRR purposes) is the mismatch of output impedance of the two transistor pairs. Without resort to any kind of trimming, this can be a large number indeed, leading to a high CMRR.

The drawback of this arrangement is that it is difficult to adapt it to variable gain. At first glance, making R_{G1} a variable component does the trick (and will result in variable gain), but under these circumstances the nonlinearities of the transistor pairs no longer cancel (except at unity gain), resulting in cubic distortion products that are likely to be unacceptable at higher gains.

Another idea is to place a resistive attenuator between the output of $A1$ and the base of $Q4$. While this technique will preserve linearity, it has the unfortunate effect of amplifying both input and output referred errors. If the gain range is small

and the corresponding input range is well defined, a very good amplifier can result, since the transconductance of both stages can be optimized. For wide gain ranges, however, the result is a noisy instrumentation amplifier with poor output referred errors and loss of bandwidth at high gain settings.

One possible method of producing a more usable instrumentation amplifier from this general idea is shown in Fig. 8. In this configuration, the nonlinearities of the transistor pairs are corrected by enclosing them in localized operational amplifier feedback loops. This enables the gain to be varied (without distortion penalties) by adjustment of the ratio of R_{G1} to R_{G2} . Some merging of the op-amp functions is possible, and a monolithic design based on this idea has been reported in the literature (11).

One interesting aspect of this configuration is that the major feedback loop (completed by op-amp $A1$) is almost totally divorced from the input section. This effectively means that as R_{G1} is reduced to increase gain (assuming R_{G2} is left alone), the loop bandwidth does not change. Thus the overall amplifier bandwidth tends to remain constant even as the gain is varied over a wide range (gains of zero to any practical upper limit are possible with this arrangement and with most other active-feedback configurations).

Unfortunately, this configuration has developed a rather complex input stage, which tends to produce high levels of input referred errors (particularly input offset voltage, input offset drift, and input referred noise). Other schemes that do not need such a complex input stage have been developed in order to alleviate this situation. Before continuing, however, a note concerning output referred errors is in order. Active-feedback amplifiers, in general, tend to have high output referred errors (their major drawback compared to more conventional techniques using op-amps and resistors). This is because the active voltage-to-current converters used to provide the feedback have much larger offset and noise components than simple resistors. The high degree of gain flexibility (usually from zero upward), intrinsically high common-mode rejection (without trimming), and potentially high speed characteristics of the active-feedback instrumentation amplifier come with a penalty in terms of precision at low gains. As a crude generalization, modern active-feedback instrumentation amplifiers offer significant advantages in terms of speed and CMRR at most gains but tend to be poor in most other respects at gains below 50 or so. At lower gains (certainly below 10), more conventional

Figure 7. Conceptual active-feedback instrumentation amplifier.

Figure 8. Active-feedback instrumentation amplifier with variable gain.

techniques are likely to provide better overall performance and, in conjunction with the current-feedback approach, are likely to be competitive in terms of speed.

PRECISION ACTIVE-FEEDBACK INSTRUMENTATION AMPLIFIERS

The basic idea for an active-feedback amplifier with a precision input stage is depicted in Fig. 9. Transistors $Q1$ and $Q2$ are biased at a quiescent point determined by the standing currents from a highly linear voltage-to-current (V -to- I) converter. Feedback provided by op-amp $A1$ to the V -to- I converter controls the differential characteristics. If the open-loop gain is high, the feedback loop will force the currents in $Q1$ and $Q2$ to be equal—regardless of differential input—while the output currents of the converter are not equal due to the presence of the gain-setting resistor, R_G . Because the input transistors are operated under identical conditions, the differential input voltage is directly forced across R_G , so the differential output currents of the V -to- I converter are $2(\Delta V_{in}/R_G)$. Since the V -to- I converter is presumed to be linear, the output voltage is now equal to the input voltage multiplied by the product of R_G

and half the differential transconductance of the converter, independent of the common-mode input voltage because of the converter's inherently high output impedance.

The output referred errors (as in previous examples) are those of the active V -to- I converter and can be comparatively high. The input errors, though, can closely approach the intrinsic errors of $Q1$ and $Q2$ alone, yielding a theoretical input stage precision about as good as anything available on a monolithic integrated circuit.

The structure of the V -to- I converter is obviously critical to the performance of this topology, and various methodologies have been used from time to time. With the inherent advantage of high CMRR without trimming, it is not surprising that the first fully integrated monolithic instrumentation amplifier would be an active-feedback design (12) (which became commercially available as the Analog Devices part number AD520). Four years later, a much improved design (13) was introduced (the AD521). Figure 10 shows the basic topology. Amplifier block $A2$ adjusts the current sources $I3$ and $I4$ to maintain constant currents in the input transistors, $Q3$ and $Q4$. Under these circumstances, the differential input voltage is accurately forced across the resistor R_G . The difference in $I3$ and $I4$ is now simply twice the input voltage divided by R_G . The current sources $I1$ and $I2$ are slaved to $I3$ and $I4$, so their difference is exactly the same. The amplifier $A1$ forces half of this difference to appear across the resistor R_s . The gain is now simply R_s/R_G . In the example presented, both R_s and R_G were external components, although there is not much flexibility in the choice of R_s because of limitations of the maximum values of the internal current sources.

The need for two amplifier blocks and parallel-connected controlled current sources tends to exacerbate output referred errors in such designs, and one method of alleviating this is to place the V -to- I converter in series with the input stage. This is not a trivial task, since the resulting V -to- I converter must reside entirely in the space left between the extremes of the common-mode input range and one of the supplies (usually the negative). One method of achieving this is shown in Fig. 11, first implemented by National Semiconductor (14).

The V -to- I converter is composed of $A2$, $A3$, $Q3$, and $Q4$ with $I1$ and $I2$ providing emitter bias current for the input stage, $Q1$ and $Q2$. To prevent negative common-mode excursions at the input from causing $Q3$ and $Q4$ to saturate, the output is attenuated and level shifted by resistors $R3$ and $R4$. Balance is restored to the other side of the V -to- I converter by an

Figure 9. Conceptual topology for a precision active-feedback instrumentation amplifier.

Figure 10. Active-feedback instrumentation amplifier using a parallel V-to-I converter.

identical network consisting of $R5$ and $R6$. $A2$ and $A3$ can now be made extremely simple because no level shifting is required and any systematic offset will cancel between the two op-amps. One drawback of this technique is that mismatches in the ratios of resistors $R3/R4$ and $R5/R6$ can cause severe degradation of the negative power-supply rejection.

The effective differential transconductance of the V-to-I converter is twice the inverse of R_{G2} , and similarly the effective input stage transconductance is twice the inverse of R_{G1} . The overall transfer function is now given by

$$G = \left(\frac{R4}{R3 + R4} \right) \left(\frac{R_{G2}}{R_{G1}} \right)$$

For the example of Ref. 14 (National part number LM363), the gains are selected by pin-strapping internal resistors to provide

gains of 10, 100, or 1000 (fixed-gain versions with gains of 10, 100, or 500 are also provided).

Other implementations of this architecture (15,16) (Analog Devices part numbers AMP-01 and AMP-05) have left R_{G1} and R_{G2} as external components with the ratio of $(R3 + R4/R4)$ internally set at 20. This results in an overall differential gain equal to $20(R_{G2}/R_{G1})$ and, like most configurations of the active-feedback amplifier, allows a user-defined gain setting from zero to any sensible upper limit.

GLOSSARY OF FREQUENTLY ENCOUNTERED TERMS

Gain

The gain specification relates to the transfer function of the instrumentation amplifier. Typically, gain can be fixed, adjustable

Figure 11. Active-feedback instrumentation amplifier using a serially connected V-to-I converter.

by pin-strapping, digitally selectable, or controlled by an external resistor (R_G). In the latter case a transfer equation will normally be provided.

Gain Range

The gain range is the overall range over which the gain equation is considered valid. At the lower end it is generally limited by the type of configuration used, while at the upper end it is often theoretically unlimited. Practically, at very high gains, all instrumentation amplifiers eventually exhibit errors that render them unusable. When an upper figure appears on a data sheet, it is usually the point above which the device manufacturer is not willing to provide any guaranteed specifications.

Gain Error

The number given by the gain error specification (usually expressed as a percentage) describes the maximum deviation from the gain equation. This is, for convenience, often quoted (and tested) at several fixed gains, with the user left to interpolate between them. Note that when an external resistor appears in the gain equation, the absolute tolerance of this component also appears as part of the gain error.

Nonlinearity

The instrumentation amplifier is assumed in simple theory to have a linear transfer characteristic from the differential input to the output. Obviously, in practice some nonlinearity will exist, and this represents an error that is nearly impossible to trim out or compensate for.

Nonlinearity is generally expressed as the peak deviation from a straight line superimposed on the plot of the output voltage as the input voltage is varied (at a particular gain setting) over a range wide enough to sweep the output over a specified excursion range. It is normally expressed as a percentage of the *maximum output excursion*, not the value of the output excursion at any other point. As such, nonlinearity is thus generally defined as an output referred error, and specifications will usually be quoted at a selection of representative gains.

The manner in which the straight line is defined can also cause some confusion. A line drawn between zero and theoretical full scale is probably the obvious one, but one argument suggests that this would produce a nonlinearity specification that includes other error terms (particularly offset voltage and gain error), which are generally specified separately (and in theory can be calibrated out). If the resulting line is drawn between measured zero and full scale, complications can occur when positive and negative signals are accommodated, since the resulting line drawn between the positive and negative full-scale output may not pass through zero. Generally, a line drawn between two arbitrary points (such as zero and theoretical full scale) gives rise to the term *end point nonlinearity*, whereas a line skewed to pass through two or more measured points with minimum peak error is termed *best-fit nonlinearity*. Careful reading of a data sheet specification is necessary to determine the effect that a given nonlinearity specification will have on an actual system.

Offset Voltage

The offset voltage of a practical instrumentation amplifier consists of two terms: the input offset voltage and the output offset

voltage. The input offset voltage is an error voltage that appears at the output multiplied by the selected (differential) gain of the amplifier. Therefore, it tends to predominate when the amplifier is configured for high gain applications. The output offset is an error term always present at the output, regardless of gain setting. Theoretically, it is defined as the error voltage at the output when the gain is set to zero, though this has to be extrapolated for many configurations where zero gain setting is impossible. The output offset voltage is obviously most troublesome at low overall amplifier gains.

Input (Bias) Current, Offset Current, and Input Impedance

The input current is simply the current drawn by one or both of the inputs when the amplifier is operated in its normal region (sometimes expressed as an average, or as a maximum of the two). This is often called an input bias current because such currents (at least in a bipolar junction transistor amplifier) are the base currents of the input transistors necessary to maintain them at their selected bias point. For amplifiers with field-effect transistor inputs, the input current generally reflects leakage currents associated with details of their fabrication.

The input offset current is the difference between the two input currents, of paramount importance when balanced source impedances are used. This is a measure of how well the two input currents are matched on a particular device.

Related specifications include differential and common-mode input impedance. The former represents the change in input offset current when a differential voltage is applied; it is normally defined as the reciprocal of the change in input offset current times the differential voltage used to induce it. The common-mode input impedance is normally defined as the reciprocal of the change in the sum of the two input currents multiplied by the common-mode voltage used to induce it. For most modern instrumentation amplifiers, the effect of both input impedance terms is usually negligible compared to the overall values of the input currents.

Common-Mode Rejection Ratio

The CMRR is a measure of the change in output voltage when both inputs are changed by equal amounts. These specifications are usually given for both a full-range input voltage change and a specified source imbalance. Because CMRR is usually a large number, it is usually expressed in decibels. For example, a CMRR of 10,000 could be expressed as 80 dB. Because CMRR generally consists of both input and output referred components but is always specified referred to the input, it will normally (apparently) increase with gain. For this reason, CMRR is almost always specified at several representative gain settings.

Common-Mode Input Voltage Range

The common-mode input voltage range represents the maximum excursion common to both inputs over which the CMRR specifications are guaranteed. For some instrumentation amplifiers, this is a function of differential input voltage, and often the input voltage range will be expressed by an equation rather than a fixed value. Another way to express the input voltage range is to specify a maximum excursion for either input, since for some amplifiers (particularly active-feedback types) this is a more realistic definition.

Power-Supply Rejection Ratio

The power-supply rejection ratio (PSRR) is a measure of the change in output voltage either when both power supplies are changed by equal amounts (in opposite directions, to remove any CMRR component) or when each supply is varied independent of the other (of course, there is only one supply to be varied in the case of a single-supply amplifier). Like CMRR, PSRR is often expressed in decibels, generally consists of both input and output referred components, is normally specified referred to the input, and will normally increase with gain.

Settling Time

Settling time is defined as that length of time required for the output voltage to approach and remain within a certain tolerance of its final value. It is usually specified for a fast full-scale input step and includes output slewing time. Since several factors contribute to the overall settling time, fast settling to 0.1% does not necessarily mean proportionately fast settling to 0.01%. In addition, settling time is not necessarily a function of gain. Some of the contributing factors include slew rate limiting, underdamping (ringing), and thermal gradients (long tails).

CURRENT SHUNTS

Electric current can be measured directly, through the physical effects of the current itself, or indirectly, by measuring the resultant voltage as the current flows through a suitable, well-defined impedance, usually called a current shunt.

Direct techniques are exemplified by the torque or force produced on a current carrying coil in a magnetic field, such as in classical D'Arsonval meters and electrodynamic meters. Other approaches have used the force on an "iron vane" produced by a current carrying coil, the expansion of a "hot wire" carrying a current to move an indicator needle, and the heating of a thermocouple junction to produce a voltage. The latter case is arguably an indirect measurement, illustrating the somewhat arbitrary nature of the distinction.

Even electrochemical methods have been used to measure current, such as the transfer of mercury across an electrolytic gap in a glass capillary tube, or the mass of a deposited metal in an electrolytic cell after a fixed time interval. These might more accurately be considered amp-hour meters, as they measure the time integral of current.

Indirect techniques are typified by the use of a low-value resistive "shunt" to convert current into a corresponding voltage. Although resistances of any value might be used to measure small currents, shunt resistances are typically in the milliohm to microohm range for currents above one amp. The use of current shunts is increasingly common with the advent of modern Digital Volt Meters (DVM), which are essentially voltage-measuring devices.

CURRENT SHUNT DEVELOPMENT

Early moving coil meters were capable of measuring currents from microamps to several amps. For higher currents, a low-value "shunting" resistance was placed in parallel with the meter, bypassing a large and well-defined fraction of the current around the meter and increasing the measurable current. For large currents, the shunt would be mounted outside the meter housing for better cooling and to allow the shunt and meter to be physically separated for convenience.

It became relatively standard to design panel meters and shunts to operate with 50 mV at full meter scale, while precision "laboratory" grade shunts were more often 100 mV full scale. This standardization allowed the same meter movement to be used for nearly any current, requiring only a suitable shunt resistance and meter scale. Modern shunts for DVMs are usually made in values divisible by a power of ten, allowing current to be read directly from voltage simply by shifting the decimal point; for example, the conductance in a 100 $\mu\Omega$ shunt is 10 A/mV, or 10,000 A/V.

Current shunts may be used for both dc and ac currents, although the design of shunts for high-frequency (kHz to MHz) ac currents is more involved than for dc or low-frequency ac current.

DC CURRENT SHUNT DESIGN CONSIDERATIONS

The principal considerations in dc and low-frequency ac shunts are accuracy and stability, which are more difficult to achieve with low resistances. The power dissipation in high-current shunts is also a complication, as shall be seen.

Contact Resistances

Contact resistance is a major factor in defining and accurately measuring resistances below 1 Ω . Current shunts are usually designed with two connections for current, and two additional connections for sensing shunt voltage (or “potential”), as shown in Fig. 1, often termed a four-terminal “Kelvin” connection. Measurement errors due to the indefinite current contact resistances (R_1 and R_2 in Fig. 1) are eliminated, as only the voltage across the shunt resistance R_s is sensed. Voltage-sense contact resistances R_3 and R_4 form a resistive divider with the voltmeter, but these resistances are usually negligible, compared with the input resistance of a voltmeter, and are thus not a significant source of error.

Power Dissipation Effects

Although the voltage drop is relatively low on a current shunt, the power dissipation can be quite significant; for example, a 1000 A, 100 mV shunt will dissipate 100 W at the rated current. The resulting temperature rise can cause two sources of error: a change in shunt resistance, and a thermal electromotive force (emf), or voltage where dissimilar metals join (a thermocouple effect).

A net thermal emf can occur when the two ends of the shunt are not at the same temperature, resulting in a shunt voltage measurement error. A thermal emf may add to or subtract from the shunt resistive voltage, depending on the algebraic sign of the thermal emf relative to the resistive voltage with a dc current.

Figure 1. Separate shunt current and potential connections are used to minimize errors due to contact resistances.

These errors are much less when measuring ac currents, as the thermal emf adds to the resistive voltage during one half of the ac cycle, and subtracts during the other half cycle. The result is a complete cancellation of the thermal emf with an average responding ac voltmeter. If the dc component is not blocked to an rms responding voltmeter, the measurement error is still only 1% with a 10% thermal emf, and a 0.01% error with a 1% thermal emf component.

Selecting a Shunt Material

Pure metals have the low resistivity desirable for shunts, but the temperature coefficients of resistance (TC, or TCR) are high, ranging from about 3 m Ω /(Ω ·°C) for platinum to 6 m Ω /(Ω ·°C) for nickel (0.3%/°C and 0.6%/°C, respectively). Alloys of metals typically have higher resistivities but lower TCRs—occasionally much lower. The thermal emf can range from less than one to tens of μ V/°C. The approximate electrical properties of selected metals and alloys are given in Table 1; resistivity and TCR may vary significantly with impurities, alloy composition and degree of work hardening or annealing.

Nichrome is a common resistance alloy with high temperature capability and good corrosion resistance, but the TCR and thermal emf are both relatively high (see Table 1). Nichrome is also physically hard and difficult to work, and cannot be soft (tin/lead) soldered, but must be welded or hard (silver) soldered. Constantan has a much lower TCR than Nichrome, but the thermal emf effect is even stronger.

Table 1. Selected Properties of Electrical Metals and Alloys

Metal	Typical Composition	Resistivity $\mu\Omega \cdot \text{cm}(20^\circ\text{C})$	TCR ppm/°C	Thermal emf ^a eV/°C	Ref.
Copper	Cu100	1.7	3,900	+2.86	1
Silver	Ag100	1.6	3,800	+2.73	1
Aluminum	Al100	2.8	3,900	−0.42	1
Tin	Sn100	11.5	4,200	+0.20	1

Figure 2. Manganin shunt alloy has a minimum resistance change at elevated temperatures to allow for significant power dissipation, while manganin wire is optimized for room temperature operation of “laboratory standard” reference resistors.

In 1889, Edward Weston discovered that alloys of copper, manganese, and nickel have very low temperature coefficients. Alloys with 10% to 13% manganese and 2% to 4% nickel are trade-named Manganin. Still the principal choice for shunts, Manganin is available from Harrison Alloys, Inc. in Harrison, New Jersey (800) 526-1256 and (201) 483-4800, and Carpenter Technologies in Reading, Pennsylvania (800) 694-6543 and (610) 208-2000. Typical changes in resistance with temperature for Manganin are shown in Fig. 2. A low positive TCR occurs at low temperatures, with a “turnover” to a negative TCR at elevated temperatures. Operation near the TC turnover point is desirable for the highest temperature stability.

Manganin resistance wire is used for precision resistor standards from about one ohm to thousands of ohms. Power dissipation is minimal in this application, so the alloy content is adjusted to have the minimum resistance variation around room temperature. On the other hand, current shunts are usually required to dissipate significant heat (as noted previously), so Manganin, for current shunt applications, has an elevated TC turnover temperature of 40 to 60 °C.

Manganin can be hard (silver) or soft (tin-lead) soldered, and has a thermal emf compatible with all of the metals and alloys commonly used in electronics: copper, brass, bronze, silver, gold, tin, and tin-lead solder. Proprietary alloys, with even lower TC, have been developed for high-precision shunts and resistance standards, such as Zeranin 43 (Cu87, Mn7, balance unspecified) by Isabellenhütte in Germany.

Shunt Resistance

The theoretical resistance of a shunt is calculated from the formula:

$$R_s = \rho l / A \quad (1)$$

where

R_s = shunt resistance;
 ρ = resistivity;
 l = effective shunt length; and
 A = total area of shunt.

This formula is only a close approximation when applied to the shunt material, as there is a small resistance contribu-

Figure 3. Shunts for currents of hundreds to thousands of amps are designed for mounting on one or more bus bars, with good heat dissipation to the bus bars and ambient air.

tion from the end blocks, leads, or other terminations. In addition, the resistivity of the shunt material will vary somewhat from published values, due to residual impurities and processing variations. Precision shunts are designed to have an initial value slightly below the desired value. A calibration adjustment to the desired value is achieved by carefully removing small amounts of shunt material, which decreases the effective area and increases resistance.

DC CURRENT SHUNT CONSTRUCTION

The construction of typical shunts is shown in Figs. 3, 4, and 5. The high current shunt of Fig. 3 is designed to be bolted directly to bus bars carrying hundreds to thousands of amps. Multiple strips of Manganin are mounted in parallel for low resistance, with spaces between strips for cooling air flow. Copper end pieces are used to minimize their contribution to resistance, and to help conduct heat from the shunt into the bus bars.

A typical 20 to 200 A meter shunt is shown in Fig. 4. The basic construction is similar to that of high-current shunts, but is physically smaller, and wire or heavy cable current connections are often used instead of bus bars. In this case, the shunt is mounted on an insulated base for mounting on a panel. Copper end pieces are preferred for higher currents, while brass may be used at lower currents.

Low-current shunts (below about 10 A) may be designed for printed circuit board (PCB) mounting, such as shown in Fig. 5.

Figure 4. Current shunts in the 20 to 200 A range are typically designed for panel mounting.

Figure 5. Low-current shunts for 1 to 20 A may be mounted on a printed circuit board. A cooling space between the shunt and board is recommended when power dissipation exceeds one watt.

Current shunts with only two terminals may be used for lower currents when high accuracy is not required; these may have wire leads and resemble a conventional resistor in all but resistance value. Low-value “chip resistor” shunts are also finding increasing use for surface mounting on a PCB or other substrate, and these are also often two terminal devices.

The accuracy of Manganin shunts can range from 1% to 0.001% or less. Obtaining the highest accuracies requires careful design, fabrication, annealing, and aging of the shunt, with operation restricted to a limited temperature range. Precision shunts may be forced-air cooled, in order to improve accuracy or current rating, although an oil bath is more common. The oil bath may be stirred and/or water cooled, in order to keep the temperature change to a few degrees or less.

HIGH-FREQUENCY AC CURRENT SHUNT DESIGN

There are two principal limitations to the accuracy of shunts at higher frequencies; inductive effects, eddy current skin, and proximity effects. Inductive effects are usually the dominant high-frequency error source, with eddy current effects only of concern in essentially “noninductive” current shunts at very high frequencies.

Shunt Inductance at High Frequencies

A typical parasitic inductance of 10 to 50 nH has little impact on the impedance of a 100 Ω or 1,000 Ω resistor below a few hundred megahertz. However, even 10 nH of equivalent series inductance (ESL) severely limits the higher frequency accuracy of a 10 m Ω shunt; the impedance increases by 1% at 22.6 kHz and 10% at 73 kHz. For wattmeter applications, the phase shift between shunt current and voltage is even more important, particularly for low-power-factor measurements, where the system voltage and current are nearly 90° out of phase. For the above shunt, a 1° phase shift occurs at 2.8 kHz, increasing to 10° at 28 kHz.

The effective ESL of a shunt is the sum of intrinsic inductance of the shunt and mutual inductance coupling between the current input and voltage output leads, although it is not always practical, or even meaningful, to try accurately to separate the two components of inductance.

Accurate current measurement with shunts at high frequencies requires that ESL or its effects be minimized; the use of wirewound resistors for low-current shunts should be avoided for this reason. The intrinsic inductance of conventional

Figure 6. The high-frequency accuracy of a current shunt is typically limited by the equivalent series inductance (ESL). The accurate bandwidth can be extended by compensating the shunt's ESL/ R_s frequency response zero with an $R_1 \times C_1$ resistor-capacitor pole (see text).

low-frequency shunts (Figs. 3 and 4) is not readily reduced, but the larger ESL effects of mutual inductance between current and potential leads can often be reduced by a factor of two to ten, by bringing one or both of the potential sense leads back along the shunt body to a common point, and exiting from the shunt with twisted wires or coaxial cable. Minimizing the inductive area of the current leads would also reduce ESL, in principle, but is usually impractical or ineffective, due to the larger size and relative inflexibility of the conductors.

Shunt ESL Compensation

The effective bandwidth of a shunt can be extended significantly by compensating or canceling the inductive effects with either of two techniques. The first approach is to use a resistor-capacitor (R - C) network, as shown schematically in Fig. 6. The R_1 - C_1 network of Fig. 6 is used to create a response pole at the same frequency as the R_s -ESL zero of the shunt resistance and inductance, which occurs when

$$(R_1)(C_1) = \text{ESL}/R_s \quad (2)$$

This technique can extend the bandwidth of a shunt by orders of magnitude, although some care must be taken in the values of the compensating resistor and capacitor, to minimize other parasitic effects. Compensation resistor values in the range of 30 to 1,000 Ω are recommended; ESL of the resistor may limit bandwidth at lower values, while parasitic capacitance becomes a factor at resistances above this range. Using compensation capacitances below 47 to 100 pF increases sensitivity to loading by other parasitic capacitances, while the ESL of capacitors

Figure 7. The high-frequency bandwidth of a current shunt can be extended by compensating or canceling the shunt's equivalent series inductance (ESL) with a negative mutual inductance ($-L_m$).

Figure 8. An example of $-L_m$ compensation of shunt ESL, achieved by routing of a potential sense lead back through the magnetic field near a current lead.

above about 1 nF may limit the upper frequency of accurate compensation. The ESL of leaded resistors and capacitors is typically 10 to 20 nH, while that of surface mount “chip” devices is significantly lower, at 1 to 5 nH. The parasitic capacitance of a 1/4 W leaded resistor is about 0.4 pF, while that of a 1206 size chip resistor is less, at about 0.1 pF.

An alternative approach to ESL compensation is to use negative mutual inductance coupling ($-L_m$) between the current and potential leads, as shown schematically in Fig. 7; when $-L_m$ is numerically equal to ESL, the effects of the shunt ESL are canceled. In this approach, the potential sense leads are arranged in the magnetic field of the current leads, in such a way as to create an induced voltage, which cancels the inductive voltage of the shunt. An illustration of this approach is shown in Fig. 8, for the printed circuit board mounted shunt resistor of Fig. 5.

The ESL of a shunt is sensitive to both shunt construction and current and voltage lead placement, so these must both be well controlled and consistent. The ESL compensation must then be calibrated, by comparing the output voltage with the input current at frequencies above and below the R_s -ESL zero frequency.

Although the frequency response of the shunt can be measured with various compensations, the simpler time domain approach shown in the test circuit of Fig. 9 is recommended. A voltage pulse from a generator is applied to a noninductive resistor (typically 50 Ω), which is in series with the (relatively low-impedance) shunt. The current in the 50 Ω resistor will have essentially the same waveform as the voltage, so the shunt compensation is adjusted to match the sensed shunt voltage waveform to the input voltage waveform. In the following discussions, the pulse will be assumed to have a smooth risetime and a flat top or plateau, although this is not essential for ESL compensator calibration.

Figure 10. The effects on output voltage waveform of over- and undercompensation of shunt ESL with an R - C network (as in Fig. 6) are shown for a pulse input using the test setup of Fig. 9. The voltage and time scales are arbitrary.

Without compensation, the ESL of a current shunt will cause a large voltage overshoot during the pulse rise time. The overshoot may be tens to thousands of times higher than the steady-state voltage, depending on the shunt resistance, shunt ESL, and the pulse rise time.

When a shunt is undercompensated with an R - C network, the shunt voltage will still overshoot the desired value, as illustrated in Fig. 10, and then decay to the final voltage at the R - C compensation time constant. Overcompensation will cause the initial rise in voltage to be less than the desired value, with a longer rise to the final value, due to the greater R - C time constant. Correct compensation will produce a shunt voltage waveform essentially identical to the input pulse voltage waveform.

Full ESL compensation with negative mutual inductance also produces a shunt waveform equal to the input waveform, but under- and overcompensation produces different waveforms, as illustrated in Fig. 11. Undercompensation produces a similar shunt voltage overshoot as with R - C compensation, but the voltage falls back to the final value immediately after the input rise is completed. Significant overcompensation will cause the sensed shunt voltage to initially

Figure 9. A recommended test setup for calibrating shunt ESL compensation, with either an R - C pole or negative mutual inductance. The compensation is adjusted to achieve the same waveforms on oscilloscope probes 1 and 2.

Figure 11. The effects on output voltage waveform of over- and undercompensation of shunt ESL with negative mutual inductance (as in Fig. 7) are shown for a pulse input using the setup of Fig. 9. The voltage and time scales are arbitrary.

undershoot, or swing in the opposite direction, with an immediate rise to the final value at the end of the input current rise.

Thus both resistor–capacitor and negative mutual inductance ESL compensation of a shunt can produce an output voltage waveform that matches the input current. The voltage waveforms due to over- and undercompensation however, are quite different.

Noninductive Shunts

Shunts can be constructed to appear noninductive at the sense voltage, although there is always some finite inductance in series with the current terminals. These shunts effectively utilize negative mutual inductance ($-L_m$) compensation, but in an automatic way, which does not require calibration.

Coaxial Shunts. Coaxial shunts are the more widely known noninductive shunt construction. A cylinder of resistive ma-

Figure 12. Cross-section of a “noninductive” coaxial shunt, which achieves automatic $-L_m$ compensation of the input ESL by bringing the potential sense leads out through a flux free region inside the resistive cylinder.

terial is incorporated in a coaxial arrangement with current and potential leads, with the potential leads brought out in a “flux free” region. One such construction is illustrated in Fig. 12.

The coaxial shunt has a nearly zero sense voltage ESL, as none of the magnetic field between the coaxial conductor and shunt material is coupled to the sense leads. However, the coaxial shunt can be inconvenient to use in many applications, particularly when coaxial conductors are not already in use. The two-terminal “insertion inductance” may also be significant (perhaps tens of nanohenries), partly due to the magnetic field between the coaxial cylinders, and partly due to the transition joint required to noncoaxial conductors.

Parallel-Plate Current Shunt. An alternative construction for a noninductive shunt is shown in Fig. 13. A relatively thin and annealed Manganin foil may be folded over at the midpoint, with thin insulation (not shown) between the foils. The ends of the foil are soft- or hard-soldered to copper current terminations, which may be left parallel or folded apart at right angles, depending on the application. Thicker or unannealed foils or strips will have to be soldered together, in place of the fold.

Narrower voltage sense lead foils are also soldered to the copper current terminations, and are brought back along the center of the Manganin foils or sheets, as shown in Fig. 13, with thin insulation between the sense leads and the Manganin. Closely spaced foil sense leads may be continued to the shunt voltage sensing point, or a transition made to coaxial cable or a twisted pair of wires.

The parallel plate current shunt can have a sense lead effective ESL nearly as low as the coaxial shunt; Shunts have been constructed with an ESL of less than 50 pH. The insertion inductance may be an order of magnitude lower than that of a coaxial shunt (perhaps several nanohenries or less) when used with noncoaxial conductors.

If the propagation delay along the sense leads of a high-frequency shunt approaches 6 to 8% of a cycle at the highest ac frequency, or a quarter of the 10 to 90% rise time with a pulse current, then transmission line termination techniques should be used to minimize reflections and the resultant waveform distortion and measurement error. If the voltmeter has a high input impedance, a “source termination” at the shunt is advised, using a series resistor equal to the transmission line impedance. This will be 50 or 75 Ω for most coaxial cable, and typically in the range of 100 to 200 Ω for a twisted pair of wires. If the voltmeter input impedance matches the transmission line impedance (typically 50 Ω for RF applications), a source termination is, generally, not necessary.

Eddy Current Effects in Shunts

Skin effect is classically thought of as the nonuniform current distribution of an isolated conductor at high frequencies, due to eddy currents induced in the conductors. In a round conductor at high frequencies, the current is uniform around the surface, while the current falls off exponentially beneath the surface. The “skin depth” is defined as the depth below the surface where the current amplitude is $1/e$ (36.8%) of the surface value. If all of the current were flowing uniformly in the first skin depth of thickness, the effective resistance would be the same. The skin depth varies as the inverse

Figure 13. Construction of a “parallel plate” current shunt. The potential leads are brought out through a nearly flux-free region, to produce an essentially noninductive shunt.

square root of frequency, but also increases as the square root of resistivity.

When two or more conductors carrying high-frequency current are brought near to each other, the current distribution on the surface will change, which is termed a “proximity effect.” Currents flowing in opposite directions in two parallel cylinders tend to concentrate on the facing surfaces. The converse effect occurs when the currents flow in the same direction, as the currents begin to avoid the facing surfaces. At the risk of oversimplification, this effect can be envisioned as parallel currents “repelling,” while opposing currents “attract.”

The concept of skin effect as “the current distribution in an isolated conductor,” however, is misleading. For example, the high-frequency current in an isolated bus bar or thin ribbon is not uniform on the surface, but tends to concentrate on the outside edges and corners. The term “skin effect” should be limited to the exponential decay of current normal to the conductor surface; that is, the current distribution perpendicular to the conductor surface.

It is recommended that the current distribution around the conductor be considered a single-conductor proximity effect, caused by the mutual repulsion of parallel current filaments in the conductor. This conceptually explains the uniform surface current distribution in a round conductor and the nonuniform current in a flat conductor, where the current filaments “pile up” at the edges and corners.

The value of this distinction can be appreciated when relatively wide and thin sheets, plates, or bus bars are placed close together and carry high-frequency current in opposite directions, as in the parallel plate current shunt of Fig. 13. The proximity effects now force the high-frequency current to be uniform across the width of the sheets or plates (although only on the facing surfaces if the sheets are thicker than one skin depth).

The skin effect causes the impedance of coaxial or parallel plate current shunts to rise as the thickness approaches a skin depth. The excess impedance is a distributed resistance-inductance effect, asymptotically rising as the square root of frequency with the voltage leading the current by 45°. As such, the skin effect cannot be compensated by a single pole, but would require a distributed R - C network or the equivalent.

Thus, skin effect represents a more fundamental upper limit to a shunt’s useful frequency than ESL, and is best dealt with by using thinner foils. (The relatively high resistivity of Manganin, about 25 times that of copper, is useful in increasing skin depth and raising the frequency of skin effect impedance increases.) For a high-frequency current penetrating a flat or tubular conductor from one side (as in the parallel plate and coaxial shunts, respectively), the impedance increases about

Figure 14. The maximum “accurate” frequency of a coaxial or parallel plate current shunt is limited by skin effects. The “one-skin-depth” frequency limit for Manganin increases rapidly with thinner material.

10% when the conductor is one skin depth thick. For Manganin sheets or tubes with current flow on one surface, the “one skin depth” limit on frequency versus Manganin thickness is given in Fig. 14.

CURRENT TRANSFORMERS

Current transformers (CT) are magnetic devices, which assist in the measurement of current. Different applications necessitate a wide variety of designs. Current transformers used in the ac power field, along with voltage or “potential” transformers, are generally known as instrument transformers, and are discussed only briefly here. Other types of CT discussed in this article are:

- high-frequency CTs;
- pulse current transformers;
- ac + dc current-sensing transformers;
- precision dc current-sensing transformers;
- Rogowski coils.

Classical ac CTs are used to change an ac current to a more convenient level for measurement, while isolating the ammeter from the current carrying conductor. Current transformers used in electrical power applications typically operate at frequencies of 50 or 60 Hz, but may range from 25 Hz to 400 Hz or so. Measured current levels may be less than an amp to thousands of amperes or more, and transformation accuracies may range from 0.1% or better for critical measurements, to several percent or more for general indication or overload detection.

Higher frequency ac current transformers are used in a number of other applications, including RF transmitters, induction heaters and electronic power converters to control output, monitor operation, or diagnose problems. Frequencies may range from hundreds of hertz to hundreds of megahertz, while current levels are usually lower at milliamperes to hundreds of amperes. Accuracy requirements are often not as stringent, often in the 1 to 10% range, although errors down to 0.1% are obtainable at frequencies up to the low megahertz band. When very wide bandwidths are required, active electronic circuits can be used to extend the low-frequency limit by several orders of magnitude, while improving accuracy at midband frequencies.

Ac transformers can be adapted to measuring pulse currents, finding use in electronic power circuits and pulse energy systems. They can operate with a small net dc current, as long as the current is zero for a sufficient interval between pulses.

Conventional ac current transformers cannot measure dc current, nor can they usually tolerate significant dc current without magnetic saturation of the core. The CT can be adapted to measure dc as well as ac current, with modifications and the addition of electronic circuitry, albeit at some potential sacrifice in available accuracy. These devices are sometimes termed current transducers, to distinguish them from “ac only” CTs. Some oscilloscope current probes also use this approach to provide broadband sensing from tens of megahertz down to dc.

A close relative of the current transformer is the Rogowski coil, which physically resembles a current transformer but (usually) without a magnetic core. The open circuit output voltage is proportional to the time derivative of the measured current, rather than the current itself. Lacking a core, the device cannot be saturated by large ac or dc currents. As such, it may find use where high currents are involved, or at very high frequencies, where magnetic cores become a hindrance to accurate measurement.

HIGH-FREQUENCY CURRENT TRANSFORMERS

High-frequency current transformers (HFCT) are similar in design and construction to an instrument CT, principally differing in the common use of ferrite cores, which perform as well or better than nickel-iron cores above about 100 kHz. Minimization of capacitive loading and parasitic coupling also become much more important at high frequencies.

The maximum initial permeability of ferrite is about 10 k, but this value holds to low flux densities and up to at least 100 kHz. This permeability is superior to that of conventional silicon steel at very low flux densities for any frequency. The permeability of nickel-iron can reach values of 100 k, but begins to fall at a few kilohertz to similar values for ferrite above 100 kHz. However, ferrite often finds use at frequencies well below 100 kHz, due to a significantly lower cost than nickel-iron.

Unlike ac line frequency CTs, HFCTs are often used over a very broad band of frequencies, typically three to six decades of frequency. HFCTs are often used to reduce the current to be measured, as are ac line frequency CTs, but not necessarily for identical reasons. The load or burden on a HFCT is usually a resistance (instead of an ammeter), to convert the current to a corresponding voltage, which is easier to measure at high frequencies. The shunt resistance required to measure currents above a few amperes is typically much less than 1 Ω , in order to limit power dissipation. The parasitic inductance of current shunts becomes problematic at high frequencies, as described in the article titled Current Shunts.

The shunt inductance problem can be greatly alleviated with current transformers, even with a moderate turns ratio. A CT with a ten-turn secondary and a one-turn primary decreases the primary current and increases the voltage by ten times on the secondary. The secondary side current shunt now has 100 times the resistance required on the primary for the same power dissipation. The useable frequency increases by the same factor for a given shunt inductance, and the higher voltage is usually easier to measure accurately. For HFCTs, the secondary side current shunt is usually known as the *CT load resistance*, and this term will be used hereinafter.

Many high-frequency CTs use a single-layer secondary winding on a toroidal core with a single-turn primary, as shown in Fig. 1. Often the primary is composed of the conductor carrying the current to be measured.

Figure 1. A high-frequency ac current transformer is typically used with a resistive load or “shunt” to measure current.

Figure 2. A clamp-on current transformer allows current measurement without breaking the circuit.

In some instances the temporary installation of a current transformer is desired when it is not feasible to break the circuit carrying the current to install the transformer. Clamp-on current transformers are made for these applications, with a split core for placing around conductors without having to open the primary circuit. A hinged version of a clamp-on transformer is shown diagrammatically in Fig. 2. Other configurations may use a split toroidal core with a hinge, or a portion of the core may be made to slide into place to complete the magnetic circuit. The inevitable air gap between core pieces tends to reduce the accuracy and raise the minimum useable frequency of clamp-on current transformers.

Current transformers will algebraically sum the currents in two or more primary windings. This ability can be quite useful and sensitive in comparing two nearly identical currents flowing in opposite directions, as the CT responds only to the current difference. This allows a comparison of two currents to within parts per million in precision laboratory test equipment, or the detection of ground fault currents of a few milliamperes out of 10 or more amperes in the humble household ground fault interrupter (GFI) breaker.

HFCT Error Sources

An equivalent circuit for a typical transformer is shown in Fig. 3, including the usual parasitic “components,” in addition

to the ideal transformer. The relative importance of the various parasitic effects are quite different for current transformers, when compared with other types of transformers.

Primary Resistance and Leakage Inductance. The primary winding resistance R_p and transformer leakage inductance L' have no direct impact on current transformation accuracy, as they are in series with the primary input current I_p . Their only effect is to increase the insertion impedance of the transformer, which may have an influence on the primary current if the insertion impedance is not insignificant, compared with the impedance of the rest of the circuit.

Core Magnetization Currents. The core magnetizing inductance L_m and parallel loss resistance R_m have been shown on the secondary side of the ideal transformer, instead of the more conventional primary side placement. This helps clarify the sources of error, as the secondary current I_s is still an “ideal” transformation of the primary current. The ideal secondary current now divides among four parallel paths:

1. the core magnetizing inductance L_m ;
2. the core's parallel loss resistance R_m ;
3. the parasitic secondary loading capacitance C_s ; and
4. the output load resistance R_l .

The currents in L_m , R_m , and C_s bypass current from R_l , and are direct sources of error in the CT. The magnetizing inductance is principally of concern at lower frequencies, below about 100 kHz for a ferrite core permeability of 10 k, and at proportionally higher frequencies if lower permeabilities are used. As long as core flux densities remain below saturation, the minimum operating frequency f_1 is defined by:

$$f_1 = \frac{1}{[2\pi L_m / (R_l + R_s)]} \quad (1)$$

which is the corner frequency below which the current in L_m exceeds that in the load resistance R_l . The transformation error at this frequency is large, about 30%, and the phase displacement is 45° . If an accurate transformation is desired, the transformer has to be designed for a much lower corner frequency. Lowering the corner frequency requires increasing the core area/magnetic path length ratio, increasing the number of primary and secondary turns, and/or using a higher permeability core if one is available.

Figure 3. An equivalent circuit of a high-frequency current transformer is useful for identifying sources of error.

A second limitation to the minimum CT operating frequency may be core saturation, which occurs when the maximum secondary voltage experienced is too high for the number of turns used. Full saturation occurs at about 0.3 to 0.4 T in ferrites, but peak flux must be kept below 0.1 to 0.2 T (depending on material and operating temperature) for operation in the high permeability “linear” region of the core B - H loop. The number of turns required with a sinusoidal voltage is given by:

$$N = \frac{U}{4.44BAf} \quad (2)$$

where N is the number of turns; U is the rms voltage across L_m , in V; B is the allowable peak flux density, in T; A is the cross section of the core, in m^2 ; and f is the operating frequency, in Hz. If core flux is too high for the required secondary voltage and operating frequency, the flux can be reduced by increasing the core area and/or the number of turns, while keeping the desired primary/secondary turns ratio. A higher core permeability will not lower the frequency of core saturation for the same saturation flux density.

The parallel loss resistance of ferrites is roughly constant at high frequencies, so R_m represents a fairly consistent “broad-band” error current. This error can also be reduced by increasing the core area/magnetic path length ratio or increasing the number of turns, but a higher or lower permeability core will not significantly affect R_m .

Secondary Capacitance Loading. The upper frequency limit of a CT usually occurs when the impedance of the secondary parasitic capacitance loading C_s becomes less than that of the load R_l . Secondary capacitance is largely composed of winding layer-to-layer capacitance, secondary winding to core capacitance, and turn-to-turn capacitance, in that approximate order. Single-layer windings are often used to eliminate large layer-to-layer capacitances, although some space between the winding ends on a toroidal core must also be provided to reduce end-to-end capacitance. Extra insulation between the winding and a toroidal core is also often useful in reducing secondary capacitance. Turn-to-turn capacitance is usually insignificant in all but the highest frequency CTs with a few secondary turns, when spaced turns or wire with a thicker insulation may be beneficial.

The number of secondary turns tends to have only a moderate effect on secondary capacitance, which may increase or decrease, depending on other winding geometric factors.

Secondary Resistance and Inductance. As long as the secondary winding resistance R_s and the impedance of the secondary output inductance L_s are less than the load resistance R_l , the voltage drop on the output shunt largely determines the voltage on L_m , R_m , C_s , and their respective error currents. Only when the impedance of R_s and L_s become comparable to or larger than R_l do they have a significant or major effect on the currents in L_m and R_m and, hence, on the current transformation error. Increasing the number of turns decreases the magnetizing current errors, but the secondary resistance will increase at least as the square of the number of turns, and as the cube of the turns if the secondary winding is kept to a single layer. A point of diminishing returns is eventually reached when $R_s > R_l$, where more turns begin to degrade accuracy. If higher accuracy is still required, a larger core may be required.

Output inductance is produced by any secondary current flux, which is not coupled to the primary. It is due partly to secondary lead inductance, and partly to “air core” inductance of the secondary winding. The impedance of L_s is usually much less than R_s , and is usually not a significant problem, except at the highest frequencies with a large number of secondary turns.

Primary to Secondary Capacitance. The primary to secondary capacitance coupling C' is usually minimized by having a single-turn primary centrally located in a toroidal CT, with significant insulation thickness on the primary. As such, C' usually has an insignificant contribution to secondary loading capacitance C_s . However, significant error currents can flow through C' , if the CT primary and secondary windings are at a high ac potential with respect to each other, which usually occurs when the CT is placed on a primary conductor at a large high-frequency voltage. The worst case occurs with square or pulse voltage waveforms, as the displacement current is

$$I_c = C'(dV/dt) \quad (3)$$

where I_c is the instantaneous capacitance displacement current, in A; C' is the primary to secondary capacitance, in F; and dV/dt is the time derivative of the voltage, in V/s.

These capacitance currents can be surprisingly high with “square-wave” voltages. For example, a 600 V p-p pulse or square wave with a 30 ns rise or fall time will produce a 200 mA pulse of current through only 10 pF of capacitance.

If large primary ac voltages exist, the best solution may be to try to move the CT to a conductor carrying the same current, but at a lower ac potential. If this is not practical and the problem is not too severe, increasing the primary-secondary spacing and going to an insulation with a lower dielectric constant (ideally “air”) may suffice.

Otherwise, an electrostatic shield is required around the secondary winding, or at least between the primary and secondary winding. This shield is preferably tied to a “ground” point in the primary circuitry, although a connection to the ground side of the secondary may also serve. Superior isolation is achieved when two shields are used, with the one closer to the primary “grounded” to the primary circuit and the secondary shield tied to the “ground” side of the secondary.

It must be noted that the term “ground,” as used here, does not refer to an “earth” connection external to the circuit, but to a low ac potential conductor of the respective circuit. This is often a dc bus for the circuit, and may be known as the *ac quiet* or *RF low* conductor.

Extending HFCT Bandwidth Accuracy with Active Circuits

It has been shown that core magnetizing currents represent the fundamental limit to CT low- and medium-frequency bandwidth and accuracy. There are two ways that active electronic circuitry can be used to reduce these errors: the “virtual ground” load, and flux cancellation through feedback.

CT Virtual Ground. The CT load resistance is usually much larger than the secondary winding resistance, so the secondary current accuracy will improve as the load resistance is decreased to zero, dropping the voltage on the core’s L_m and R_m to a minimum limited by R_s (and L_s , if significant).

Figure 4. An operational amplifier (op amp) can be used to create a “virtual ground” on the secondary of a CT, improving accuracy and lowering the minimum usable frequency.

Unfortunately, the error in reading the shunt voltage tends to increase with lower voltages, due to system noise and other effects. One way to overcome this tradeoff is to use feedback to force the secondary output voltage to zero (creating a virtual ground on the secondary winding), while measuring the current required to achieve the virtual ground.

The simplest virtual ground load circuit uses an operational amplifier (op amp) A_1 , as shown in Fig. 4. The “ground” side of the CT secondary is connected to the positive (noninverting) input of A_1 , while the other side is connected to the negative (inverting) input. A feedback resistor R_f is connected between the A_1 output and the inverting input. The high gain of A_1 forces the voltage on the negative input to be essentially equal to the “zero voltage” on the positive input. The current required to do this flows through R_f , so the output voltage is, essentially,

$$V_o = I_s \times R_f \quad (4)$$

where V_o is the output voltage, in V; I_s is the secondary current, in A; and R_f represents feedback resistance, in Ω . In effect, the feedback resistor R_f becomes the CT load resistor, but the CT does not “see” this voltage on the secondary.

A blocking capacitor C_b may be required in series with the CT secondary, to avoid gain multiplication of the A_1 input offset voltage V_{os} . Without C_b , the dc output of A_1 would be V_{os} times R_f/R_s , while, with C_b , the dc output is simply equal to V_{os} . C_b must be a relatively large capacitor, to avoid limiting the low-frequency bandwidth; specifically,

$$(C_b R_s) \text{ great } L_m / R_s \quad (5)$$

where C_b is the dc blocking capacity, in F; R_s signifies secondary winding resistance, in Ω ; and L_m is the secondary winding magnetizing inductance, in H.

Figure 5. The operational amplifier current required to create a “virtual ground” on the secondary of a CT is reduced by the ratio of $R_1/(R_1 + R_2)$.

Figure 6. A noninverting buffer amplifier can be used with a CT shunt or load resistance of $R_1 < R_s$, to extend the low-frequency bandwidth.

The equivalent series resistance (ESR) of C_b should be less than R_s , and C_b should have an rms current rating equal to the full secondary current. A low-voltage electrolytic capacitor will usually suffice, which need not be a nonpolar type as the dc voltage will only be the input offset voltage of A_1 , which is usually less than 5 to 20 mV.

A drawback of this simple but effective circuit is that A_1 must be able to source the full CT secondary current through R_f , while the current capability of most op amps is limited to 10 to 100 mA. The feedback resistance R_f will usually be much less than the CT magnetizing resistance R_m , so a unity gain stable op amp is required, and the output HF bandwidth is limited by the gain–bandwidth of A_1 .

This limitation can be partially circumvented by the circuit of Fig. 5, where the op amp current is reduced by the current division ratio of $R_1/(R_1 + R_2)$. R_1 must be less than R_s , to avoid raising the L_F end of the bandwidth. The op amp A_1 need now only be stable at a gain of $R_f/(R_1 + R_2)$, which can increase the HF bandwidth (the actual voltage gain is R_f/R_2). An alternative circuit, with a noninverting gain of $(R_f + R_2)/R_2$, is shown in Fig. 6.

Flux Cancellation with Feedback. The low-frequency bandwidth of a HFCT can be extended even further, with circuits that sense and cancel the CT core flux through feedback techniques (1). A basic circuit that illustrates this principle is shown conceptually in Fig. 7. The HFCT now has a tertiary winding with turns N_t , which drive the inputs of high-gain amplifier

Figure 7. Using feedback to cancel the core flux of a CT extends the low-frequency bandwidth by orders of magnitude and enhances mid-band accuracy.

A_1 , while the output of A_1 drives a current through the secondary winding and load resistor R_1 . The high gain of A_1 forces a secondary current to flow, which almost exactly cancels the primary current, in order to hold the voltage on the tertiary winding to nearly zero. With essentially no current in the tertiary winding, and thus no $I \times R$ voltage drop, the core flux and magnetizing current errors are also forced to be nearly zero.

Whereas the circuits of Figs. 4, 5, or 6 may lower the LF end of the bandwidth by a factor of ten or more, flux cancellation can lower the minimum frequency by a factor of 1,000 or more. Both approaches also improve midband accuracy by similar factors and, in the case of flux cancellation, it becomes difficult to measure the actual midband CT error.

The circuit of Fig. 7 is not a practical circuit as shown. A dc feedback path must be provided around A_1 , and stability of the circuit must be ensured at both the lower and upper unity gain crossover frequencies. With “zero” magnetizing current the LF bandwidth could extend arbitrarily close to dc. In principle, the finite open loop gain of the op amp limits the minimum frequency, but, in practice, the maximum gain must be controlled, in order to achieve a stable unity gain crossover at the low-frequency end.

Ac current transformers tend to be 10 to 100 times larger than power transformers of the same “power” or volt-ampere rating, but active flux canceling allows the size of CTs to be reduced dramatically, particularly at lower frequencies. A practical limitation is that the op amp must again be able to supply the full secondary current.

A major advantage of the circuit of Fig. 7 is that the HF bandwidth is not necessarily limited by the bandwidth of A_1 . If the output of A_1 has a low impedance, and the input can tolerate the tertiary voltage, the circuit reverts to normal CT operation at frequencies greater than the bandwidth of A_1 .

PULSE CURRENT TRANSFORMERS

Pulse current transformers (PCT) may resemble ac current transformers, but the performance parameters of interest are somewhat different. The principle specifications for an ac CT are frequency range, maximum current, maximum burden or load resistance, and accuracy. Critical ratings for a pulse transformer are maximum peak current, rise time, pulse top droop, and the maximum current-time product for a pulse.

Low Duty Cycle PCTs

An ac current transformer with a resistive load can be operated with unipolar pulse currents, if the duty cycle is sufficiently low (often less than 1%) and other conditions are met:

1. The volt-seconds on the CT windings during the pulse must not cause the core flux to reach saturation.
2. The primary current must be zero between current pulses.
3. The interval between pulses must be long enough to allow the core to reset with the resistive load on the secondary.

Residual flux B_r in the core may become a significant portion of the saturation flux with some core materials, which reduces the pulse amp-second product. Occasionally a very small core “air gap” is introduced to reduce B_r . This also allows the PCT to

operate with a slightly greater amount of dc current, but at the expense of a similar drop in magnetizing inductance, which increases pulse droop. For applications with a significant dc current, a “dc compensation” winding must usually be added, to cancel the dc flux in the core.

This type of pulse transformer is usually also rated for high-frequency ac CT use. They are usually supplied with an internal resistive load to produce an output voltage proportional to current, and are typically terminated with a 50 Ω source impedance for driving coaxial cables (2) and/or 50 Ω load impedances. Clamp-on versions are also produced, which can operate over broad frequency ranges (3).

High Duty Cycle PCTs

In some applications, like switched mode power converters, it is desirable to operate a PCT with a relatively high duty cycle. This can be readily accomplished for unipolar pulses with the addition of a rectifying diode D_1 between the CT and the resistive load, as shown in Fig. 8.

During the current pulse, D_1 conducts to connect the CT to the resistive load. After the current pulse, D_1 conduction stops and allows the magnetizing inductance of the CT to “kick back” and generate a reverse voltage, which can reset the core very quickly if the kick back voltage is much higher than the forward voltage during the pulse. Pulse duty cycles of >90% can be accommodated with this simple modification to a CT.

A reset voltage clamp is also shown in Fig. 8, which prevents reverse breakdown of D_1 . The clamp typically consists of a Zener or avalanche diode Z_1 and a second diode D_2 , which blocks forward conduction of Z_1 during the pulse. Schottky diodes may be used for D_1 at high frequencies, partly to minimize additional secondary voltage when the CT resistive load voltage is about a volt or less, and partly for the high switching speed of Schottky diodes. The current rating of the Schottky diode should not greatly exceed that of the actual CT secondary current, as the high diode capacitance will tend to slow down the rise of the reset voltage. $p-n$ junction diodes for D_1 (and D_2) should be of the ultra-fast epitaxial variety, with reverse recovery times of 20 to 40 ns.

The voltage clamp is not always required for short current pulses, particularly for those of less than 1 to 10 μs duration. The maximum possible reset voltage on a PCT is limited by the peak magnetizing current in L_m (in Fig. 3), flowing through the core loss resistance R_m .

This core loss limit to the reset voltage also tends to limit the maximum pulse duty cycle with short pulses. However, an incomplete core reset after one pulse will leave a residual

Figure 8. A CT secondary side diode allows unipolar pulse currents to be monitored.

Figure 9. The pulse magnetization current of a ferrite has an initial step in current due to core losses. The effect is shown for a permeability of 10,000, where the core loss current exceeds the inductive magnetization current for about 200 to 300 ns.

magnetizing current in L_m , which adds to the reset current after the next pulse and increases the reset voltage. The residual magnetizing current may build up to a stable value before core saturation, which could be acceptable if the increase in magnetizing error current can be tolerated. Alternatives are to use a lower permeability core with more magnetizing current, or to provide a small core reset bias current.

The core loss resistance also creates an unexpectedly high magnetizing current for short pulses, as illustrated in Fig. 9 for a typical 10,000 permeability ferrite. For a pulse duration of 100 ns, the magnetizing current is four times higher than would be calculated from the low-frequency permeability of the ferrite alone. Under these conditions, the open circuit CT kick back voltage can be no higher than $\frac{1}{3}$ of the forward voltage during the pulse.

The high duty cycle PCT is not limited to unipolar pulse currents. The antiparallel diodes D_1 and D_2 of Fig. 10 allow sensing of bipolar current pulses, while still allowing for resetting of residual core magnetizing currents during the zero current interval between pulses. Alternatively, the bipolar input current pulses can be rectified to unipolar output voltage pulses with the circuit of Fig. 11.

The secondary volt-second mismatch between the two polarities of input pulse cannot be too great, or the core will not be able to reset between pulses with the reset voltage limited to a diode drop. More reset voltage is available with p - n diodes than Schottky diodes, and several diodes could be used in series to allow greater reset voltages. A drawback is that the diode voltage also adds to the load voltage and magnetizing current errors.

Figure 10. Antiparallel CT secondary diodes allow bipolar pulse currents to be monitored.

Figure 11. A center tapped current transformer secondary can be used to rectify bipolar current pulses to unipolar output voltage pulses.

It must always be borne in mind that PCT core resetting requires that the input current be zero for a finite interval. A pulse current waveform like that shown in Fig. 12 cannot be accurately sensed.

DC + AC CURRENT TRANSFORMERS

Dc current-sensing capability can be added to an ac current transformer by placing a Hall effect element in a small air gap in the CT core (4), as sketched in Fig. 13. A Hall effect element is typically a small semiconductor chip, with current input and voltage output electrodes on opposite edges, which is placed in a magnetic field with the flux normal to the surface. The output Hall effect voltage is proportional to the input current I_e and the flux density.

An amplifier A_1 senses the Hall voltage produced by a current in the primary, and produces a current in a secondary winding to cancel the core flux produced by the primary winding. Operation is similar to the flux canceling circuit of Fig. 5 in most regards, except that the flux-sensing tertiary winding is replaced with the Hall effect element. Since the Hall effect responds to dc as well as ac flux, the frequency response extends to dc. The necessary gap in the core of the CT, however, degrades the performance of the device. In practice, the accuracy is limited to a few tenths of a percent.

As in the flux-canceling circuit of Fig. 5, the bandwidth can exceed that of the amplifier, as the circuit can revert to conventional ac CT operation at high frequencies, which may range from tens of kilohertz to tens of megahertz.

Other designs eliminate the flux canceling winding in Fig. 13, and just amplify the output of the Hall effect element directly for current indication. The advantages are lower cost and power consumption, at the expense of reduced bandwidth and accuracy.

Figure 12. A pulse current waveform with no finite $I = 0$ interval, such as that shown here, cannot be monitored with a pulse current transformer.

Figure 13. A Hall effect element is placed in an air gap in the core of a flux-cancellation CT circuit, to extend the low-frequency response to dc.

PRECISION DC CURRENT TRANSFORMERS

Although the conventional CT cannot measure dc current directly, a number of ingenious techniques have been developed (4–7) which use magnetic transformers to sense and measure dc current, with accuracies of parts per million in some cases. Typically, these approaches use two to four magnetic cores, one or two of which are driven to the verge of saturation or beyond by an ac source. A winding with the dc current to be measured links all cores, as does a dc compensation or canceling winding. Any dc amp-turn imbalance between the measured and compensation windings causes an asymmetrical response in the cores with an ac flux, which is sensed by a feedback and control circuit which adjusts the compensation current to remove the imbalance. The measured current is known from the compensation current and the turns ratios of the windings. Some of these circuits are suitable for measuring ac as well as dc current. A detailed description of these specialized approaches is beyond the scope of this overview article.

AIR-CORED CURRENT TRANSFORMERS (ROGOWSKI COILS)

The construction of classical Rogowski coils (8) is similar to that of ac current transformers, but with a nonmagnetic or “air” core. The “secondary” winding is usually in the shape of a toroid, with the return conductor brought back inside the winding to minimize spurious response to ambient magnetic fields, as shown in Fig. 14.

The output of the Rogowski coil is proportional to the rate of change of the enclosed magnetic field, or to the dI/dt of a conductor through the middle of the toroid. The response of a Rogowski coil is theoretically uniform to any current inside the hole of the toroid, and zero to any current outside the toroid. In practice, the response is usually slightly nonuniform to internal currents, with a slight spurious response to external currents, depending on the uniformity of the coil winding. These nonideal responses are typically within a few percent for well-constructed coils.

Figure 14. The output of a Rogowski coil is proportional to the derivative of the sensed current, and requires an integrator to reconstruct the primary current waveform.

The output voltage may be used directly to monitor the amplitude of sinusoidal currents of a constant frequency, but the voltage is usually integrated to produce a flat response over a range of frequencies (9,10). If phase shifts in the integrator are well controlled, the time domain fidelity of the waveform can be within one percent over a broad range of frequencies (11).

Rogowski coils have several advantages over conventional CTs. Although they cannot measure dc current, their performance is not affected even by very large dc currents. They cannot be saturated by large ac currents, and actually become increasingly advantageous as ac current increases. Conventional CTs require secondary turns to increase as measured currents rise to keep the output current constant, while Rogowski coils require fewer turns at higher currents, to produce a constant output voltage. Thus Rogowski coils can be much smaller than CTs at high current levels.

Magnetic Cores for Rogowski Coils

Rogowski coils tend to become less useful at low currents and low frequencies, where an excessive number of turns becomes required to produce a useful output voltage. This can be somewhat overcome by using a magnetic core, which increases the output in proportion to the permeability. However, the effective permeability must be stable and well defined, and insensitive to frequency, temperature, and dc and ac flux density over the operating conditions. This stability does not occur with solid ferromagnetic cores, but can be achieved with a core (such as ferrite) with one or more discrete air gaps. Unfortunately, the discrete gaps will increase sensitivity to external fields and primary conductor placement, unless a large number of equally spaced air gaps are used.

The best alternative is to use a “distributed gap” material. The most suitable types are molypermalloy powder (MPP) cores, which are available in permeabilities of 14 to 300. Achievable stabilities vs. flux range from better than $\pm 1\%$ at $\mu = 14$ to about $\pm 4\%$ at $\mu = 300$, although the initial standard tolerance of $\pm 8\%$ on permeability usually requires calibration for reasonable accuracy. The -3 dB permeability rolloff frequency ranges from about 600 kHz for $\mu = 300$ to about 20 MHz for $\mu = 14$.

Powdered iron cores are not recommended, in general, because they typically have relatively low permeabilities and

exhibit large changes in permeability with ac flux density. Possible exceptions are the unannealed carbonyl iron powder cores, which have stable permeabilities of about ten or less, but are useable to hundreds of megahertz.

Note that the output voltage of a CT (for a given load resistance) is proportional to N_p/N_s , while the output voltage of a Rogowski coil is proportional to $N_p \times N_s$. The sensitivity to low currents with either device can be increased by increasing the number of primary turns.

Design of Rogowski Coils

If the secondary inductance of the Rogowski coil is known, the output voltage for a sinusoidal primary current is

$$V_o = 6.28 f L_s I_p (N_p/N_s) \quad (6)$$

where V_o = output voltage, in V; f = frequency, in Hz; L_s = secondary inductance, in H; I_p = primary current, in A; N_p = number of primary turns (usually $N_p = 1$); and N_s = number of secondary turns.

For an arbitrary current waveform

$$V_o = L_s (N_p/N_s) (dI_p/dt) \quad (7)$$

where V_o represents the instantaneous output voltage, in V and dI_p/dt is the time derivative of primary current, in A/s. The inductance of a toroidal winding (or any cored inductor) is

$$L = (1.257 \times 10^{-6}) (N^2 A_e \mu) / l_e \quad (8)$$

where L = inductance, in H; N = number of turns; A_e = magnetic core area, or winding area for air core, in m^2 ; μ = relative core permeability ($\mu = 1$ for air); and l_e = magnetic path length, in m.

Replacing L in Eqs. (6) and (7) with the formula in Eq. (8),

$$V_o = (7.896 \times 10^{-6}) (f I_p N_s N_p A_e \mu) / l_e \quad (9)$$

for sinusoidal currents, and

$$V_o = (1.257 \times 10^{-6} N_s N_p A_e \mu) (dI_p/dt) / l_e \quad (10)$$

for an arbitrary primary current waveform.

INSTRUMENT TRANSFORMERS

An instrument transformer (IT), like all ac transformers, consists of a ferromagnetic core on which a primary winding and a secondary winding are applied. The windings may be isolated from each other (double wound), or one winding may be a tapping off the other (auto wound). The basic difference between a power transformer and an IT is that the latter is used with little or no load connected to its secondary winding, and, as such, an accurate transformation of voltage or current can be attained.

In the electrical supply industry, ITs are widely used to extend the range of an instrument such as a voltmeter, an ammeter, a wattmeter, a watthour meter, or an item of protection or control equipment. In addition to its use as a range-extending device, a double-wound IT may also serve to isolate an instrument from a high-voltage circuit.

It is usually impractical to manufacture precision indicating instruments with voltage ranges above about 500 V, or current ranges above about 20 A. As the electrical supply industry is required to measure or detect voltages and currents very much higher than these values, a convenient way to do so is to use an IT to transform such voltages and currents down to measurable values. Also, an IT may be required to transform low voltages or low currents up to values which can be accurately measured on available indicating instruments.

TRANSFORMER RATIO

An IT used as a ratio standard is probably the most accurate and stable of all electrical ratio devices. To a first order of accuracy, the ratio is dependent only on numbers of turns wound on the ferromagnetic core.

In the case of a voltage transformer (VT), the external load (known as the *burden*) connected to the secondary terminals must be of high impedance. When this is so, a voltage applied to the primary winding causes a voltage to be induced in the secondary winding that is nearly equal to the applied voltage divided by the ratio of primary to secondary turns. In other words, the voltage on each winding is nominally proportional to number of turns.

In the case of a current transformer (CT), the external load connected to the secondary terminals must be of low impedance. When this is so, a current passed through the primary winding causes a current to be induced in the secondary winding that is

Figure 1. Use of instrument transformers to extend the range of a wattmeter. The voltage transformer and current transformer avoid the need to apply high voltages and currents to the wattmeter itself.

nearly equal to the primary current multiplied by the ratio of primary to secondary turns. In other words, the current passing through each winding is nominally inversely proportional to number of turns.

USE OF INSTRUMENT TRANSFORMERS

When a VT is used to extend the range of a voltmeter or voltage circuit of a wattmeter, the voltage to be measured must be connected to the primary winding of the VT. A connection must then be made from the secondary terminals of the VT to the voltmeter. Where the VT is double-wound, it would be normal (for safety reasons) to connect an earth to one secondary terminal. Any exposed metal casing of the VT must always be earthed.

When a CT is used to extend the range of an ammeter or current circuit of a wattmeter, the circuit must be opened at the point where the current is to be measured, and the primary winding of the CT must be connected across this opening. A connection must then be made between the secondary terminals of the CT and the ammeter. Where the CT is double-wound, it would be normal (again for safety reasons) to connect an earth to one secondary terminal. For additional safety, a short-circuiting switch is usually connected across the secondary winding of a CT. This should be kept closed until all connections are complete. The reason for this is that if appreciable current is passed through a primary winding of a CT with an open circuit on its secondary, dangerously high peak voltages are likely to be induced in the secondary (see Fig. 1).

VOLTAGE TRANSFORMER CONSTRUCTION

A VT consists typically of a closed, oil-filled metal tank into which the core together with its windings have been inserted. The winding terminations are typically brought out to terminals through porcelain insulators which are secured to the top of the tank (see Fig. 2). In most parts of the world, the secondary-voltage rating is standardized at 110 V. A VT may have more than one primary- or secondary-voltage tapping if it is intended for multiple ratio use. VTs intended only for laboratory use may incorporate Bakelite or other plastic insulators; or, instead of being oil-filled, their whole assembly may be encapsulated in an epoxy molding. VTs rated at voltages below about 1 kV are rarely oil-filled or epoxy-encapsulated.

Figure 2. Typical voltage transformer in a metal tank, with outdoor-type primary-terminal insulators.

A VT may be designated according to international standards (1) as “unearthed,” in which case two equal-size insulators (as in Fig. 2) will be used for its primary terminations. Such a VT will be suitable for connection between phases of a three-phase system. A designated “earthed” VT will be designed for one end of its primary winding to be suitable for connection to a potential close to earth only.

During manufacture, so as to grade the insulation most efficiently, it is most common to apply the lowest-voltage winding of a VT closest to the core and then work outwards to the higher-voltage windings.

Most modern VTs, except those designed for special laboratory use, incorporate a ferromagnetic core made from cold-rolled silicon iron (also referred to as *grain-oriented silicon steel*, or GOSS). This ferromagnetic material is chosen because it is relatively cheap and has a high saturation flux density of about 1.8 T. The use of a more expensive, high-permeability, nickel-iron core could result in the VT having lower errors of transformation but, with a saturation flux density of only about 0.4 T, might cause the VT to be prohibitively large in size. A third alternative core material, known as *amorphous metal* or *glassy metal*, can be formulated to combine high saturation flux density with high permeability, but this material is usually too expensive for ITs.

The actual core construction of a VT typically consists of laminations as in a power transformer, with the windings applied on cylindrical formers through which the laminations pass. Such a construction is usually referred to as a “shell iron” VT.

Where specially high accuracy of transformation is required, a ring-type core might be used, where the core is wound up from a long length of strip as in a clock spring. Then the windings must be applied toroidally round the core. The advantage of such construction is that the windings are likely to be coupled more closely, and any component of error due to flux leakage will be minimized. Also, as the iron is used more efficiently, a lighter construction should result. Such construction (usually referred to as “toroidal”) is more expensive than the use of laminations.

CAPACITIVE VOLTAGE TRANSFORMERS

VTs with voltage ratings greater than about 150 kV would often become too large and expensive to be manufactured by conventional means. In such cases it is common to use what is called a *capacitive voltage transformer* (CVT). Such a device is constructed in two parts. The first part consists of a capacitive divider with a low-voltage tapping at about 10 kV. The second part (known as the *electromagnetic unit*) consists of a conventional double-wound VT with its primary winding connected across the low-voltage tapping of the capacitive divider. An additional feature of the CVT is that the input inductance of the electromagnetic unit is arranged to resonate (at rated frequency) with the capacitive divider. This in turn enables the capacitive divider to be much smaller in size than would otherwise be the case for a given accuracy. A disadvantage of a CVT is that its errors are frequency dependent.

INDUCTIVE VOLTAGE DIVIDERS

A special type of VT, intended only for laboratory use, is known as an *inductive voltage divider* (IVD). An IVD is basically a step-down autotransformer with multiple secondary tapings arranged in decades. Intended for very high accuracy use, IVDs are made with the highest-permeability cores. Also, all windings of each decade are stranded together in a bunch or rope so that they are very well coupled with each other. A typical IVD has six decades so that the input voltage can be subdivided to a resolution of one part per million. IVDs are rarely made for an input voltage rating much greater than 100 V at 50 Hz.

CURRENT TRANSFORMER CONSTRUCTION

As the magnetizing forces (ampere turns) generated by the primary and secondary windings of a CT are nearly equal and are opposite in phase, the net ampere turns—and hence the working flux density—are normally very low. Also, as the permeability of cheap, silicon-iron cores drops away to almost zero at very low flux density, it is normal to construct CTs intended for accurate measurements with nickel-iron cores, which retain their high permeability down to very low excitation. However, protection CTs, where freedom from saturation of the core under overload conditions is more important than accuracy of transformation, usually incorporate silicon-iron cores.

Care needs to be taken when handling nickel-iron cores because mechanical shock is liable to greatly reduce their permeability. For this reason, many manufacturers will enclose their cores in a protective case so that the pressure of the windings themselves on the core do not cause loss of permeability.

In most parts of the world, the secondary-current rating for CTs intended for measurement use is 5 A, while for protection CTs it is 1 A. Laboratory standard CTs often have secondary tapings of both 1 A and 5 A, although the latter is more common.

The normal method of constructing a CT is to apply the secondary winding first, so that it couples the core closely. Thus, secondary-winding leakage-reactance is minimized. Although it is also desirable that the primary winding closely couples the core, leakage reactance in the primary, no matter how large, is

Figure 3. Typical current transformer for insertion onto a busbar, where the busbar itself forms a single-turn primary winding.

simply in series with the wiring to the load and is of no consequence as far as errors of the CT are concerned.

The most common type of CT encountered in the electricity supply industry is the “window” or “through” type, where a secondary winding is applied on a toroidal core, and the aperture of the core (the window) is left open so that one or more cables can be fed through it by hand to form the primary winding (Fig. 3).

When a window-type CT is used on a high-voltage transmission line, the clearance in the aperture must be large enough for there to be no possibility of a breakdown between the primary and secondary windings. Alternatively, solid insulation must be applied in the aperture.

In the highest-quality CT designs, terminals are made from plain copper, and all internal connections are soldered. Many manufacturers, however, use nickel- or chromium-plated terminals, often with detrimental effects. Research has shown (2) that the hard oxides on these plating materials can cause partial rectification at the contact faces, which in turn causes dc to flow in the windings. This component of dc will cause the permeability of the core to change or even cause saturation of the core. Plain, copper-to-copper connections, however, even when badly oxidized, rarely cause any trouble. Plain brass is a reasonable alternative metal to use for terminals, although when oxidized and poorly tightened, brass-to-copper connections can cause partial rectification.

TRANSFORMER ERROR

Due to various losses, the actual transformation ratio of an IT is never exactly equal to the ratio as defined by numbers of turns. Therefore, where the highest accuracy of measurement is required, the error in the transformation ratio must be determined and allowed for. The following are six effects which may give rise to errors in ITs, or which may cause the actual ratio to be unstable.

Effect of Loading

In a well-designed IT, the greatest contribution to error is that due to loading. The larger the volt-amperes delivered to the external burden connected to the secondary terminals, the greater

will be the losses internal to the IT, and hence the greater the errors.

Effect of Insulation-Leakage Currents

In applications where the voltage applied to an IT is high, or where a high voltage is induced in one of the windings, insulation-leakage currents may contribute appreciably to the errors. ITs that fall into this category are VTs with voltage ratings above about 30 kV, CTs with current ratings below about 0.5 A, and ITs operating at high frequency. In most cases it is the capacitance of the insulation material that has the major effect. Up to a point, capacitance leakage can be a good thing, because this current tends to cancel out the magnetizing current, which in turn, particularly in a CT, can reduce the component of error due to loading. However, excessive capacitance leakage currents can become a serious liability as far as the errors of the IT are concerned.

Effect of Partial Coupling and Flux Leakage

When the turns of the primary and secondary windings do not closely couple each other, such as when one or both windings are not uniformly distributed around the circumference of the ferromagnetic core, some lines of magnetic flux generated by one winding will not link all turns of another winding. This in turn will fractionally change the effective turns ratio. In a VT, this effect usually gives rise to the secondary voltage being less than nominal, while in a CT it usually gives rise to the secondary current being greater than nominal. This effect is usually associated with VTs, where, for ease and cheapness of construction, the primary and secondary windings are not concentric with each other or with window-type CTs. This effect should not be confused with the circumstances which might arise in a window-type CT where leakage fluxes become so large that, in some regions of the core, local saturation occurs. This in turn will cause the secondary current to become much lower than nominal (3).

Turns Ratio Error

If, during manufacture, the number of turns on any winding is wrongly applied, this will give rise to an error in the actual ratio.

Bad Contacts

In an otherwise-well-designed IT, errors can occur due to bad contacts in the internal or external circuit. These errors are usually associated with CTs where partial rectification at contact faces of connections causes a small direct current to flow in one of the windings. This in turn causes the permeability of the core to change temporarily, and hence causes a change in the errors. The slow deterioration of bad internal connections of an IT can take tens of years before they start to cause serious instability.

Partial Discharges

As a result of air voids or bubbles that may be present in the insulating materials of an IT, ionization of the air in these voids can occur when high enough voltages are present. When the ionization voltage is reached, alternate breakdown and

recovery of the air path in the void will rapidly occur. This effect is known as *partial discharges* (PDs). As a result of these PDs, a high-frequency voltage will be superimposed on the windings. Errors due to this effect are almost entirely associated with badly designed or constructed, high-voltage VTs. As often as not, the apparent error that these discharges cause is due to the behavior of the instrument connected to the IT and is not due to the IT itself, and therefore any calibration made of an IT exhibiting appreciable PDs could be meaningless. An additional effect that PDs can have on an IT is to degrade the insulation slowly with time and eventually cause its complete breakdown.

DEFINITIONS

Transformation Ratio

The transformation ratio of an IT (usually just referred to as “ratio”) is universally defined as the actual primary voltage or current divided by the actual secondary voltage or current. For this definition to have some useful meaning, the voltages or currents must be their root-mean-square (rms) values. This fact is not always made clear in definitions made by some standards organizations, although it will be assumed throughout this article.

In order to express the error in the ratio of an IT, some organizations define this as the quotient of “true ratio” (as defined above), divided by “nominal ratio” (as stated on the rating plate of the IT). Some organizations (particularly in the United States) refer to this quotient as the “ratio correction factor” (RCF). According to the above definition, a perfect IT would have an RCF of unity.

Turns Ratio

The turns ratio of a VT is universally defined as primary-winding turns divided by secondary-winding turns. Turns ratio of a CT is defined by some standards organizations as primary-winding turns divided by secondary-winding turns, but by others as the inverse of this. When using formulae quoted by standards organizations, metrologists should therefore be careful that they check on how the turns ratio of a CT is defined.

Voltage Error of a VT

According to international standards (1), the error in the ratio of a VT is defined as follows:

The error which a transformer introduces into the measurement of a voltage and which arises when the actual transformation ratio is not equal to the rated transformation ratio. The voltage error, expressed in percent, is given by the formula

$$\text{voltage error \%} = \frac{k_n U_s - U_p}{U_p} \times 100 \quad (1)$$

where

k_n is the rated transformation ratio

U_p is the actual primary voltage

U_s is the actual secondary voltage when U_p is applied under the conditions of measurement.

According to the above definition, a perfect VT would have a voltage error of zero. Although not clearly stated in the above definition, U_p and U_s are the magnitude of their values (i.e., they are not vector quantities).

Current Error of a CT

According to the same international standards, the error in the ratio of a CT is defined as in Eq. (1) above except that the word "voltage" is replaced by "current" and the symbol U is replaced by I .

Phase Displacement

In some applications, particularly when an IT extends the range of a wattmeter or watthour meter not working at unity power factor, it is necessary to know the displacement in phase between the primary and secondary voltages or currents. According to international standards, phase displacement is defined for a VT as follows:

"The difference in phase between the primary and secondary voltage vectors, the direction of the vectors being so chosen that the angle is zero for a perfect transformer. The phase displacement is said to be positive when the secondary voltage vector leads the primary voltage vector. *Note.* This definition is strictly correct for sinusoidal voltages only."

Substitute the word "current" for "voltage" in the definition of phase displacement for a CT. There are slight variations in wording between various world organizations in the definition of phase displacement (some organizations call it "phase angle" and others call it "phase error"), but numerically they are all the same.

Most standards organizations give the preference that phase displacement is expressed in centiradians because this unit is logically equivalent to voltage error or current error expressed in percent. Throughout the world, however, many electricity authorities still prefer to express phase displacement in "minutes" because this was the preferred unit used up until about 1970.

From the above, it is clear that IT errors are defined in polar coordinates. In circuit analysis and in technical papers, it is often more convenient to express IT error in rectangular coordinates in the form " $a + jb$ ". The definition of IT error in rectangular coordinates is identical to the definition of voltage error or current error above, except that the voltages or currents concerned must all be complex quantities.

In these definitions, the sign of the quadrature component of error in rectangular coordinates is the same as the sign of the phase displacement in polar coordinates.

TRANSFORMER CLASS

It is the practice among most manufacturers to assign an accuracy class to an IT. In its simplest form, this class designation consists of a number, which indicates the limits of voltage error or current error in percent and the limits of phase displacement in centiradians which should apply during normal use. The range of voltage or current levels, or range of burden levels over which the limits of error should apply, varies from one type of IT to another and also varies from one standards organization to another. Commonly, VTs are required to be within class

between 90% and 110% of rated voltage; CTs between 10% and 125% of rated current; and all ITs between 25% and 100% of rated burden. Burden is usually expressed in "millisiemens" for a VT and in "ohms" for a CT, although before about 1970 it was normal to express burden for both VTs and CTs in volt-amperes (VA). It will therefore be noted that many older ITs have rated burden expressed in "VA" on their rating plate.

In addition to a number, a class designation may also include one or more letters. These letters, for instance "L," mean that the IT is intended for laboratory use; "M" would mean that the IT is for measurement use in the field; while "P" would mean that the IT is for protection use. There are also many subclasses of protection ITs which are designated with additional letters or numbers.

The main difference between measurement ITs and protection ITs is that the latter need to maintain their accuracy at voltages or currents many times greater than their rated voltages or currents. This is particularly the case in protection CTs where their class designation may require them to perform satisfactorily at up to 20 times rated current.

EQUIVALENT CIRCUIT OF AN INSTRUMENT TRANSFORMER

If an IT is analyzed (from basic electrical principles) as two mutually coupled windings each having coupled and uncoupled impedance, the equivalent circuit of Fig. 4 can be derived. For simplicity, this equivalent circuit shows an IT with a nominal ratio of unity.

In Fig. 4, the combined effect of less-than-perfect coupling between primary and secondary windings and the effect of turns-ratio error are shown as a tapping " a " off the secondary winding. Some textbooks like to show the effect of less-than-perfect coupling as an additional reactive impedance in series with one of the windings.

In reality, if no local saturation of the core occurs, it is rare for the effects of less-than-perfect coupling to directly cause errors greater than 0.01% or 0.01 crad at 50 Hz, even when the primary and secondary windings are concentrated in different regions of the core circumference. When a situation is reached in a window-type CT where the ampere-turns become so unbalanced that local saturation of the core occurs, errors are likely to become as high as 10% and 10 crad. At the other extreme, however, when high-permeability toroidal cores are used with uniformly distributed windings, the effect of less-than-perfect coupling would not be expected to cause errors much greater than one part per million at 50 Hz.

The circuit of Fig. 4 does not take into account insulation leakage effects. However, for most practical purposes, particularly for CTs, this can be represented by a single impedance shunting the primary terminals.

Figure 4. Equivalent circuit of an instrument transformer having a nominal ratio of unity.

TERMINAL MARKING CONVENTION

The universally accepted polarity convention for currents and voltages in an IT is shown in Fig. 4. When the instantaneous directions of the voltages and currents are as shown, the heavy dots represent a similarly marked terminal.

CALIBRATION OF INSTRUMENT TRANSFORMERS

The most common method of calibrating ITs is to compare them in a differential circuit with a standard IT of the same nominal ratio and of known error.

Voltage Transformer Testing Circuits

A basic circuit for the intercomparison of two VTs is that of Fig. 5. In this circuit, “V1” represents an ac instrument which indicates (in terms of V2) the magnitude and phase of the difference in voltage between the secondaries of the standard VT and the VT under test. An instrument designed to compare one VT with another is commonly called a *voltage transformer testing set* (VTTS).

The earthing arrangement should be specially noted in Fig. 5. For safety reasons, one of the secondary terminals of both VTs must be connected to earth. This means that there is no choice but to have the measuring circuit (V1 in Fig. 5), floating up at the secondary voltage of the VTs unless an isolating VT is connected between the “high” ends of the two secondary windings. The alternative of measuring the difference voltage between the “low” ends of the two secondary windings could lead to a large systematic error in the measurement. This is because any insulation leakage currents between the primary and secondary windings of one of the VTs, driven by the full primary voltage, will flow to earth through the measuring circuit. In most test circuits (except where two designated “unearthed” VTs connected between phases of a three-phase system are being compared), it will also be necessary to earth one primary terminal of both VTs.

Current Transformer Testing Circuits

A basic circuit for the intercomparison of two CTs is that of Fig. 6. In this circuit, “A1” represents an ac instrument which indicates (in terms of A2) the magnitude and phase of the difference in current between the secondaries of the standard CT, and the CT under test. An instrument designed to compare

Figure 5. Differential circuit for intercomparing two voltage transformers. The same voltage is applied to both primary windings, while voltmeter V1 simply reads the difference between the two secondary voltages.

Figure 6. Differential circuit for intercomparing two current transformers. The same current is passed through both primary windings, while the ammeter A1 simply reads the difference between the two secondary currents.

one CT with another is commonly called a *current transformer testing set* (CTTS).

The earthing arrangement of a CT testing circuit is not as critical from the safety point of view as that of a VT testing circuit. In order to minimize measurement errors, however, it is important that one point on the primary circuit and one point on the secondary circuit are earthed. Figure 6 shows the common secondary terminals as earthed. This not only defines the potentials of both CT secondaries, but also eliminates any errors due to the measuring circuit not being at earth potential.

There is no best position for the earth on the primary circuit, however. This is because if one side of the supply is earthed, the primary winding of one or other of the two CTs will be floating above earth, which might cause its errors to change. If the common primary terminal is earthed, any leakage currents between one side of the supply and earth will cause the primary currents of the standard CT and CT under test to be unequal. In order to estimate systematic errors due to earthing arrangements in a CT testing circuit, it is necessary for the metrologist to investigate changes in error with all possible earthing arrangements for each individual CT under test and, from these, assign a component of uncertainty. When the highest accuracy of measurement is required, changes in errors due to different earthing arrangements can be eliminated by employing electrostatically screened standard CTs (4).

Coordinate Systems

There are basically two types of instrument transformer testing sets (ITTSs). The first is where the difference voltage or current is balanced manually against a voltage or current derived from an ac potentiometer. In this method, the out-of-balance voltage or current is displayed on a galvanometer or amplifier-driven cathode ray tube, and, at balance, the error quantities are read on the balancing dials. In the second type, the difference voltage or current is fed into a microprocessor-driven circuit which outputs the error measurement as a digital readout. In practically all commercial ITTSs, the circuitry is such that the difference voltage or current is resolved into rectangular components.

Provided that the error being measured is within about 0.1 % and 0.1 crad, the difference in indication between the measured

quantity in rectangular coordinates and the defined quantities in polar coordinates, is insignificantly small. If larger errors than these are indicated, corrections can be applied to convert from rectangular to polar coordinates according to the following formulae (5).

$$C_R = \sqrt{(1+a)^2 + b^2} - (1+a) \quad (2)$$

$$C_P = \left[\tan^{-1} \frac{b}{(1+a)} \right] - b \quad (3)$$

where

C_R is the correction to the indicated voltage error or current error in per unit

C_P is the correction to the indicated phase displacement in radians

a is the indicated voltage error or current error in per unit

b is the indicated phase displacement in radians

For all practical purposes, these formulae may be approximated to the following:

$$C_R \approx \frac{1}{2}b^2 \quad (4)$$

$$C_P \approx -ab \quad (5)$$

Some manufacturers of ITTSs do not indicate in their literature whether or not these corrections must be applied. With the microprocessor-controlled type of ITTS, it is common for these rectangular-to-polar coordinate corrections to be applied automatically as part of the software.

Calibration Procedure

As a preliminary procedure before calibrating CTs, both the standard CT and CT under test should be demagnetized. This is necessary because during previous use, one of the CTs might have been subjected to switching surges or a component of dc in one of its windings, either of which might polarize the core. This in turn will change the magnetizing current and hence change the errors. Demagnetization can be achieved by applying a voltage to the winding with the highest number of turns with all other windings open circuited. The voltage should be obtained from a variable-voltage source and raised slowly until saturation of the core occurs. Saturation can be detected on an ammeter in series with the winding to which the voltage is applied. Before saturation, little or no current will be seen to flow, but on the inception of saturation a sudden increase of current will occur. The voltage should then be lowered slowly to zero again. It is extremely important that demagnetization is not obtained by applying voltage to the winding with fewest turns, because if it is, then high peak-voltages might be induced in the winding with the highest turns. This in turn could break down insulation or cause electric shock.

The primary voltage or current in an IT testing circuit should never be fed directly from a voltage-regulating device or electronic amplifier. Small components of dc are likely to emanate from either such device which will change the characteristics of the ITs in the test circuit. To block such currents from the test circuit, an isolating transformer should always be used as a buffer.

It is rarely necessary to demagnetize VTs before a test because the very action of applying rated voltage to their primary winding is enough to eliminate any residual polarization that might be present in the core.

When calibrating ITs using a differential circuit, first apply a minimal amount of voltage or current while checking that polarities are correct. If full-load excitation is applied with incorrect polarity on one of the ITs, double full-load voltage or current will be applied to a measuring circuit, and this could cause a lot of damage. If all is well with polarities, then momentarily apply full-load excitation (without taking any readings) to eliminate any remaining polarization of the core.

If the calibration is to be made over a range of voltages or currents, start from the lowest excitation required, and finally, after working upwards to the highest excitation, repeat the reading at the lowest excitation. The difference in readings between the first and last settings will then be an indication of any component of uncertainty due to instability.

When calibrating VTs using a manually balanced VTTS, it may be discovered that when the excitation reaches a certain value, instability is detected on the balance-indicating device. If this instability becomes worse as the excitation is raised further, it is a probable sign that PDs are present either internally to one of the VTs, or externally to the VTs in the form of corona. In either case, if the effects cannot be eliminated, the ITTS's readings may have little useful meaning.

When calibrating CTs, it may be discovered that when a certain excitation is reached, the CTTS's reading slowly drifts with time. If this instability becomes worse as excitation is raised further, it is a probable sign that a small component of dc has entered into the circuit due to bad contacts. Upon detecting such instability, it will be necessary to check the tightness of all contacts and demagnetize all CTs in the circuit again; otherwise the readings may have little useful meaning. If the effect recurs, it will be necessary to search for nickel- or chromium-plated terminals in the circuit and, in extreme cases, remove the plating from the actual contact faces.

AUTOMATIC INSTRUMENT TRANSFORMER TESTING SETS

There is at least one serious shortcoming with all automatically balancing, digital-readout ITTS. That is, any instability that might be present in either the standard IT or IT under test, such as the inception of partial discharges, will not be evident (as it would be on a testing set balanced with the use of a galvanometer or cathode ray tube), and, as a result, a false indication may occur. Users of such ITTSs should therefore make alternative arrangements to detect instabilities, such as connecting a cathode ray oscilloscope across the secondary terminals.

APPLYING CORRECTIONS FOR INSTRUMENT TRANSFORMERS

Standard Transformers

When an IT is calibrated by comparing it with a standard IT, the errors of the standard, in both magnitude and phase, must be added to the indicated errors to obtain (within the uncertainties) the true errors of the IT under test.

Transformers Used in Wattmeter Circuits

When a VT and CT are used to extend the range of a wattmeter or watthour meter, corrections must be made to the indicated value of watts or watthours for the errors of the ITs. These corrections are according to the following formula:

$$\text{Correction} = -(a + b) + (\beta - \alpha) \tan(\cos^{-1} pf) \quad (6)$$

where

a is the voltage error of the VT in per-unit

b is the current error of the CT in per-unit

α is the phase displacement of the VT in radians

β is the phase displacement of the CT in radians

pf is the power factor

Note that all the terms in Eq. (6) are algebraic quantities including power factor. When the power factor is leading, the sign of the power factor (from the point of view of this formula) is positive; and when the power factor is lagging, the sign of the power factor is negative. Note also that this formula is correct for sinusoidal quantities only.

Some organizations use a convention where a positive sign is assigned to the value of a lagging power factor. Therefore metrologists should be careful that the power-factor sign convention is stated before they use any formulae given for wattmeter corrections. In ITTSs, however, the universally adopted convention is for a positive sign to be synonymous with a leading phase displacement and vice versa.

UNCERTAINTIES IN THE ERRORS OF INSTRUMENT TRANSFORMERS

The errors of an IT will change by small amounts with small changes in excitation level, frequency, burden, and temperature. Therefore when calibrating or using an IT, separate investigations should be made to ascertain the coefficients for these parameters so that components of uncertainty can be applied for whatever arbitrary limits are to be assigned to likely changes in these parameters. As a guide, these components of uncertainty can be estimated as follows.

Excitation Level

If the calibration is made over a range of different voltages or currents, a curve of error against excitation level can be plotted; and from the slope of the curve at any excitation, a component of uncertainty can be estimated. In most cases it will be found that the slope of the curve is greatest at the lowest excitation; and therefore from simple inspection of the figures at the two lowest levels of excitation, a component of uncertainty can be estimated. An exception to this rule might occur in an IT which is so constructed that at the highest level of excitation, the core flux density is close to saturation. In such cases it will be found that the errors (particularly the phase displacement) will change very rapidly as full excitation is reached. With such an IT, a separate uncertainty may need to be given for different excitation levels.

When an indicating instrument in the secondary circuit is used to set the voltage or current in the primary circuit, care should be taken (when doing so) to take into account the error

in ratio of the IT. If this is not done, an additional uncertainty will result.

Frequency

Most electricity authorities in Western countries guarantee their frequency to be within $\pm 0.2\%$ of nominal at all times except under fault conditions, so this is a good starting point for estimating a component of uncertainty for frequency. It is not usually convenient or even possible to make deliberate changes in frequency so as to estimate a frequency coefficient of the IT. Theory states, however, that the change in error due to change in frequency in a VT will be the same as for the same percentage change in voltage level. Similarly in a CT, the change in error with change in frequency will be the same as for the same percentage change in total burden. Note that total burden of a CT is an impedance equal to the externally connected burden plus the internal resistance and leakage reactance of the secondary winding. For the purpose of estimating the internal burden of a CT, the dc resistance can usually be taken, because the leakage reactance should be negligible.

Burden

The greatest component of uncertainty during both the use of an IT and during its calibration is usually that due to errors in applying its correct burden. It is usually easy to make a deliberate small change in burden during calibration to ascertain the IT's burden coefficient.

Temperature

It is not usually convenient or possible to change the temperature of an IT during calibration to ascertain its temperature coefficient. However, calculations can be made of the temperature coefficient from measured internal-circuit parameters of the IT and certain assumptions. These assumptions are as follows:

1. Winding resistances changes by $+0.4\%$ per $^{\circ}\text{C}$.
2. Excitation reactance changes by -0.1% per $^{\circ}\text{C}$.
3. Excitation resistance does not change with temperature.
4. Leakage reactances are negligible compared with winding resistances.

Other Components of Uncertainty

Other components of uncertainty that should be considered during the calibration of an IT are as follows:

1. The uncertainty in the standard IT against which the IT under test is calibrated.
2. The uncertainty in the ITTS's indication.
3. Uncertainties due to rounding off of both the reported errors and the reported uncertainty.
4. The effect of different earthing arrangements.
5. The effect of primary conductor configuration in a window type CT.
6. Possible change in errors due to self-heating (usually negligible).
7. Instabilities.

VOLTAGE TRANSFORMERS CONNECTED PHASE-TO-PHASE

A standard VT is normally calibrated with one of its primary terminals at earth potential. However, if such a VT needs to be used with its primary winding connected between phases of a three-phase system, the additional errors that will result can be estimated. These additional errors are based on the assumption (verified from practical experiment) that a VT has a component of error proportional to the voltage (in magnitude and phase) of the midpoint of its primary winding above earth.

A VT intended for use with its primary winding connected between phases of a three-phase system can be calibrated as follows. First calibrate the VT with one of its primary terminals earthed (say the "A" terminal), and then repeat the calibration with the other terminal earthed (say the "B" terminal). The formulae below can then be used to calculate the additional errors (from those measured with the "A" terminal earthed) for the case where the VT is connected between phases of a three-phase system of phase sequence A-B-C.

$$\Delta VE = -\frac{(VE_A - VE_B)}{2} - \frac{(PD_A - PD_B)}{2\sqrt{3}} \quad (7)$$

$$\Delta PD = -\frac{(PD_A - PD_B)}{2} + \frac{(VE_A - VE_B)}{2\sqrt{3}} \quad (8)$$

where

ΔVE is additional voltage error (in per unit)

ΔPD is additional phase displacement (in radians)

VE_A is voltage error (in per unit) with terminal "A" earthed

VE_B is voltage error (in per unit) with terminal "B" earthed

PD_A is phase displacement (in radians) with terminal "A" earthed

PD_B is phase displacement (in radians) with terminal "B" earthed

Corrections for the above additional errors are difficult to apply with confidence, particularly because the phase sequence of the supply must be known with certainty. If the phase sequence is the reverse of A-B-C, the signs of the second terms in Eqs. (7) and (8) must also be reversed. As the additional errors are usually no more than a few parts per million, it is probably safer to apply them as an additional component of uncertainty rather than risk applying the wrong sign to a correction.

CALIBRATION OF THREE-PHASE VOLTAGE TRANSFORMERS

When one phase of a three-phase VT is calibrated against a single-phase standard VT, all three phases must be energized during the calibration; otherwise a systematic error will be introduced. Experience has shown that this is necessary even if the three-phase VT consists of three single-phase VTs mounted in the same tank. Also, the phase sequence of the supply must be noted as part of the calibration, because if the phase sequence is reversed, significant changes in the VT's errors are likely to occur.

ABSOLUTE CALIBRATION OF INSTRUMENT TRANSFORMERS

When it is not appropriate to calibrate an IT by a differential method against a standard IT, such as in a laboratory that is the highest authority in a country, an absolute method must be used.

Most absolute methods of VT calibration involve comparing a VT with a capacitance divider in a bridge circuit, with either (a) the capacitors themselves being calibrated by some other absolute method or (b) the relative values of the capacitors being calibrated by a "buildup" method (6). In the United States and some other countries, the term "bootstrap" tends to be used instead of the term "buildup." A capacitance buildup usually involves measuring a number of three-terminal capacitors individually against one arbitrary reference capacitor and then reconnecting one or more of these capacitors in parallel in each arm of a bridge.

A method for the absolute calibration of VTs or CTs is to construct a special IT with a primary winding made up of sections which can be connected in various series-parallel arrangements. If one of the winding arrangements results in a ratio of unity, which can be calibrated absolutely in a differential circuit by comparing the primary directly with the secondary, it could be assumed that all the other ratios will have the same errors. Such an assumption would be conditional that errors due to insulation leakage currents had been eliminated, as would errors due to imperfect sharing of currents when the winding sections are connected in parallel.

An extension of the above can be used in the absolute calibration of CTs where two CTs of known errors, connected with their primaries in parallel and their secondaries in series, are used to obtain a known, composite CT of higher ratio (7).

An extension of either of the above can be used in the absolute calibration of CTs where a window-type CT is calibrated with multiple inserted primary turns and then assumed to have the same errors with fewer primary turns. For this assumption to be valid, it would be necessary to know that the CT is insensitive to primary-turns configuration.

COMPENSATED INSTRUMENT TRANSFORMERS

Compensation methods may be divided into the categories of (1) simple passive methods, (2) amplifier aiding, and (3) two-staging. Also, any combination of the three categories might be used together.

Simple Passive Compensation

The simplest and most common method of compensation used in measurement-class ITs is what is termed "turns compensation." For example, if the component of voltage error or current error (at rated burden) due to loading is -1% , all that is needed is to make the secondary turns 1% greater than nominal in a VT or 1% fewer than nominal in a CT for the error in ratio to be minimized. Of course, the amount by which the errors change with change of burden will not be improved, while the phase displacement will not be improved at all. Therefore this method of compensation is only efficient for those ITs used in the measurement of voltage or current, or in the measurement of watts where the power factor is close to unity.

Other methods of simple passive compensation (8,9) effectively supply the IT with a negative burden from a separate, adjustable source which cancels out the positive burden supplied to the load.

Amplifier Aiding

There have been large numbers of circuits devised where electronic amplifiers are used to reduce the errors of ITs. Basically, most amplifier aiding methods incorporate a unity-gain buffer amplifier on the output of the IT so that the IT itself is supplying zero burden and the amplifier is supplying the load (10); or the amplifier acts separately to supply the magnetizing current, and hence reduces the voltage drop in the windings (11). Few, if any, of the amplifier-aiding methods compensate for errors due to less-than-perfect coupling between windings, or turns-ratio errors, while most do not compensate for errors due to insulation leakage. A disadvantage of amplifier aiding is that a separate supply must be brought into the IT to power the amplifier.

Two-Staging

The theory behind the two-stage IT was first proposed by Brooks and Holtz as early as 1922 (12). Two-staging involves an IT with two cores, although not all two-core ITs are two-stage ITs. Basically, the primary and secondary windings of a two-stage IT are applied equally to both cores, and an auxiliary winding (often called the *magnetizing winding*) is applied to just one of the cores (Fig. 7). In a two-stage VT, the auxiliary winding has the same number of turns as the primary winding and is connected in parallel with the primary. In a two-stage CT, the auxiliary winding has the same number of turns as the secondary winding and is connected in parallel with the secondary. Toroidal cores are usually used in two-stage ITs. After the auxiliary winding is applied to the first core, the two cores may be stacked together axially before the main windings are applied. Alternatively, the second core may be constructed in such a way that it totally encloses the first core. If the latter core configuration is used, the second core is often referred to as a *magnetic shield*.

Mathematically, it can be shown that the errors of a two-stage IT can be reduced almost to zero at zero external-burden. This will be so no matter what the internal winding impedance. If the external burden connected to an IT is not zero, or at least is not small, the application of two-staging will result in an

Figure 7. Winding arrangement of a two-stage current transformer.

Figure 8. Two-stage current transformer in a differential calibration circuit. The two-core standard is in effect two current transformers, where that on core 2 does the work, and that on core 1 compensates for the errors.

IT with larger errors than would have resulted if the same amount of iron and copper had been used in a single-stage IT. Two-staging does not reduce components of error due to insulation leakage impedance, turns-ratio error, or less-than-perfect coupling between the windings.

From the above it might appear that two-staging would be of very little practical use. However, by various circuit additions, good use can be made of the low-error potential of a two-stage IT. For example, in a two-stage VT, an unloading addition to the circuit can be added as described in Ref. 13.

In a two-stage CT, a unit-gain buffer amplifier can be connected between the auxiliary-winding output and the secondary terminals. With such a system, the component of error due to loading would remain negligible for any external burden up to the limit of output of the amplifier. Also of note is that the amplifier would only need to cope with the small error component of current whereas a single-stage, amplifier-aided CT would require the amplifier to cope with the full secondary current. Some manufacturers make two-stage laboratory-standard CTs amplifier-aided as described above.

Another practical example of the use of a two-stage CT is in a differential calibration circuit (14). If the auxiliary winding is connected directly into the difference current part of the circuit as shown in Fig. 8, the burden applied to the auxiliary winding is practically zero, and the same reduction in error will be obtained as with amplifier aiding.

A special example of a two-stage CT in a differential calibration circuit is the so-called "current comparator" (15). With such a system, ammeter A1 in Fig. 8 is replaced by a current injection circuit derived from A2, and the magnitude and phase of this injected current is adjusted until zero flux is detected in the core to which the auxiliary winding is applied. This zero flux is detected by measuring zero voltage across an open-circuited winding (Fig. 9).

It should be emphasized that the very small error potential of the standard CTs shown in Figs. 8 and 9 will not be realized if the CT is taken out of the differential circuit.

OTHER SPECIAL DESIGNS OF INSTRUMENT TRANSFORMERS

Balancing Windings

In window-type CTs with ampere-turn ratings greater than about 2000, the magnetizing forces of the primary and

Figure 9. Basic circuit of a current comparator. This is fundamentally the same as the circuit of Figure 8, with the additional feature that the flux in core 1 is forced to be zero.

secondary windings are very large. Although these forces are almost equal and opposite, and almost cancel each other out where both windings are uniformly distributed around the core circumference, any small imbalance of primary conductor configuration will cause large leakage fluxes to flow across air paths (3).

A method of reducing these leakage fluxes, and hence making the CT insensitive to the primary-conductor configuration, is with the use of balancing windings. Such windings consist of a number of equal sections (usually at least eight) all with the same number of turns, each occupying a separate sector of the core circumference, all of them open circuited, and all of them connected in parallel. The effect of these windings is that any imbalance of ampere turns around the core circumference will cause circulating currents to flow between the balancing-winding sections. This in turn will decrease the flux in those regions of the core where the magnetizing forces are greater, but will increase it where the forces are lesser.

For these balancing windings to be effective, there must be little voltage drop in the windings themselves. In order to achieve this aim, practical experiment has shown that the sum of the weight of copper in all the balancing-windings sections should be at least equal to the weight of copper in the secondary winding. Also, the resistance of the paralleling links should be no more than one-tenth of the resistance of any of the balancing-winding sections.

Another way of achieving ampere-turn balance is to enclose the whole of the core and winding assembly in a toroidal, conducting metal envelope made in such a way that it does not form a short-circuited turn. This in effect is an infinite number of single-turn open-circuited windings connected in parallel. Such an arrangement is often referred to as a "magnetic shield," although this is not the same thing as a magnetic shield already described as used in a two-stage IT. Magnetic shields as described above are usually made from copper or aluminum, and again their weight should be at least equal to the weight of copper in the secondary winding.

Transformer Windings with Large Numbers of Turns

When the number of turns on the primary winding of an IT is greater than about 2000, insulation leakage currents between winding layers are likely to contribute a major component of

error in the IT. A method of reducing this component of error could be to increase the insulation between winding layers, but a more efficient method is to divide the winding in question into series-connected sections, with each section confined to a separate sector of the core circumference. By so doing, this component of error can be reduced by a factor of up to n^2 , where n is the number of sections (13,16). In order to gain the full effect of this winding method, however, extra insulation must be applied between the winding in question and any other winding or electrostatic screen.

GENERAL-PURPOSE INSTRUMENTATION AND MEASUREMENT

MULTIMETERS

The term multimeter is used to describe many different types of instruments. Multimeters are just what the name describes, meters that can measure multiple quantities with the same instrument. The most basic multimeters measure voltage, and current both ac and dc, and more advanced digital multimeters (DMMs) measure voltage, current, resistance, frequency, and temperature, and they can trend this information. Top of the line DMMs now have waveform capture capabilities, digital storing capabilities, and printing functions. Some models can communicate with personal computers (PCs). This allows users to store and recall setups, save measurement data to disk, and perform postprocessing functions on the data. This communication feature enables the use of measurement data in documents used for reporting and verification testing.

Technicians, engineers, facilities managers, and repair technicians use multimeters to diagnose a multitude of problems with equipment and power systems. These tools are an invaluable part of any field service personnel's toolbox. Making simple continuity checks is a snap with instruments that use an audible signal to alert the user of resistance values less than 20 Ω .

This article presents a historical account of multimeters, volt-ohm meters (VOMs), and the techniques used to make measurements in electronic and electrical circuits.

HISTORY OF METER MOVEMENTS

Primitive humans were in awe of lightning. Lightning was used as a source of fire for heat and cooking. The early Greeks were the first known to question the phenomenon of lightning. Although for years the Greeks had known about the attraction of particles and the forces of magnetic substances, it wasn't until approximately 700 BC that one Greek astronomer offered an explanation. This astronomer, Thales of Miletus, suggested that magnetic substances had a soul and were alive (1).

Throughout human history in other places there have been scientists who experimented with electricity and magnetism. In 376 BC the Chinese developed the first compass using magnetism. In the late eighteenth century Benjamin Franklin demonstrated that lightning was really an electrical phenomenon. In 1796 Alessandro Volta developed the first battery. In 1820 Hans Oersted discovered the relationship between current and magnetism. Using this information, André Marie Ampère showed the relationship between current flow and magnetism. He actually proved that a current flowing through a wire acted in the same manner as a magnet. In 1827 Georg Simon Ohm discovered one of the most basic and useful principles of electrical engineering, the relationship between voltage, current, and resistance, known as Ohm's law.

In 1881 Jacques d'Arsonval developed and patented a moving coil based on Oersted's principle known as the moving-coil galvanometer (see Fig. 1). The basic principle of operation of

the d'Arsonval meter movement is much like that of a permanent magnet dc motor. As current passes through the windings of the moving coil, north and south poles are set up on the coil, also known as the armature. These poles interact with the poles of the permanent magnet and cause the needle to deflect. The direction of rotation depends on the direction of current flow. Therefore the polarity of the meter movement is crucial, and the terminals on the movement are marked accordingly. The spring that is attached to the moving coil is used to retract the needle to the "zero" position after current is removed (2).

Before we begin the discussion of DMMs, we must first look at their predecessor, the volt-ohm meter, or VOM. The VOM is an analog device that is capable of measuring several different electrical quantities: voltage, current, and resistance. A majority of VOMs incorporate the use of a d'Arsonval meter movement. A simplified diagram of the d'Arsonval meter movement is shown in Fig. 1.

This type of meter responds to the average value of the current that passes through the moving coil. The amount of current passing through the meter movement is dependent on the design and calibration of the instrument. The d'Arsonval meter movement responds to current flow, not the quantity that the scale indicates. In other words, when the meter is being used to measure ohms, the scale may read 100 Ω , but the meter is actually responding to the average amount of current being passed through the moving coil.

This type of meter is rated with a full-scale deflection, usually measured in microamps, that relates the amount of current needed to make the needle move from "zero" to its maximum value. This value is important when designing a meter that incorporates the use of a d'Arsonval meter movement. Resistors placed in series with and in shunt with the meter movement allow the measurement of greater currents and voltages than is indicated by the full-scale deflection of the meter movement.

Figure 1. Basic diagram of the d'Arsonval meter movement.

The following sections discuss the use of the d'Arsonval meter movement and its uses in various types of meters. There are three basic measurements performed with VOMs and DMMs: current, voltage, and resistance. Basic design theory for each measurement is addressed.

Direct Current (dc) Meters

Perhaps the most common use for the d'Arsonval meter movement is in the dc ammeter. Figure 2 illustrates the most basic type of dc ammeter. A resistor is placed in shunt with the meter movement in order to limit the amount of current that passes through the meter movement. The value for R_{shunt} will vary depending on the desired full-scale reading of the ammeter.

Given a meter movement with a full-scale deflection of 10 mA and an internal resistance of 100 Ω , the value of R_{shunt} can be calculated as follows for an ammeter with a full-scale reading of 10 A.

The voltage drop across the meter movement at full scale would be 10 mA times 100 Ω , which gives 1.0 V. The voltage across the shunt resistor is the same as the voltage across the meter movement. The amount of current that must pass through the shunt resistor is the total full-scale reading (10 A) minus the current that passes through meter movement (10 mA). This value is 9.99 A. Therefore the value for R_{shunt} would be

$$R_{\text{shunt}} = \frac{V_{\text{shunt}}}{I_{\text{shunt}}} = \frac{1.0 \text{ V}}{9.99 \text{ A}} = 0.1001 \Omega \quad (1)$$

The power requirements of the shunt resistors must be taken into account when designing ammeters. The physical and electrical size of the shunt resistor plays an important role in the overall physical design of the instrument. The power requirement for the shunt resistor in our example was found by taking $I^2 R$ to be approximately 10 W.

The previous example illustrates how the d'Arsonval meter movement was used to make an ammeter capable of measuring current from 0 A to 10 A using a meter movement with a full-scale deflection of 10 mA. It is desirable, however, to have an instrument capable of measuring various ranges of current. Figure 3 is an example of such a meter. The meter in Fig. 3 incorporates the use of the Ayrton shunt.

This type of design allows for multiple scales in one meter. The values for the shunt resistors R_a through R_d are calculated in a similar manner to the shunt for the single-range meter. The actual values for the resistors that comprise the shunt are calculated starting from the most sensitive range to the least sensitive range. In the case of the meter shown in Fig. 3, the instrument is switched to its most sensitive range. The value

Figure 2. Schematic diagram for basic dc amp meter.

Figure 3. Schematic diagram for a multiple-range dc ammeter using the d'Arsonval meter movement and the Ayrton shunt.

for the shunt resistor for that range is $R_a + R_b + R_c + R_d$. The equations will not be derived for determining the values of the individual resistors. Instead, the reader is referred to Ref. 2.

Direct Current (dc) Voltmeter

As mentioned previously, another use for the d'Arsonval meter movement is for measuring voltage. However, some modification to the meter movement is necessary to make the meter practical. If the meter movement configuration in our previous example were used as is, it would only be able to measure 1 V. By placing resistors in series with the meter movement, as opposed to in parallel as in the ammeter, the deflection of the meter movement can be made to represent voltages of various magnitudes. Figure 4 is a schematic diagram of a simple voltmeter. Proper selection of the series resistors, sometimes called multipliers, R_a , R_b , and R_c results in a three-range voltmeter as shown. Given the internal resistance (100 Ω) and full-scale deflection (10 mA) of the meter movement, the values for the series resistor can be calculated. The three ranges of the meter are 2 V, 20 V, and 200 V.

The current through the meter will be the same as the current that passes through the series resistor. Therefore, for the 2 V range, we calculate the total resistance of the meter and series resistor to be 200 Ω (2 V divided by 10 mA). The value of the series resistor R_c is 100 Ω (200 Ω – 100 Ω). It follows that the values for R_b and R_a are 1900 Ω and 19,900 Ω , respectively.

Figure 4. Schematic diagram of a multiple-voltmeter incorporating the use of a d'Arsonval meter movement.

Another commonly used way to calculate the series resistors is to use the sensitivity of the meter movement. The sensitivity of the meter movement is the inverse of the full-scale current rating of the meter movement. To determine the resistor size, simply multiply the desired voltage range by the sensitivity of the meter movement; then subtract the value of the internal resistance of the meter. In our example, the sensitivity of the meter movement is 1 divided by 10 mA. This gives a sensitivity of 100 Ω/V . Therefore the value for R_c , the series resistor for the 2 V range, would be

$$R_c = \left[100 \frac{\Omega}{\text{V}} \cdot 2 \right] - 100 \Omega = 100 \Omega \quad (2)$$

For the 20 V range the value for R_b would be calculated as

$$R_b = \left[100 \frac{\Omega}{\text{V}} \cdot 20 \right] - 100 \Omega = 1900 \Omega \quad (3)$$

Values for other series resistors can be found in the same way. The only limitation on the magnitude of the measured voltage is the dielectric strength of the series resistors used in the multiplication.

When the direct current voltmeter is used to measure the voltage across a component in a given circuit, the voltmeter is in parallel with the circuit and changes the total resistance of the circuit. The resistance in the circuit is now smaller than either of the two resistances, and the voltage measured is less than the actual voltage across the test component. For this reason it is desirable to make the resistance of the voltage meter much larger than the resistance of the circuit under test. In other words, the sensitivity of the voltmeter should be high, on the order of 20 k Ω/V . Quality voltmeters typically have an input impedance of 1 M Ω or higher.

The Ohmmeter

As discussed earlier the d'Arsonval meter movement measures the amount of current that passes through its coil. Using Ohm's law, an instrument that measures resistance can be developed according to the d'Arsonval meter movement principle. Figure 5 gives the basic schematic diagram of an ohmmeter that incorporates the d'Arsonval meter movement. There is one major difference in the diagram of the ohmmeter compared with the voltmeter and ammeter—a voltage source. The ohmmeter requires a voltage source, since it is used to measure a passive element or circuit. Unlike the voltmeter and ammeter, there is no current flow in the circuit unless a source is supplied. A

Figure 5. Schematic diagram for an ohmmeter that incorporates the use of a d'Arsonval meter movement.

Figure 6. Schematic diagram for a multiple-range ohmmeter that incorporates the d'Arsonval meter movement.

potentiometer or variable resistance is used to “zero” the meter. The potentiometer compensates for fluctuations in the source voltage, lead resistance, and meter resistance changes due to temperature fluctuations.

The principle of operation of the ohmmeter is basically the same as that of the voltmeter or the ammeter. That is, it relates the deflection of the needle to the quantity under test. In this case the deflection of the needle represents the resistance of the element.

Multiple-Range Ohmmeters

Figure 6 is a schematic diagram of a multiple-range ohmmeter. By using some type of switch, usually a rotary switch, different ranges on the ohmmeter can be easily selected.

The Multimeter. The multimeter was developed because scientists, engineers, technicians, and electricians needed to make different types of measurements. The multimeter is simply a meter that is made up of several of the meters previously discussed. Multimeters typically measure dc volts and amperes, ac volts, and dc resistance. Each of these meters uses the same basic d'Arsonval meter movement for its operation, and therefore it is reasonable to assume that one instrument, using the same meter movement, can measure several quantities. Multimeters come in various shapes and sizes with different functions and accuracy. Figure 7 illustrates a differential, laboratory grade multimeter used for measuring both ac and dc quantities.

Up to this point we have discussed the use of the d'Arsonval meter movement with dc voltage and current readings. The d'Arsonval meter movement can also be used for ac measurements. The following sections address the issues of concern in using a d'Arsonval meter movement for ac measurements.

Alternating Current (ac) Meters

Measuring ac quantities can be more difficult than measuring dc quantities. With dc, the value of the voltage or current under test remains constant with time. However, with ac, the value of the voltage or current changes with time. Since the d'Arsonval meter movement responds to the average value of a signal, meter manufacturers are faced with a design dilemma. For dc, the average value of the signal is equal to the rms or effective value. For ac, the average value of the signal is equal

Figure 7. Photograph of the Fluke 803 differential dc-ac voltmeter. Reproduced with permission from Fluke Corporation.

to zero (assuming that only one frequency is present and that the negative and positive half-cycles are equal).

The rms value of a signal is the value that causes the same heating effect in a circuit element as a dc signal. The rms value of a signal, or the effective value of the signal, is found by squaring the signal, then computing the average value or the mean, and then taking the square root of the result (6).

Manufacturers have developed different methods for dealing with ac quantities when using the d'Arsonval meter movement. For example, two such methods are half-wave and full-wave rectification. Figure 8 illustrates a sinusoid, its half-wave rectified signal, and its full-wave rectified signal.

Half-Wave Rectification. When a diode is placed in series with the meter movement, the ac signal seen by the meter

Figure 8. Illustration of the average value for three ac signals.

Figure 9. Example ac voltmeter incorporating full-wave rectification technique. Photo by Bill Dabbs.

movement is half-wave rectified. This produces an ac signal with an average value of 0.318 times the peak value of the signal. By this principle, the scale on the meter itself can be calibrated to read correctly for a purely sinusoidal signal.

If the same meter movement and circuit is used as in Fig. 4, the sensitivity of the meter would be approximately 45% of the dc voltmeter's sensitivity. Therefore a new circuit is developed so that the full-scale deflection of the meter is obtained when a 2 V, 20 V, or 200 V rms ac signal is applied.

Full-Wave Rectification. By using full-wave rectification, the sensitivity of the ac voltmeter can be improved to 90% of the dc voltmeter. The average value of a full-wave rectified ac signal is twice the value (0.636 times) of a half-wave rectified signal.

Both half-wave and full-wave rectification techniques are only valid for pure sinusoidal waveforms. For nonsinusoidal signals, ac voltmeters employing half-wave or full-wave rectification will give erroneous readings. These types of signals will be addressed later in the article.

There are other types of meter movements that are used for both ac and dc measurements:

- Electrodynamometer movements
- Iron-vane meter movements
- Thermocouple meter movements

However, these types of meter movements will not be discussed here. The reader is directed to Ref. 2 for further reading on these meter movements. Figure 9 is a picture of an ac voltmeter that incorporates the full-wave rectification technique.

DIGITAL MULTIMETERS—ELECTRONIC METERS

With the development of the semiconductor in the 1950s came a new breed of instrumentation, the digital multimeter (DMM). Semiconductor technology has advanced greatly since the 1950s and has allowed the development of smaller, more accurate meters. Today's DMMs measure the same quantities as their predecessors, the analog meters. Similar to analog meters, the DMM can be used to measure many quantities

Figure 10. Example of a typical pocket DMM. Photo by Bill Dabbs.

including:

- ac voltage and current
- dc voltage and current
- dc resistance
- Frequency
- Diode characteristics
- Minimum, average, and maximum values
- Capacitance

Manufacturers have developed small pocket multimeters that incorporate basic measurement functions like voltage, current, and resistance. Figure 10 is an example of a small pocket multimeter that measures voltage, both ac and dc, calculates dc resistance, and has an audible indication of continuity for resistance under 20 Ω . Other multifunction DMMs are also available. Any quantity can be measured with a DMM provided that the proper transducer is used. Quantities like temperature, vibration, and pressure are easily measured with a DMM and a transducer. The transducer is used to convert the mechanical quantity into either a voltage or a current. The developed voltage or current is measured by the DMM, and the result is displayed. Using the ratio between the mechanical quantity and the electrical quantity, the actual quantity can be calculated. Several meter manufacturers offer instruments with transducers scaled in such a way that when the DMM displays volts they are directly proportional to the quantity being tested. In other words, 158 mV may be equivalent to 158°F. An example of a popular high-quality DMM is illustrated in Fig. 11.

Theory of Operation

Most digital meters function in a similar way. The signal under test is reduced to an appropriate level for the circuit that will be measuring the signal. This is normally accomplished by using a voltage divider network much like the ones in analog meters. However, once the signal has been transformed, the similarities between analog meters and digital meters end. Digital meters incorporate a digitizer, or analog-to-digital converter (ADC). The function of the ADC is to change the analog

Figure 11. Photograph of the Fluke 87 III true rms multimeter. Reproduced with Permission from Fluke Corporation.

signal into a digital word. Many DMMs incorporate the use of a $3\frac{1}{2}$ digit ADC.

Number of Digits

Most DMMs have a digit or value associated with them. This value is the number of digits that can be displayed. A $3\frac{1}{2}$ digit display can display values from 0 to 1999. Similarly a $4\frac{1}{2}$ digit display can display numbers ranging from 0 to 19,999. This value serves another purpose, apart from indicating the number of digits a meter can display. The number of digits also gives an indication as to the number of “counts” that an instrument uses. A $3\frac{1}{2}$ digit instrument has 1999 counts, and a $4\frac{1}{2}$ digit instrument has 19,999 counts. The count is the highest number that can be displayed on the instrument. Figure 12 is a typical $4\frac{1}{2}$ digit display.

DMM Resolution

The resolution of DMMs is typically given in the specification sheet of the instrument. The resolution of an instrument is the smallest change in a measured value to which the instrument will respond. For an analog instrument, the resolution is one-minor scale division. For digital instruments, the digitizer or ADC determines the resolution. The range that is selected on the instrument determines the resolution in measured units. An example of this calculation follows.

Figure 12. Typical $4\frac{1}{2}$ digit display for a DMM.

This example calculates the resolution of a $3\frac{1}{2}$ digit DMM. The instrument for this example is a $3\frac{1}{2}$ digit, 2000 count DMM on the 200 V range:

$$\text{Resolution} = \frac{\text{Range}}{\text{Count}} = \frac{200 \text{ V}}{2000 \text{ counts}} = 0.1 \text{ V} \quad (4)$$

If the number of counts for this instrument were 20,000, the resolution of the instrument on the 200 V scale would then be 0.01 V.

Sensitivity

Sensitivity of an instrument is the smallest level to which the instrument can respond. This value is usually specified by the least detectable change on the lowest range. For an analog instrument on the 1 V scale with 100 divisions, the sensitivity would be 0.01 V (10 mV). For a digital instrument with $4\frac{1}{2}$ digits on the lowest range of 200 mV, the sensitivity would be 0.01 mV. An example follows.

The instrument is an analog meter with 100 divisions on the scale. The lowest range on the instrument is the 1 V scale. Therefore the sensitivity of the instrument can be calculated as

$$S = \frac{1 \text{ V full scale}}{100 \text{ divisions}} = 0.01 \text{ V} = 10 \text{ mV} \quad (5)$$

To determine the sensitivity of a digital meter, we need to know the number of counts used and the range at which the instrument is set. For our example, suppose we have a 20,000 count DMM that is set to the 200 V range. The sensitivity or maximum resolution on the 200 V range would be 0.01 V. The equation used to determine the sensitivity is

$$S = \frac{\text{DMM range}}{\text{Number of counts}} = \frac{200 \text{ V}}{20,000 \text{ counts}} = 0.01 \text{ V} = 10 \text{ mV} \quad (6)$$

Accuracy and Uncertainty

Accuracy and uncertainty are complementary terms. An accuracy of 99.9% has an uncertainty of 0.1%. Accuracy is a measure of “closeness” to a known or given value. If an instrument has an accuracy of 1%, this means that the measurement will be within plus or minus 1%. Accuracy is given in two ways.

- Percent of full scale
- Percent of reading

There can be quite a difference between these two methods of determining accuracy. The following example illustrates the difference.

Given an instrument with a full-scale reading of 200 V and an accuracy of 1% of the full-scale value. The accuracy is $\pm 1\%$ of the 200 V, or 2 V. A reading of 100 V could actually be 102 V or 98 V. This produces an error of 2%. A reading of 10 V could actually be 12 or 8 V. This produces an error of 20%.

An instrument with an accuracy of $\pm 1\%$ of the reading produces drastically different results than a meter with an accuracy of $\pm 1\%$ of the full-scale value. Measuring the same 100 V would result in a reading between 99 V and 101 V. This is an error of 1%. A reading of 10 V could actually be between 9.9 V and 10.1 V. This also is an error of 1%.

The accuracy depends on temperature and other environmental conditions. Manufacturers often state accuracy in typical values, not the worst case values.

Voltage

Ac, dc, rms. The most important factor to consider when selecting and using a DMM is the method of calculation used in the meter. All of the commonly used meters are calibrated to give an rms value for the measured signal. A number of different methods are used to calculate the rms value. The three most common methods are

- Peak method
- Averaging method
- True rms method

Peak Method. A peak-detecting DMM uses a peak detection circuit to determine the peak of the signal. The circuitry in the meter determines the peak value and divides the result by 1.414 (square root of 2) to obtain the rms value. The rms value of a pure sinusoidal signal is related to the peak value by a factor of 1.414. This is also known as the crest factor of a signal.

Average Responding. An average-responding meter determines the average value of a rectified signal, as does the d’Arsonval meter movement. For a clean sinusoidal signal, the average value is related to the rms value by the constant, $k = 1.11$. This value is used to scale all waveforms measured. As with the d’Arsonval meter movement, the average value of a sinusoid is 0.636 times the peak value. Therefore the rms value of the rectified signal can be found by multiplying the average value $(0.636 \times \text{peak}) \times 1.11$.

True rms. The rms value of a signal is a measure of the heating which will result if the voltage is impressed across a resistive load. One method of detecting the true rms value is to actually use a thermal detector to measure a heating value. Modern digital meters calculate the rms value by squaring the signal on a sample by sample basis, averaging over a period, and then taking the square root of the result. Figure 13 illustrates a good-quality true rms DMM.

In today’s electronic environment, it is important to use instruments that read true rms quantities (Fig. 14). Electronic equipment is nonlinear. That is to say, the current wave shape does not follow the voltage wave shape. As mentioned previously, several techniques used to measure rms quantities

Figure 13. Photograph of the Fluke 87 III true rms multimeter. Reproduced with Permission from Fluke Corporation.

are only valid for purely sinusoidal signals. When electronic equipment is present in a circuit, the current drawn by the load contains harmonic components, currents of frequencies other than the 60 Hz fundamental. Table 1 shows the error produced by three different meter types when measuring nonsinusoidal quantities.

For the true rms method, the instrument displays the correct value for the rms quantity under test. However, the peak detection method and the average responding method produce an error when measuring quantities that are not purely sinusoidal.

Transducers

Many DMMs on the market today can measure current. The maximum current that can be measured directly is usually less than 10 A rms. In most cases it is necessary to interrupt, or break, the circuit under test in order to measure current. DMM manufacturers have recognized this as a problem and now offer current probes or transducers (CTs) for use with their

equipment. These CTs are usually clamp-on type devices that allow you to clamp around a conductor without interrupting the circuit. The CTs also extend the range of the DMM and allow the user to measure current up to 1000 A rms. The CT uses the same principles as a regular transformer except that the turns ratio is designed to give a low-level voltage or current on the secondary winding of the CT that is proportional to the current passing through the primary winding (the jaw of a clamp on CT). As with transformers, CTs are only capable of transforming ac signals. The electric field around a current-carrying conductor changes with time for an ac signal. Therefore the flux and the resulting voltage induced in the secondary of the CT coil change also. For dc, the flux does not change, and no voltage is induced in the secondary of the CT. For dc measurements, a Hall effect current probe must be used. Hall effect CTs work off the magnetic field produced by current flowing through a conductor. These devices often require a separate voltage source to drive the circuits internal to the current probe. Figure 15 illustrate several different models and styles of current probes that can be used with DMMs.

Table 1. Methods for Measuring Voltages and Currents in Multimeters

Meter Type	Circuit	Sine Wave	Square Wave	PC Current	Light Dimmer	Triangle Wave
						
Peak method	Peak/1.414	100%	82%	184%	113%	121%
Average responding	Sine avg. × 1.1	100	110	60	84	96
True rms	rms converter	100	100	100	100	100

Source: Reference 4.

Figure 14. Photograph of the Fluke 8060A true rms multimeter. Reproduced with permission from Fluke Corporation.

Several manufacturers of DMMs incorporate the clamp-on CT into the design of the DMM. This type of DMM is capable of measuring currents into the hundreds of amps as well as voltage, resistance, and other electrical quantities. Figure 16 is an example of this type of instrument.

Figure 15. Example of a clamp on DMM. Photo by Bill Dabbs.

SAFETY

As with any instrument used to measure electricity, some safety concerns must be addressed. This section deals with several safety considerations that must be kept in mind when using multimeters. It is not intended to be the final word on safety, nor is it intended to supersede any manufacturer's safety practices or recommendations. Several standards are cited, and the reader is encouraged to review these standards prior to purchasing and using any instrument.

When working with electrical circuits it is ultimately your responsibility to ensure your safety. Working on dead or de-energized circuits whenever possible is recommended. However, certain situations do not allow measurements to be performed on dead circuits. If working on live or energized circuits, remember the following:

Never work alone. Always work in pairs in case you accidentally come in contact with the circuit you are measuring. Your partner can disconnect the circuit or knock you away from the live circuit.

Always use protective gear. You should always wear eye protection and insulated gloves with leather protectors. This equipment should be tested annually to ensure that its electrical withstand capability has not degraded. Never wear jewelry, watches, or other metallic articles of dress when working on electrical circuits. Any electrical conductor coming in contact with a live circuit can have disastrous results. Flame resistant clothing is also a good idea.

When performing measurements on live circuits, follow these basic steps to ensure your safety:

Table 2. Effects of Current on the Human Body

<i>Current Applied to Skin</i>	<i>Effect of Prolonged Contact</i>
6 A or more	Sustained myocardial contraction followed by abnormal rhythm. Temporary respiratory paralysis. Burns on contact area.
0.1 to 2–3 A	Ventricular fibrillation. Respiratory center intact.
30 to 50 mA	Pain, fainting, exhaustion. On prolonged duration, death often results.
16 mA	“Let Go” current, muscle contraction.
1 mA	Threshold of perception, tingling.
<i>Current Applied to Myocardium</i>	<i>Effect of Prolonged Contact</i>
100 μ A	Ventricular fibrillation.
10 μ A	Recommended maximum leakage current for patient connected biomedical equipment.

1. Always connect the ground lead first then the hot lead. Removal of the test leads is in reverse order. Remove the hot lead first then the ground lead.
2. Use the three-point test method. When performing measurements, it is important to ensure that the test equipment is functioning properly. First, perform a similar measurement on a known source prior to connecting the instrument to the test circuit. Second, perform the measurements on the circuit under test. Third, test the meter on the known circuit to verify its operation after the measurement.
3. Use one hand. Whenever possible, only use one hand when connecting and disconnecting test leads from a live circuit. This lessens the chance that you will come in contact with a live circuit. More important, it lessens the chance that you will receive an electrical shock across your chest and through your heart.

When the human body comes in contact with live electrical circuits, current flows through the body. If this current flow is across the chest and heart, the result can be disastrous. Table 2 lists different levels of current and their effect on the human body. Using the information in Table 2, we can calculate a threshold for a hazardous voltage. Under dry conditions the approximate skin resistance across a human body is 1000 Ω . Using Ohm's law, a voltage of 35 V would produce a current of 35 mA. From Table 2 it can be seen that this would cause loss of breathing and possible death. When the skin is wet, the hazardous voltage can be as low as 10 V.

Voltage Rating

All multimeters are tested against and are rated in accordance with safety standards. The International Electrotechnical

Commission (IEC) has several safety standards by which instruments are tested. One standard, IEC 1010, is a test procedure that uses three criteria to determine a multimeter's voltage rating. They are the steady-state voltage, peak voltage, and source impedance. These three criteria are used to describe the meters true withstand capability. Table 3 lists the different levels of overvoltage categories and the values used for each criterion.

Another concern with safety is the test leads. If an instrument is rated CAT III 600 V, but the leads are only CAT II 600 V, the leads become the actual rating of the measurement system. In other words, don't overlook the test leads. Choose test leads that are certified in the same category and voltage rating as the meter or higher. Test leads are also rated by IEC 1010.

Another safety concern is that the meter is connected properly. Many DMMs can measure both voltage and current. When a voltage measurement is made, there is a high input impedance (usually 10 M Ω) on the voltage circuit. This impedance conditions the voltage or reduces the voltage to appropriate levels for the circuitry within the instrument. However, when measuring current, the instrument is placed in series with the load under test. The burden, or input impedance, is typically 0.01 Ω or less. This low impedance doesn't affect the current that the instrument is trying to measure. The voltage developed across the burden is read, and using ohm's law, the measured current is displayed. In order to avoid confusion, meter manufacturers typically use a common jack (COM), a volts jack (V Ω), and an amps jack (A); see Fig. 17. When performing voltage measurements, the leads are connected to “COM” and “V Ω .” When performing current measurements, the leads are connected to “COM” and “A.” However, if the leads are

Table 3. Transient Test Values for Overvoltage Withstand Capabilities

Overvoltage Category	Working Voltage (volts)	Peak Impulse Transient (volts)	Test Source Impedance (ohms)
CAT I	600	2500	30
CAT I	1000	4000	30
CAT II	600	4000	12
CAT II	1000	6000	12
CAT III	600	6000	2
CAT III	1000	8000	2

**Figure 17.** Example DMM connection jacks.

left connected to “COM” and “A” and a voltage measurement is performed, the low impedance of the burden is effectively a short circuit. This short circuit occurs even if the selector switch or dial of the meter is turned to volts. For this reason fuses must protect the amp terminals, and one must make sure to use the fuses specified by the manufacturer. These fuses are generally high energy and have an interrupting capacity to protect users (4).

SUMMARY

Multimeters are used worldwide by many people and in different professions. Since their invention, they have proved to be invaluable tools for technicians, electricians, engineers, and homeowners. Multimeters can be used to troubleshoot equipment, verify proper operation of equipment, and determine values of electrical components. Advances made in multimeter technology have made them more affordable and economical for practically any individual to own.

When used properly, multimeters serve the user well. Safety is of the utmost importance, and meter manufacturers take great pains to ensure that they produce safe products for the consumer. International committees have developed standards that rate multimeters. Consumers should use these ratings to ensure that the multimeter they are using meets or exceeds the requirements of the work being performed.

DIGITAL MULTIMETERS

Analog multimeters were created in the early part of the twentieth century. The most common form measured dc and ac voltage, resistance, and dc current, and these became known as volt-ohm-milliammeters or VOMs.

In 1955, the first digital voltmeter was marketed by Non Linear Systems, Inc. This meter scaled inputs and then digitized them, displaying the results in a numeric digital display.

Figure 1. Modern full feature DMM (Fluke 87 III).

Digital measurement and display technologies developed in parallel with digital integrated circuit technology until finally, in the late 1960s, portable digital versions of the VOM appeared. This form of meter shown in Fig. 1 has since become known as the digital multimeter (DMM).

THE ELEMENTS OF A DMM

A DMM is made up of several basic functional elements shown in Fig. 2.

1. Signal conditioning
2. Analog/digital conversion (A/D)
3. Numeric digital display

Signal Conditioning

The analog-to-digital converter (ADC) in most DMMs converts a dc voltage input to a digital form for display. Ac or dc voltage, current, and resistance are the most common parameters to be measured. Now many DMMs also measure frequency, and additional functions, such as temperature, have also appeared.

Figure 2. Basic DMM block diagram shows the basic flow of information from the analog input signal through the various analog signal conversion circuits which convert the measured quantity to a dc voltage equivalent. Then the ADC translates this dc signal to digital form, and the display system shows the resultant value with appropriate annunciation, such as measurement units of the original input signals. Not shown are the necessary, but not directly related, parts of the DMM. These include the power supply and mechanical packaging.

Figure 3. VOM input multiplier—dc volts. The basic input configuration for dc voltage input to an analog VOM. The major point of this diagram is that the input resistance varies as a function of range to maintain current through the meter movement within its limited dynamic range. This configuration leads to the common VOM sensitivity specification in ohms per volt. A 20,000 Ω/V meter draws 50 μA from the input at full scale indication on any dc voltage range.

First these inputs must be switched and conditioned to present an equivalent dc voltage of the appropriate range to the ADC or a sealed input to the counting circuits.

Dc Voltage

It is necessary to scale a wide range of dc voltage inputs to the limited range of the ADC. A resistive divider and switching are generally used for this function. One of the major differences between the classical analog VOM and the DMM is in the way this scaling occurs.

In the analog VOM, the input circuit is designed to provide full-scale current to operate the d'Arsonval meter movement (refer to Fig. 3). A typical meter has 50 μA full-scale sensitivity. The input sensitivity of such a meter is specified by calculating the series resistance per volt at 50 μA , $R = 1/0.00005$ or 20,000 Ω/V . A 5 V range therefore has an input resistance of 100,000 Ω , and a 500 V range has an input resistance of 10 M Ω as more resistors are added to the input multiplier.

The DMM, on the other hand, operates with a fixed resistive divider across the input (typically 10 M Ω) regardless of the range chosen (see Fig. 4). In this case the input resistance is a divider with output taps switched to present a voltage, usually less than 1 V, to the ADC. For this reason, the DMM uses much less current (is more sensitive) on the lower voltage ranges than the typical VOM, thereby reducing circuit loading errors.

Another difference between the VOM and the DMM is in the rejection of ac noise which is present along with the dc voltage to be measured. In the VOM, the mechanical damping provided by the d'Arsonval meter movement averages this noise and presents a stable reading even when the noise is

Figure 4. DMM input divider—dc volts. The constant input resistance input divider network in the typical DMM. The total resistance at the input terminals is relatively high, usually 10 M Ω . Output taps are selected to present a small voltage (less than 1 V) to the ADC even when the applied input is 500 V or more. The same divider is often used for AC voltage scaling. In this case, shunt capacitance should be specified.

Figure 5. The positive half-cycle (180°) of a sine wave and the relationship between peak, rms, and average values. The simplest and least expensive DMMs have always used the rectified average value scaled to equivalent rms for display. This relationship is true only for the sine wave whereas most 'real-world' measurements are of waveforms that range from square to narrow pulse with varying rise and fall times. Therefore, this method is usually inaccurate to some degree, and it is difficult to predict the amount or direction of the error. A similar problem occurs when the peak value is scaled to the rms. The end message: If the rms value is important, measure the true rms.

a significant portion of the signal being measured. The DMM input circuit, combined with the ADC method used must filter to provide equal or better performance. See a discussion of noise rejection in the section on A/D conversion.

Ac Voltage

For ac voltage, the signal must be scaled and then converted to a dc equivalent value before sending it to the ADC. Following are two popular methods of conversion (refer to Fig. 5).

Average Sensing-Rms Indicating ac Measurements. In the analog VOM, ac to dc conversion is accomplished by using a bridge rectifier in the meter circuit to provide a single polarity current that deflects the meter needle. This current has significant ripple at twice the frequency of the measured ac signal, but this is effectively filtered (or averaged) by the mechanical damping of the meter movement. In the DMM, an operational rectifier circuit is used, but the output must be filtered to reduce the ripple before it is applied to the ADC.

This rectified average value is equal to $2/\pi$, or 0.637 times the peak value for a sine wave. The desired ac voltage (or current) value is the rms, or heating value, which is equal to $1/\sqrt{2}$, or 0.707 times the peak of a sine wave. Therefore average analog or digital sensing meters, scale the rectified signal by $\pi/(2 \times \sqrt{2})$, or 1.111 times the rectified average value. This ratio of rms to average value is known as the form factor of the input waveform. Although this method works for a sine wave of a single frequency, significant errors occur when the waveform is distorted because these ratios are no longer true if harmonics are present.

True Rms ac Measurements. A more accurate conversion provides the true rms value—equivalent to a dc voltage which would heat a resistor to the same temperature. With true rms conversion, this is true regardless of waveform. Most DMMs, which offer true rms capability, use an analog computing circuit to perform the necessary calculation (Fig. 6).

Figure 6. An early 1980s true rms DMM (Fluke 8060A).

Rms stands for root-mean-square, which is expressed mathematically as $\text{rms} = \sqrt{(\sum i^2/n)}$, where i is the instantaneous value and n is the number of points i (1 to n), which are squared and summed for use in the calculation (see Fig. 7).

Some DMMs also allow measuring the peak value of the ac waveform.

Dc and ac Current. To measure current with a DMM, it is necessary to convert the current at the input to a voltage for use by the ADC. This is done through a series of switched resistors, called shunts. A small-valued resistor in the input is placed in series with the current to be measured and Ohm's law ($E = IR$) defines the small voltage proportional to the input current which is then measured.

Ac current uses the same method except that the voltage across the shunt is routed through an ac-dc voltage converter before going to the ADC.

Burden Voltage. The voltage drop across the current input resistance of a DMM connected in a series circuit is known

Figure 7. True rms ac-to-dc conversion. The functional blocks of the basic analog circuit that produce a dc voltage proportional to the rms value of a complex waveform. The logarithmic conversion for squaring is accomplished by using the current versus voltage relationship of a forward-biased base-emitter junction of a transistor. Factors which affect the performance of this conversion process include frequency response, crest factor, and slew rate. Commercial converters are available. Analog Devices (ADI) in Norwood, MA, has several products. Their rms converter website is <http://products.analog.com/products.html/list-gen.117.html>

as burden voltage and is subtracted from the voltage normally available to the load. Therefore the resistance added to the measured circuit should be kept as small as possible to minimize measurement error.

Resistance

Because the ADC measures only dc volts, it is necessary to create a voltage proportional to the resistance when that measurement is desired. The DMM input circuit must provide a dc current flowing through the resistor and then measure the resulting voltage. Ohm's Law provides the necessary relationship ($R = E/I$). Of course, it is necessary to know the applied current value for this method to be useful. Many DMMs provide a calibrated constant current source for this purpose. Many others use reference resistors in series with the resistor being measured, and then measure the unknown and reference voltage drops. When combined with the known reference resistor values, this voltage ratio technique also yields the desired resistance value.

ANALOG-TO-DIGITAL CONVERSION

There have been several schemes used for the ADC conversion in DMMs. Some of them read voltage by using successive approximation, a technique which measures the voltage directly with a digital-to-analog converter (DAC) and voltage comparator. Many others rely on time-counting techniques. The most common of these by far is dual-slope integration.

Dual-Slope Integration

This process uses an operational amplifier configured as an integrator [Fig. 8(a)]. First the integrator is set to zero. Then the input voltage (V_{input}) is applied for a precise period of time controlled by a counter. The input is then switched to a reference voltage of the opposite polarity ($V_{\text{reference}}$), and the time required to integrate back to zero is counted. When done correctly, this process relies only on the stability of the integrator capacitor, the precision and stability of the counter, and the accuracy of the voltage reference to achieve the desired result.

The process just described is represented by the voltage versus time diagram in Fig. 8(b). V_1 represents the integrator voltage output at the end of the fixed period when an input voltage is applied. T_1 represents the time required for the integrator to return to zero when the appropriate reference voltage is selected. A similar case is shown for a larger input voltage (V_2) where a longer time (T_2) is required to return to zero.

In the dual-slope ADC, the time required to deintegrate (return to zero) is directly proportional to the integrator voltage at T_0 , which, in turn, is directly proportional to the input voltage.

NOISE REJECTION

Normal-Mode Noise

Common implementations of the dual-slope ADC use the unique noise rejection characteristics of the process to minimize the effects of the major noise source, the 50 Hz or 60 Hz power system. The inherent filtering characteristic of this

Figure 8. (a) The basic elements of the analog integrator circuit of the dual-slope integrator. The circuit uses an inverting operational amplifier to convert an input current (through input resistor $R1$) to a voltage across the integrator capacitor $C1$. From an initial condition when the voltage across $C1$ is zero, $R1$ is connected to V_{Input} , and integration occurs for a fixed period of time. This is the first slope of the dual-slope process. The polarity of the charge on $C1$ is determined, and a reference voltage, $V_{\text{Reference}}$ is selected. The purpose of the second slope integration is to determine the time needed to return the voltage on $C1$ to zero. This time is proportional to the voltage on $C1$ at the end of the first slope which, in turn, is proportional to the applied input voltage. (b) The voltage versus time diagram.

Figure 9. Dual-slope integrator normal-mode rejection (NMR)—100 ms integration time. The rejection characteristic of input frequencies whose periods are directly related to the inverse of the signal integration time. The 100 ms time used for this example equals a period of one cycle at 10 Hz. Therefore there is near infinite rejection of 10 Hz and its integral multiples.

Figure 10. Normal (series)-mode noise. The interfering signal (noise) is a part of the measured signal seen by the meter. It may be ripple in the output of a power supply or may be induced in the signal leads connecting the input source and the DMM.

converter, set to integrate for 100 ms, is shown in Fig. 9. This integration time results in near infinite rejection of noise at integral multiples of 10 Hz and because exactly 5 cycles of 50 Hz and 6 cycles of 60 Hz occur in 100 ms, this technique addresses power system noise directly.

The presence of noise directly affects the performance of a DMM by causing a reading error or instability. The noise may be an integral part of the signal being measured but is outside the passband of the measuring system. In the preceding case, the circuit measures dc voltage, and the noise is at the power frequency. This is referred to as normal-mode or series-mode noise (Fig. 10).

In Fig. 9, normal-mode noise rejection is expressed as a ratio of peak display disturbance divided by the in-band signal being measured. For example, if the DMM is reading 5.000 V with noise up to ± 0.050 V, then $0.05/5.0$ yields a normal-mode rejection ratio (NMRR) of 0.01—expressed in decibels as 40 dB NMRR.

Common-Mode Noise

If the noise is present between a third point and the two measurement connections in common, then it is known as common-mode noise (Fig. 11).

The common-mode rejection ratio (CMRR) is calculated similarly to the ratio for normal-mode noise, the peak error or instability displayed in the measurement reading divided by the nominal reading value.

These examples have shown dc voltages affected by ac noise. However, the same principle also applies to ac measurements. For example, when measuring the ac voltage in a three-phase power system, neither input terminal is at ground, and a large common-mode signal with respect to ground is present. Now this frequency is the same as the frequency of the voltage being measured. The result may be a measurement that is stable, but either higher or lower than the actual phase-to-phase voltage. Reversing the test leads shows this possible “turnover”

Figure 11. Common-mode noise. The interfering signal (noise) influences both the input and common leads of the DMM input. This type of noise results when the circuit being measured is floating with respect to local “ground.”

Figure 12. Common-mode capacitive leakage effects. The common lead of the meter is usually more closely associated with shields and power supply reference in the meter and therefore has the lowest impedance for possible ground loops. The voltage input is the high (typically 10 M Ω) input. The net effect is for the common-mode signal to appear as an equivalent normal-mode noise input in this unbalanced circuit.

error. The shielding and filtering characteristics of the DMM become important in minimizing the effect of leakage capacitance (Fig. 12).

Dc voltage measurements also show this effect with a dc common-mode voltage. In this case, leakage resistance is the issue.

DIGITAL DISPLAY

The final element of the DMM is the digital display. Several display devices are in use now including vacuum fluorescent, light-emitting diode (LED), and liquid crystal display (LCD) technologies. The LCD is the most common display in use today, primarily because it requires the least power to operate. Typical digital displays show the measured value using seven segments per digit plus decimal points and polarity indicators. More capable DMMs also provide bar graph and measurement unit annunciation elements. Typical displays are shown in Fig. 13.

DISPLAY RANGE, RESOLUTION, AND ACCURACY

Range

The effective range of a DMM display is described in several different ways:

1. In counts (2000 counts, 3000 counts, etc.). The count reference comes from the fact that most DMMs use a COUNTER circuit to drive the display circuitry.
2. As a number of digits (3 1/2, 4 3/4, etc.). Referring to a display as “3 1/2 digits” or “4 3/4 digits” indicates that the leading, or most significant, digit in the display never exceeds the numeral 2, 3, or 4. A 3 1/2 digit meter might

Figure 13. (a) Dc volts on 30 V range. (b) Ac volts on 400 V range.

operate to 2.999, a 4 3/4 digit might operate to 3.999, etc. Attempts have been made to make the reference scientific by calculating the base 10 logarithm of the maximum number. For example, 1999 has 3.3 digits, 2999 has 3.5 digits, and 39999 has 4.6 digits.

3. By showing the actual measurement limits in volts, etc. (–2.999 to +2.999). This is the simplest and least ambiguous way to describe the effective measurement range of a DMM.

Resolution

The resolution of measurement may be specified in least significant digits (LSD), counts, percentage of range, or absolute units (0.01 V), or it may be implied in the range specification. When in the 2.999 V range, for example, the implied resolution is 0.001 volts.

From a practical standpoint, usable resolution is sometimes less than display resolution. Reading instabilities may dictate that the usable resolution of a meter is only ± 0.002 V or 0.003 V even though it has a display resolution of 0.001 V.

Accuracy

An accuracy statement for a DMM includes many factors. Among these are resolution, linearity, long-term stability, ambient temperature, and humidity.

Single-Term Accuracy. The simplest DMM accuracy specification uses one term, such as 3% of range, for each function. This applies over all temperature and humidity conditions for some period of time. One year is a common period. This is the usual way to specify the accuracy of analog VOMs whose ranges may be organized in 1, 2, 5 or 1, 3, 10 sequence. For example, $\pm 3\%$ of full scale on the 10 V range (± 0.3 V) means that the accuracy of a 10 V reading is 3% of the reading whereas that of a 3 V reading on the same range is 10% of the reading. The user can switch to a 3 V range in this case and return to 3% of reading accuracy at full-scale.

In the DMM, however, the digital display ranges are in decades, such as a 3, 30, 300 sequence. Ranging occurs near one-tenth of range. For the following descriptions it will be helpful to refer to Fig. 14.

Single-Term DMM Accuracy. A reading on the 30.00 range displays 3.00 (10 mV resolution) before ranging allows a change to 3.000 where 1 mV resolution is possible. A specification of 1% of full scale (± 0.3 V) becomes 10% of the reading at 3 V before the range is changed. This leads to an accuracy statement which combines a percentage of the reading term and a resolution-based (percentage of range) term.

Two-Term Accuracy. The input divider, amplifier gain, and reference voltage accuracies are combined in a percentage of reading term because they all contribute to the actual value displayed. The amplifier offset, noise, and least significant digit considerations for the ADC and display are combined in a percentage of range term stated as counts, digits, or percentage of range. In the 30 V range example before, such a specification might read as follows: $\pm(1\% \text{ of reading} + 2 \text{ counts})$.

At 30 V, the resulting maximum error is 1% of 30.00 (0.3) plus 2 counts (2×0.01 or 0.02) for a total of 30.00 ± 0.32 V.

Figure 14. Single-term (dashed line) versus two-term (solid line) accuracy. The graph assumes that range change occurs exactly at the 3 V point. In fact, when an instrument is autoranged, the decision to down range comes at about 90% of the next lowest range. This is at 2.7 V in this example. The reason for the overlap is to minimize “hunting” of the ranging circuit because of slight instability or noise near the ranging point.

Taken as a percentage of the reading, this equals about 1.07% of the reading. At 3 V in the same range, the error is 1% of 3.00 (0.03) plus the same two counts (0.02) for a total of 0.05 V. As a percentage of reading this is now only 1.6% of the 3 V input, far better than the single-term (% of full-scale) accuracy described previously.

Other Factors To Be Considered

Resolution and linearity are included in the basic accuracy specification for most DMMs. Most specifications indicate the time (6 months, 1 year, etc.) for which the specification applies. This takes care of the long-term stability consideration. An accuracy specification may also indicate a temperature range and humidity level which are included in the basic statement. Additional specifications may be furnished to indicate added error terms for operating temperatures and humidities outside the basic range stated.

APPLICABLE STANDARDS AND RATINGS

International Safety Standards for DMMs

IEC 61010 establishes international safety requirements for electrical equipment for measurement, control and laboratory use. There are four categories, CAT I, CAT II, CAT III, and CAT IV ranging from electronic to outdoor electrical power distribution, respectively. There are also maximum voltage ratings that indicate the maximum service voltage to be applied to a meter which is so rated. A meter intended for use at interior single-phase receptacles might carry a notation of CAT II, 300 V, for example. Independent testing organization, such as UL, CSA, TUV, certify that a DMM meets the appropriate IEC standards. Overload ratings are also useful. These ratings indicate maximum values of voltage or current that may be applied to a DMM input without causing damage.

Standards for DMM Measurements and Accuracy Statements

Work began in 1961 to develop a standard that covers digital measuring instruments. At the end of that decade, American

National Standard Requirements for Automatic Digital Voltmeters and Ratio Meters, ANSI C39.6-1969, was approved. It was published by ANSI in 1970. The last revision of this standard was approved in 1982 and published in 1983 as the American National Standard for Electrical Instrumentation-Digital Measuring Instruments, ANSI C39.6-1983. Although this standard has been withdrawn and is no longer in effect, many of the definitions of terms, testing methods, and specification presentations for DMMs today are based on the examples set in this standard.

OHMMETERS

An ohmmeter measures direct current (dc) electrical resistance (in ohms), a basic electrical quantity. Most commonly, it is one function of a digital multimeter (DMM), which combines voltage (V), current (I), and resistance (R) measurements in one instrument. These three quantities are related through Ohm's law, $V = RI$. Multiple ranges (by factors of 10) are needed to cover the wide range of resistance normally encountered in electrical/electronic devices (0.01 Ω to 10 M Ω). More specialized meters cover much lower and higher ranges (below $10^{-6} \Omega$ and above $10^{15} \Omega$).

Generally dc resistances are highly linear; that is, they obey Ohm's law to within measurement precision. This is especially true of commercial resistors and of metal conductors such as copper. Three exceptions are (1) temperature-sensitive resistors, which are heated by the power dissipated in the resistor; (2) semiconductor devices such as diodes, which may have very nonlinear $I - V$ properties; and (3) ionic conductors, including biomedical electrodes and aqueous solutions.

Resistance may be measured by applying a known voltage (constant voltage source) across the device under test and measuring the current that flows, or by applying a known current (constant current source) and measuring the voltage developed across the device. The current and voltage are limited to avoid damage to the device being tested (e.g., 5 V or 10 mA). Ohm's law is used to convert to resistance with the appropriate scaling factors. For example, a 1 mA current source will produce a 1 V drop across a 1 k Ω resistor so that a voltmeter calibrated as an ohmmeter (e.g., 1 k Ω at 1 V) will read the resistance out directly.

Digital ohmmeters have an analog input section with an operational amplifier to supply a constant current (Fig. 1). The

Figure 1. Digital ohmmeter.

amplifier adjusts its output so that the voltage drop produced by the current, across a known internal resistor, is equal to a reference voltage.

Switching the internal resistor changes the current (source) range and thus the resistance range. The operational amplifier will produce a constant current only up to a maximum voltage, which is chosen to be above the corresponding full scale of the readout. In any case, it is less than the amplifier supply (e.g., battery) voltage.

Loading effects of the voltmeter may limit the upper resistance range, as indicated in Fig. 2. An ideal voltmeter would have an infinite resistance and draw zero current. FET input amplifiers approximate this requirement. The meter input resistance R_{mi} and/or input leakage current provides a shunting path to the current provided by the current source so that the effective resistance R_x is reduced. Input impedances over $10^{10} \Omega$ and input under 0.1 nA are readily achievable with FET-type operational amplifiers. Most commercial DMM and DVMs (digital voltmeters) have a built-in dual-ramp-type analog-to-digital converter and also drivers for three or four digital (seven segment) displays.

Older design ohmmeters use a moving coil milliammeter or d'Arsonval meter as an analog indicator. As illustrated in Fig. 3, they may use operational amplifiers or other amplifiers. There are two general types: shunt and series. With the series type, the unknown resistance R_x is connected in series with a battery (e.g., 1.5 V) and the milliammeter. A variable resistor R_2 compensates for variable battery voltage. It is adjusted so that the meter is full scale when the leads are shorted ($R_x = 0$). The scale marked on the meter face is nonlinear, a disadvantage, since the current is inversely proportional to the resistance. At the low-current end, the resistance is infinite. This causes increasing crowding and inaccuracy at the high-resistance end of the scale. The resistance range can be reduced by introducing one or more current shunting resistors at position R_3 . A multiple position switch SW_i is used for multiple ranges.

With a shunt-type ohmmeter, the unknown resistance R_x is in parallel with the voltmeter readout (Fig. 3b), but the voltage source and standard resistor ($R_s = R_1, R_1 + R_2, \dots$) is in series. The gain resistor is adjusted so that the meter is full scale at $R_x = \infty$. Half scale corresponds to $R_x = R_s$ and 0 V to 0 Ω . The scale is obviously also nonlinear. The amplifier can be replaced

Figure 2. Voltmeter loading effect.

by a milliammeter acting as a finite-resistance voltmeter, but the sensitivity is less.

Low-resistance measurements may be inaccurate because contact and lead resistances become a significant fraction of the measured resistance R_x . Contact resistances in the 0.01 Ω to 0.1 Ω range are common. Often they are not reproducible. To overcome this, a four-probe or Kelvin method of measurement may be used (Fig. 4). A constant current source I_0 supplies the current through the resistor under test. The current passes through the "current" probes or leads with presumably low, but otherwise unknown resistances (R_{I1}, R_{I2}). Assume that the total load on the current source ($R_x + R_{I1} + R_{I2}$) is within its linear output voltage range; the source will deliver the specified current I_0 independent of the load, even if the contact and lead resistances change. The voltage drop as measured across the resistance and also, if unloaded, at the voltage probes or leads V_x is exactly $I_0 R_x$. The differential or instrumentation

Figure 4. Example of a four-probe or Kelvin method of measurement.

amplifier, which must have a high common mode rejection and high input resistance, transfers this balanced voltage to the measurement voltmeter, which is unbalanced with respect to ground (one input grounded). Thus $R_x = V_x I_0$, independent of contact resistance. Some ohmmeters (over 20 M Ω) intended for very high resistance such as insulation resistance use a relatively high source voltage (e.g., 100 V or more). This is because insulators will absorb (soak) charge for some time after the potential is applied so that a stable reading in a reasonable time is not obtained unless higher voltages are used. Care must be taken in this case not to damage the device being tested by overvoltage.

ELECTROMETERS

An electrometer is a sensitive, high input impedance instrument used for specialized measurements of dc voltage, dc current, and resistance. An electrometer may also measure electrical charge (a coulombmeter). Superficially, an electrometer

is an elegant dc multimeter. In reality, an electrometer is a specialized voltage and current measurement device possessing exceptionally high impedance. This very high input impedance, more than any other technical criterion, is the distinguishing characteristic of instruments in the electrometer class. The similarity to a dc multimeter makes electrometer use fairly intuitive, although a thorough appreciation of performance determinants (e.g., noise and settling time) and careful control of materials, lead routing, and other fixturing details are essential to obtaining the full accuracy and resolution within the capabilities of these exceptional instruments.

Few instruments in measurement science can exceed the electrometer's dynamic range of units. A quality electrometer is capable of presenting very small [atto-amperes (aA) (10^{-18} A)] and very large [petaohms (P Ω) (10^{15} Ω)] units of measure unfamiliar even to experienced equipment users. The general reader will find the standard prefix definitions in Table 1 helpful.

The term electrometer is found in the earliest literature of the electrical sciences—it was employed in the contemporary sense by none other than James Clerk Maxwell (1). Instruments capable of measuring very small currents are sometimes called electrometers, although such usage may be a misnomer (this will be discussed below in “Applications, Current Measurements”).

Interestingly, the *IEEE Standard Dictionary of Electrical and Electronics Terms* has no definition of an electrometer, although it tells the reader an electrometer tube is “a vacuum tube having a very low control-electrode conductance to facilitate the measurement of extremely small direct current or voltage” [(2), p. 425]. Lack of specificity is not uncommon, as similar findings are evident in some standard handbooks for electrical and electronics engineers (3), physicists (4), and in textbooks (5–7). For purposes of the following discussion, an electrometer is taken to be an instrument which, as a consequence of possessing exceptionally high input impedance, may be used to make sensitive measurements of voltage, current, and charge.

However ill-defined an electrometer may be in a formal dictionary sense, an electrometer has certain characteristic features. Foremost among the electrometer's defining features

Table 1. Standard Prefix Definitions

Symbol	Prefix	Exponent
y	yocto-	10^{-24}
z	zepto-	10^{-21}
a	atto-	10^{-18}
f	femto-	10^{-15}
p	pico-	10^{-12}
n	nano-	10^{-9}
μ	micro-	10^{-6}
m	milli-	10^{-3}
—	—	—
k	kilo-	10^3
M	mega-	10^6
G	giga-	10^9
T	terra-	10^{12}

E	exa-	10^{18}
Z	zetta-	10^{21}
Y	yotta-	10^{24}

is exceptionally high input impedance. Input impedances are measured in hundreds of teraohms $[(T\Omega) (10^{12} \Omega)]$ or even in petaohms in better quality commercial equipment. The electrometer's high input impedance is responsible for many of the instrument's operating characteristics. Other significant features of an electrometer are the ability to measure small voltages, small currents, and low-level electrical charges. These features alone, however, do not necessarily place an instrument in the electrometer class, for many higher quality, general purpose instruments can measure signals in the microvolt and submicroampere range *if source impedance is low*.

Voltage or current measurement is so commonplace as to be unremarkable in routine laboratory work. This situation prevails because most sensors and virtually all amplifiers present low output impedance to the external world. Instrument makers have gone to considerable pains to make measurement equipment simple to use in very general situations. Even inexpensive instruments have input impedances in the megohm range (clearly, this discussion excludes voltage and current measurements for audio, RF, and other specific applications where impedance matching is a major consideration or where electrometer time constants are prohibitively long). Laboratory quality instruments present relatively high input impedances to the typically low impedance sources producing signals to be measured.

Some measurement applications require an instrument with exceptionally high input impedance because the source itself has unusually high output impedance. Examples of such high impedance signal sources are large-ratio voltage dividers used in high-voltage measurements, ECG scalp electrodes, pH probes, ionization chambers, large resistances, photodiodes, dielectric measurements, and certain semiconductor measurements. The electrometer's high input impedance is required to prevent or reduce circuit loading by the measuring instrument, that is, undesired voltage or current dividers established between source output impedance and measurement device input impedance.

The electrometer's high input impedance is difficult to establish and maintain, is influenced by many subtle error sources, and is also the ultimate reason why electrometers are fundamentally dc or, at best, very low frequency instruments. Shunt capacitance at the instrument input is a physical reality that cannot be entirely eliminated, and the interaction of input shunt capacitance and source resistance establishes the frequency limit of the instrument. This frequency limit is so low as to make an electrometer a dc instrument, and the associated input settling time is a consideration of considerable importance.

The significance of input impedance is easily appreciated in the context of voltage measurements (for example, as in an oscilloscope). If we wish to determine the voltage across a circuit impedance Z_c , a very high impedance measurement circuit with impedance Z_m , produces little or no circuit disturbance. An ideal measurement circuit with infinite input impedance (infinite resistance with zero capacitance) would produce no circuit disturbance at all. The circuit impedance in parallel with the ideal measurement circuit produces a net impedance that is the circuit impedance itself, that is,

$$Z_p = \frac{Z_c Z_m}{Z_c + Z_m} \quad (1)$$

and

$$\lim_{Z_m \rightarrow \infty} Z_p = Z_c \quad (2)$$

Although measurement device impedance may be very large, it is not infinite for a physically realizable instrument. Thus, as source impedance increases, the error produced by the measurement device's finite input impedance becomes an increasingly greater contribution to total measurement error. A measurement device of the electrometer class closely approximates the theoretical idealization of infinite input impedance near dc, thereby reducing circuit-loading effects and improving voltage-transfer accuracy.

Many general instrument users experience input impedance problems only at higher frequencies, when shunt capacitance of common instrument inputs can no longer be neglected. The most familiar example of this phenomenon is high-frequency signal attenuation produced by the shunt capacitance of an oscilloscope probe. The -3 dBV response frequency and net impedance of the probe's parallel RC input are well known. As operating frequency increases, probe capacitance reduces the oscilloscope's net input impedance. At sufficiently high frequency, probe capacitance begins to influence and then dominate circuit response. Said another way, as impedance decreases with frequency, the oscilloscope probe places an increasingly greater load on the circuit being measured. The same effects are observed in the interplay between generalized source and measurement impedances, making discussions of oscilloscope probe losses instructive to the general reader as analogous background information (8–10).

The need to avoid input circuit loading is a major consideration requiring the use of an electrometer (the other is noise). Consider the simple circuit of Fig. 1, which represents the low-frequency impedances of a pH electrode (R_e) and the measuring instrument (R_m). Let the voltage actually produced by the pH electrode be V_e , and the voltage actually transferred to the voltage measurement circuit be V_m . By simple voltage division, the low-frequency signal transferred to the input of the voltage measurement elements is given by

$$V_m = \left(\frac{R_m}{R_e + R_m} \right) V_e \quad (3)$$

If, for example, a pH electrode has $100 \text{ M}\Omega$ source impedance (11), a common voltage measurement instrument with $10 \text{ M}\Omega$ input impedance would introduce a grossly unacceptable

Figure 1. pH electrode source resistance and measurement circuit input resistance form voltage divider.

measurement error, even though the same 10 M Ω impedance would be thoroughly satisfactory for general laboratory work. An input impedance of 1 G Ω would be only just acceptable, forming a voltage divider transferring roughly 90% of the electrode signal voltage (at best) to the voltage-measurement elements. An input impedance of nearly 10 G Ω is required if the measuring instrument is to transfer 99% of the pH electrode voltage to the voltage-measuring circuit elements.

Establishing and maintaining input impedances in the high G Ω and T Ω ranges is no simple task. Minuscule error currents, ordinarily negligible and themselves difficult to measure directly, become serious errors. Tiny shunt capacitances in combination with such large impedances severely limit the electrometer's time-domain performance. Thermal effects, humidity, dust, circuit board contaminants, vibration, thermocouple effects, material properties, and other considerations all weigh heavily in electrometer design. The old political adage applies: the devil is in the details.

APPLICATIONS

The electrometer's superficial similarity to a dc multimeter makes fundamental instrument application simple and intuitive. Although electrometer application basics are easy to appreciate, it is not simple to obtain the greatest possible accuracy and resolution from the instrument. Error sources can be very subtle, and test fixturing is unusually important. The following material provides an introduction to the use and application of electrometers and related instruments. Little design-related information is included. Excellent introductions to design considerations are available in (17) and in the instrumentation and measurement literature.

Noise Analysis

Electrometer performance analysis is tied intimately to noise analysis. The performance of any measurement instrument is ultimately limited by noise. Noise analysis is especially important to understanding electrometer applications properly because electrometers routinely tread the edge of the theoretical noise limit. A few major results from noise analysis are given below. The more advanced reader will wish to consult other references for a detailed treatment. Noise analysis is covered in a great many texts, and only a few representative examples are cited. Communication theory is a comfortable context for many readers (12–14), more specific discussions [see (15,16)] are useful for their treatment of specific noise mechanisms.

External noise sources, including the interaction of test articles and cabling with electrical, magnetic, and propagating electromagnetic fields, can be attenuated, minimized, or eliminated by test fixture design and shielding. External noise effects are not to be trivialized and are discussed later, but there is often some redress for external noise effects. Internal noise sources, such as thermal noise (Johnson noise) of resistors, shot noise from movement of charge carriers in amplifier input bias currents, and low-frequency ($1/f$) noise, are major noise sources within the electrometer itself. These internal noise sources exist in any physical device and ultimately establish the noise floor (hence, the ultimate sensitivity limit) of the electrometer, even if all external noise sources were reduced to zero.

These same noise mechanisms also exist in source impedances. Proper appreciation of the best theoretically possible noise limit is essential if the user is to obtain reliable measurements from any instrument.

Thermal noise and shot noise are the most common noise mechanisms governing the performance limits of measurement systems, and their significance to electrometer applications is considerable. Root mean square (rms) thermal noise current is given by

$$i_{T,rms} = \sqrt{\frac{4kT}{R}}(NBW) \quad (4)$$

where k is Boltzmann's constant (1.38×10^{-23} J/K), T is temperature in kelvins, R is resistance in Ω , and NBW is noise bandwidth in hertz. Root mean square shot noise is given by

$$i_{s,rms} = \sqrt{2qI_B}(NBW) \quad (5)$$

where q is electron charge (1.60×10^{-19} C), I_B is bias current in amperes, and NBW is noise bandwidth in hertz. These noise currents may be converted to equivalent noise voltages using knowledge of circuit impedances.

Consider the electrometer input stage. Thermal noise is an explicit function of absolute temperature. Because semiconductor device bias currents vary (ordinarily, they increase) with temperature, shot noise is also a function of absolute temperature and noise bandwidth. Noise signals produced by various mechanisms are often treated as random white Gaussian signals, allowing individual noise components to be combined as a quadrature sum. Although $1/f$ noise is not Gaussian because of its frequency dependence, $1/f$ noise is often included in an overall noise envelope, a piecewise linear fit including the effects of major noise sources. In the near-dc regime of the electrometer, $1/f$ noise is incorporated in the lumped specified noise performance (regardless of origin) of the instrument.

Although noise considerations are sometimes ignored in routine work, noise relationships are important determinants of electrometer performance and must be understood. The instrument designer understands that noise bandwidth and input bias currents must be minimized and that temperature should be maintained at a reasonable level. The instrument user must recognize that certain physical realities (e.g., noise) impose limits on instrument performance and that both system design and instrument specifications must conform to these realities. For example, a specification requiring or implying 1 nV resolution from a 1 MHz bandwidth source should be recognized for what it is: a practical impossibility. Although an electrometer generates measurements with apparent precision, the user can avoid embarrassment by interpreting instrument measurements in the light of the theoretical noise limits of the problem.

Time Constant

Electrometers are distinguished from other test instruments by their uncommonly high input impedance. As Fig. 2 demonstrates, the electrometer input circuit may be represented by a resistance R_m and a capacitance C_m . In a voltage measurement configuration, the signal source impedance R_s and the electrometer input impedance form a voltage divider connection.

Figure 2. Equivalent circuit of source resistance and electrometer input impedance.

In this case, the voltage transfer function in the Laplace transform domain is obtained as

$$\frac{V_{out}(s)}{V_{in}(s)} = \frac{R_m}{R_s + R_m} \left[\frac{1}{1 + sC_m R_p} \right] \quad (6)$$

where

$$R_p = \frac{R_s R_m}{R_s + R_m} \quad (7)$$

The equivalent time-domain step response is the familiar first-order step response given by

$$V_0(t) = (1 - e^{-t/\tau})u(t) \quad (8)$$

where $u(t)$ is the unit step function and $\tau = C_m R_p$ is the time constant.

Although realizable electrometers do not actually possess infinite real input impedance, it is very frequently true that $R_m \gg R_s$. If R_m is sufficiently large with respect to R_s , as it often will be, then the result given in Eq. (6) simplifies to

$$\frac{V_{out}(s)}{V_{in}(s)} = \frac{1}{1 + sC_m R_s}$$

and the result given in Eq. (7) simplifies to $R_p \cong R_s$. The time constant, τ , is determined by the source resistance and electrometer input capacitance according to $\tau = C_m R_s$ when this approximation for R_p is used.

Previous discussion related the dc divider ratio to the overall signal measurement or voltage transfer accuracy. However, there is an associated time-domain response as given previously which introduces significant error if signal sampling is done incorrectly. This time-domain consideration is often described as the settling time, that is, the amount of time required for an input step change to settle to within some arbitrary accuracy of the total step. Settling time is most often expressed in terms of the time constant τ . For example, if only a single time constant elapses between application of a step change and a measurement, evaluation of Eq. (8) reveals that only 63% of the step amplitude will be measured. Table 2 indicates the relationship between elapsed time constants and relative measurement accuracy. At least five time constants (5τ) must be allowed for settling if the step change is to be represented with 99% fidelity. In highly precise applications, those in which accuracies are measured in parts per million (ppm), settling times may be much longer. For example, fourteen time constants (14τ) are required for a settling error less than 1 ppm.

Table 2. Relationship Between Elapsed Time Constants and Relative Measurement Accuracy

Time Constants Elapsed ($\tau = RC$)	Fraction of Step Attained	Error (ppm)
τ	0.632121	367,879
2τ	0.864665	135,335
3τ	0.950213	49,787
4τ	0.981684	18,316
5τ	0.993262	6,738
6τ	0.997521	2,479
7τ	0.999088	912
8τ	0.999665	335
9τ	0.999878	122
10τ	0.999955	45
11τ	0.999983	17
12τ	0.999994	6
13τ	0.999998	2
14τ	>0.999999	<1

Thus, accuracy considerations require the passage of not one but many time constants before the instrument input settles. As shown in Table 2, a settling time of 4τ to 5τ , longer if possible, should be allowed to benefit from a good electrometer's basic accuracy. Settling time is a significant system constraint and is one of the reasons why an electrometer is a dc instrument.

Because an electrometer has very high input impedance, source resistance and input capacitance usually determine the input time constant. Response time is reduced only by reducing electrometer input capacitance or by reducing source resistance (which often is not possible). Various design and construction alternatives, such as driven guard cables, circuit board guard rings, and special mechanical structures are used to reduce input capacitance, thereby improving settling time (17). These techniques may increase net capacitance to ground.

Leakage Current

In the context of an electrometer, leakage current refers to tiny currents present in the instrument input leads. In an ideal instrument, leakage currents are identically zero. Readers familiar with operational amplifier design understand that similar leakage currents interact with circuit impedances to produce various categories of offset errors and other effects. This general problem is especially troublesome in electrometer design for at least two reasons.

First, electrometers are employed with signal sources having very large source impedance and, as noted already, the electrometer itself presents exceptionally high input impedance. Thus, instrument leakage current preferentially finds a path to signal common through the signal source impedance. In the voltage measurement mode, very small electrometer leakage currents through the relatively large signal source impedance can produce highly undesirable voltage offset components at the electrometer input. This is the familiar problem of input offset voltage production in operational amplifier design. In current and charge measurement modes, instrument leakage currents directly interfere with the current being measured.

Second, although the complication is less obvious, recall that shot noise is proportional to the square root of current. Thus, as leakage current increases, shot noise increases. Therefore, input leakage current produces two highly undesirable effects. It directly obscures or interferes with the parameter (voltage,

current, or charge) being measured, and it contributes additional noise (uncertainty) to the measurement.

Careful attention to device selection, component matching, thermal environment, and details of assembly and fabrication minimize instrument leakage current. Special signal processing techniques may be used to reduce the apparent effects of signal leakage current, although primary emphasis should be on error prevention rather than error compensation.

Ammeter

Electrometers are dc instruments optimized for sensitivity and accuracy at low (usually microampere and lower) current levels. Many contemporary commercial instruments have maximum input currents of 20 mA, making them of limited utility as general-purpose ammeters. Older instrument designs still in production have higher maximum input current ratings, although full-scale input current is still usually less than 1 A. An electrometer may be used to measure the voltage developed across an external current shunt with great accuracy. Although this approach extends the useful full-scale current range of the composite measurement system, long settling time, limited maximum input current, and cost usually contraindicate using an electrometer as a general-purpose ammeter.

Current Measurement. Current measurement applications include tasks, such as photodiode responses, photodiode dark current variations with temperature, semiconductor current measurements, and other measurement problems characterized by the need to measure small currents and also by the need to handle a wide dynamic range of signal currents. Commercial instruments in computer-controlled test sets accommodate the dynamic range problem by CPU-generated instrument range changes or by the use of logarithmic outputs. The literature contains descriptions of application-specific current measurement devices which approach the dynamic range problem in other ways.

Electrometers are widely employed for low-level current measurement. A device known as a *shunt picoammeter* is an electrometer variant with an input current shunt optimized specifically for low-level current measurements. The differences between an electrometer-based shunt picoammeter and an electrometer are not necessarily substantial, as the two instruments are fundamentally the same in most respects. Identifiable differences between an electrometer and a shunt picoammeter are associated with the shunt resistor and other optimizations for current measurement. The shunt picoammeter has a somewhat lower voltage burden, somewhat faster response time, somewhat reduced sensitivity, and lower cost (17) than an electrometer. This optimization is obtained at the expense of overall versatility.

One especially common and useful application circuit deserves special consideration in this discussion. This circuit, usually called a *transimpedance amplifier* or *feedback picoammeter* (also a current-to-voltage converter) is widely used to measure small currents in a multitude of applications, for example, in conjunction with photodiode detectors in computed tomography (CT) detectors and similar low-signal tasks. Because transimpedance amplifiers are used to measure very small currents, they and apparatus using them are sometimes erroneously described as electrometers, a practice difficult to discourage in the absence of a formal definition of an

Figure 3. Transimpedance amplifier used as picoammeter.

electrometer. Not all authorities agree that the transimpedance amplifier configuration constitutes an electrometer. One school of thought maintains that the transimpedance amplifier is a picoammeter but *not* an electrometer, although papers can be found in the engineering literature which make the equivalence. Nevertheless, the transimpedance amplifier configuration clearly provides useful analog signal processing of very small currents.

The transimpedance amplifier uses an inverting amplifier connection, as shown in Fig. 3. Assuming an ideal operational amplifier having zero input current, the amplifier's output produces an output current equal exactly to the input current I_i appearing on the inverting input, thereby satisfying Kirchhoff's current law. To do so, the amplifier output voltage V_o , must satisfy the relationship

$$V_o = -R_f I_i$$

The feedback resistance R_f , is often nothing more than a single resistance. In many cases, a plurality of feedback resistances are switch selectable. The choice of multiple feedback resistances is advantageous when a wide dynamic range is anticipated.

Several features should be apparent. The input of the amplifier is a virtual ground, making the input impedance of the device a great deal less than what would normally be considered useful for electrometer applications. It also requires that the signal source behave like an ideal current source. Current errors are dominated by the input bias current of the amplifier, although these errors are relatively low with contemporary FET-input devices. The transimpedance configuration is highly desirable when something other than near-dc operation is required. The -3 dBV frequency is established primarily by the feedback resistor R_f and capacitance associated with the feedback resistor.

Charge Measurement

Electrometers measure charge in at least two ways. Charge may be determined by current integration using a feedback picoammeter with a standard capacitor rather than a resistor in the feedback loop, or charge may be determined by accurately measuring the voltage produced when the charge is transferred into a known (standard) capacitor. In both types of measurement, charge measurement is made possible by the electrometer's exceptionally low input bias currents. The virtual absence of instrument bias current introduces little error into the integration of an external current. In the case of stored charge measurement, the near-zero instrument input bias current removes or deposits almost no charge from or into a known external capacitance, allowing charge to be determined directly from the relationship $Q = CV$.

Table 3. Instrument Minimum Resolvable Inputs and Maximum Full-Scale Inputs

Digits	Model	Volts	Amps	Coulombs	Ohms	R_{in} (max)
<i>Electrometer^a—Minimum Resolvable Input / Maximum Input</i>

^a Model numbers given are manufactured by Keithley Instruments, Cleveland, OH, unless otherwise specified.

In a closely related application, electrometer measurements can be used for experimentally estimating small unknown capacitances by determining the charge transferred from a standard capacitor to an unknown capacitor under conditions in which charge must be conserved.

Voltmeter

Voltage measurement is among the most common applications for electrometers. Just as manufacturers produce an electrometer variant for optimized low-level current measurement (the picoammeter), manufacturers also produce an electrometer variant optimized for low-level voltage measurement, commonly called a *nanovoltmeter*. Although optimized for small voltage measurements, nanovoltmeters ordinarily do not possess the exceptionally high input impedance associated with true electrometers because measuring exceptionally small voltages assumes lower source impedances. If this were not the case, source thermal noise would easily obscure the measurement. Nanovoltmeter optimization sacrifices the ability to work with the highest possible source impedances. It is usually not cost-effective to use an electrometer or nanovoltmeter as a general-purpose voltmeter.

Resistance Measurement

Electrometers are especially useful for measuring very high resistances or resistivities. This ability usually requires a current source in the electrometer, a configuration sometimes called a “source-measurement” combination. The electrometer measures current driven through the unknown resistance and also measures the resulting voltage developed across the unknown.

Sensitivity and Resolution

The sensitivity of an instrument is the smallest quantity that can be measured. Resolution, a closely related concept, is the smallest quantity that can be displayed. The resolution of an electrometer, as that of any other instrument, depends on full-scale amplitude and quantization accuracy (a digital display is assumed). At this time, most commercial instruments have

4 $\frac{1}{2}$ digit displays and a 20,000:1 ratio between full-scale signal and the minimum resolvable quantity corresponding to that full-scale signal. On the instrument’s most sensitive scale, sensitivity and resolution become essentially the same thing. In the discussion which follows, sensitivity is used in the sense of the smallest measurable quantity capable of display on the most sensitive scale.

The state of the art progresses rapidly. The minimum resolvable inputs (best resolutions) and maximum full-scale inputs shown in Table 3 are typical now of contemporary commercial instruments.

It is worth remembering that the quantity of charge associated with a single electron is roughly 0.160 aC, thus, a sensitivity of 100 aA corresponds to a current of roughly 629 electrons per second. The notion of electrical current is a macroscopic concept in which large numbers of charged particles (electrons) are in motion per unit time. At current levels measured in hundreds of attoamperes, measurement specialists often begin to speak of “electron counting,” for the notion of electrical current as a macroscopic behavioral average begins to break down. Current fluctuations become more pronounced. At the most fundamental level, each electron carries a 0.160 aC packet of electrical charge. When only relatively few electrons are in motion, the concept of electrical current increasingly becomes a statistic of average rates of arrival. Similarly, the ability to resolve electrical charge in steps of 10 fC corresponds to charge quantization in steps of slightly less than 63,000 electrons.

Commercial electrometers usually have voltage sensitivities of 10 μ V out of 200 mV full scale. On resistance measurements, resolutions usually range from 100 m Ω (out of a 2 k Ω full scale) to 1 G Ω (out of 200 T Ω full scale). Resistance measurements are most often implemented using a constant current source to drive the device under test with Kelvin connections to the voltmeter section. Resistance is a calculated value that takes advantage of the electrometer’s ability to make high-resolution voltage and current measurements.

Nanovoltmeters are electrometer-like instruments optimized for measuring small voltages. Nanovoltmeters do not possess the exceptionally high input impedance of a true electrometer, although they can hardly be regarded as low input impedance devices. At the present time, a high-quality

standard commercial instrument is sensitive to 1 nV out of a full-scale signal of 3 mV.

Because a great many small-current applications do not require the expense, versatility, and exceptional sensitivity of a full-blown electrometer, some instruments are optimized for small current measurements and reduced cost. These instruments are called picoammeters. As their name suggests, the available sensitivity is usually 1 pA, although at least one commercial picoammeter instrument has an advertised sensitivity of 1 fA. Picoammeters are exceptionally useful for laboratory work, as they accommodate the current measurement requirements of a large percentage of precision applications.

Nullmeter

One common early use of electrometers was to indicate null, or zero voltage, in precision bridges. This application is still important, and variations of the concept are found in servo loops and certain other automatic control applications where it is desirable to drive a loop to a null condition.

Oddly enough, nulling applications are somewhat vulnerable to an infrequently considered, yet surprisingly difficult, type of error, namely, the difficulty in determining exactly what is zero volts. A small piece of copper wire (a shorting bar) across the input terminals does not provide a completely satisfactory answer to this seemingly simple question, because such a simple approach is vulnerable to subtle thermocouple and low-level motion effects.

In response to this need and for calibration checks, instrument manufacturers have special electrometer accessories known as *low thermal shorting plugs*. These assemblies are indeed little more than sophisticated shorting bars, but they are important because they allow the user to verify that an indicated zero volt reading or null actually represents a zero volt differential when thermal and mechanical effects are controlled. The material of all connecting wires needs to be known.

Circuit of Electrometers

Complex networks of more than one electrometer require good measurement practices. The particular sensitivity of electrometer-class instruments demands careful consideration of the physical locations and connections of apparatus. Unanticipated input capacitance increases, low-level ground loops, thermal gradients, poor isolation practices, and lack of good shielding from stray fields are all common problems in low-level test applications. An electrometer in the test environment does not, by itself, make such problems more acute, but the consequences of poor test practices may be more severe because of the high impedance of the signal source (the fact that an electrometer is employed suggests that the signal source is a high-impedance source as well).

Many general instrument users are aware that thermocouple effects perturb delicate dc measurements. Most general users are surprised to learn that simple movement and vibration of the wire interconnecting test articles and test apparatus are a significant problem due to the triboelectric effect, the generation of small voltages as a conductor moves within an insulator. Likewise, a wire moving or swinging in a magnetic field gives rise to undesired signals by electromagnetic induction, just as in an electric generator. Insulator deformation can result in piezoelectric behavior which generates error signals. Such considerations as relative humidity, dust, and cleanliness

of the apparatus often have major impact when the investigator wishes to partition signal currents into current bins smaller than one fA. Dust adhering to a fingerprint across two circuit traces represents a surprisingly low impedance (relative to impedances of several hundred T Ω or higher), especially on a humid day. For these reasons, some commercial instruments have ancillary displays of temperature and relative humidity on the electrometer face.

Measurement Standards

The ability to measure fundamental electrical quantities, namely, voltage, current, and charge, with such sensitivities is quite remarkable. Various circuit elements, such as voltage references, digitizers (A/D converters), amplifiers, and related functional devices, can be isolated and refined during the normal course of engineering development. The process of insuring that measurements made worldwide respond uniformly to the same potential differences is one aspect of the problem of measurement standards. The actual primary standards themselves, for example, the standard volt, are the province of various national laboratories and international standard-setting bodies [in the United States, the National Institute of Science and Technology (NIST)].

Development and maintenance of standard units is a fascinating study in its own right but is outside the scope of this article. The instrument user is normally unconcerned with measurement standards other than to ensure that the instrument is properly calibrated periodically. Measurement standards involve a multitiered system of primary standards (at the national and international level), secondary standards (calibrated to the primary standard), and working standards calibrated to secondary standards. For example, various national and international bodies determine what absolute potential difference constitutes the standard volt and maintain the physical artifacts producing the standard volt. The instrument manufacturer maintains standards traceable to the primary physical standard and makes sure that all subsequent operations (quantizations or otherwise) ultimately agree with the physical standards.

ADVANCED TOPICS

The manufacturer specifies performance of an electrometer instrument which may be considered to begin at the input connector. Mechanical and electrical details inside the instrument are carefully designed to maintain high input impedance and to reduce error contributions from a great many sources. Conceptually, the electrometer is a highly sophisticated dc multimeter, and the operating concepts are intuitive. The electrometer is an instrument capable of operating at the theoretical limit of source thermal noise, and there is little the user can do to improve on the instrument's performance. There is, however, much the user can do to degrade the instrument's performance if the external test apparatus is carelessly made. The advanced user ordinarily does not struggle with circuit details on the electrometer side of the input connector. The instrument manufacturer does that, but the advanced user expends effort to connect the test article to the instrument while minimizing stray leakage paths, electrostatic effects, piezoelectric effects, triboelectric effects, inductive coupling, thermocouple effects, and a great many other low-level problems.

It is not possible to anticipate all problems that arise. Each application is different in its details, which is where the problems hide. Major considerations are introduced only briefly here. An excellent and detailed practical discussion is found in (17).

Input Guarding

Input guarding is the use of a driven guard structure around the input signal lines. This may be a guard conductor in a cable or guard ring traces on a circuit board. The practice is common in electrometer applications, and a guard connector is ordinarily available at the instrument input. The principle is to control guard ring potential so as to minimize potential difference between the input signal lines and surrounding structures, thereby nulling leakage current, although capacitance to ground increases. This is an important consideration, because instrument response time (settling time) is directly affected by input capacitance. Uncontrolled input capacitance introduces measurement error by allowing insufficient settling time for the measurement cycle.

Cable Selection and Preparation

In general, it is probably best to mount test cables rigidly so that capacitance and leakage are constant and controlled. This is not always possible. Specialty cables are available which provide shielding in the usual sense and also minimize triboelectric and other motion-related noise. Cable preparation is extremely important if the full benefits of specialty cables and connectors are to be realized.

Materials Selection

Materials employed as substrates, insulators, and stand-offs in the test apparatus substantially affect measurement quality. In large part, this dependence on materials is more pronounced in electrometer applications because source and instrument impedances are very high. Materials must be selected with the utmost care, and this often involves compromises between material properties, machining qualities, cost, and other factors.

Cleanliness

Thoroughly appropriate material selection can be defeated by lack of cleanliness. Surface contamination from skin oils, soldering residues, dust, and similar sources produces stray leakage paths which interfere with the intended signal path. This is especially true in relatively high humidity, and the combined effect of variable or elevated humidity and a contaminated surface can be very, very serious. Wear clean, lint-free gloves when you work on the apparatus or be prepared to clean it thoroughly after the work is complete.

Mechanical Rigidity

Mechanical rigidity of the test apparatus is important for several reasons. Triboelectric effects arise from the relative motions of a conductor and associated insulator. If there is no relative motion, there is no triboelectric effect. Additionally, some materials are more piezoelectric than others, and eliminating motion eliminates the opportunity for piezoelectric signal generation.

Electromagnetic Shielding

Electromagnetic shielding is employed to eliminate or minimize the effects of external (relative to the test article) electromagnetic fields. This topic is covered in great details in many sources (16). Low-frequency magnetic shielding is difficult to implement, but a reasonable number of options are available if the test cell volume is relatively small. Test leads and the test article together constitute an inductive loop. The effects of inductive signal pickup can be minimized by reducing loop area and by reorienting the loop geometry of the test apparatus relative to the interfering field source. Electrostatic shielding is ordinarily much simpler to implement.

Temperature Control

Temperature control is important because temperature is a consideration in thermal noise, semiconductor leakage current, thermocouple effects, and other similar phenomena. Semiconductor leakage currents, in particular, are strong functions of temperature. Measuring an offset voltage for later subtraction from a reading includes the tacit assumption that temperature (hence, offset) remains constant over the measurement interval. Thermal gradients across semiconductor devices can introduce unpredictable offset behavior, and for this reason most instruments have a specified warm-up period to guarantee full accuracy. Thermal gradients also arise from air flow around the test apparatus, and thus air flow should be controlled. Every connection in the test apparatus is a thermocouple junction, and temperature affects each of them.

Humidity Control

Humidity is a problem less obvious than temperature, but it also must be controlled. Humidity changes are especially troublesome because the insulating properties of dielectrics often depend on humidity. If someone handles a circuit board with bare hands and leaves a fingerprint across the measurement terminals, the resulting high (but finite) impedance leakage path strongly depends on relative humidity. Electrometers may have input impedances of 100 T Ω or more, the signal source being measured may have a source impedance measured in many G Ω . A leakage path, even one measured in hundreds of M Ω , can have a very detrimental impact on measurements. If a leakage path is a strong and highly variable function of relative humidity, as is true of many contamination paths, the effect can be very serious yet erratic.

Some upper end electrometers have built-in humidity indicators. This gives the operator an indication of the humidity inside the instrument, a consideration useful in obtaining the highest possible instrument accuracy, but humidity may very well exert a more serious influence on the test apparatus.

Light

The photoelectric effect was discovered early in the history of semiconductors. The photoelectric effect can be a problem during semiconductor measurements, especially measurements made at the die level. Diodes are especially light-sensitive, but care is warranted in all cases. If there is any question about the light-tightness of a device package, be aware that ambient light falling on the wrong junction can be a problem.

BALANCES

Balances are usually considered devices that weigh. Here, we will take a more general approach because even the ordinary beam balance in school laboratories uses one force balanced against another, so that static equilibrium of the device is maintained. More generally, then, a balance is a device that determines an unknown force by balancing a known or calibrated force. For example, lever-arm balances use a known mass at a known position to measure an unknown mass at a known location. Spring balances use the displacement of a spring with known elastic properties to measure unknown forces. A modified version of a spring balance is the cantilever-type, where an elastic arm supported at one end bends under load. Another related class of balances is the torsion balance, in which a thin torsion fiber suspends a beam that twists because of forces solely in a horizontal plane. The amount of twist per unit torque is determined by the elastic properties of the fiber. The principles governing the various balance types are discussed more thoroughly in the following subsections.

Many commercial balances available today have automated recording systems, so that force signals are converted either to electrical voltage or current. Specialized precision balances for measuring masses of minute quantities, investigating chemical reactions, or studying gaseous-phase processes have also benefited from automation. Automation allows continuous monitoring of experimental variables as well as measuring in environments such as vacuums. Instrumentation typical of automated balances is discussed in the next section.

The last section describes recent designs for microbalances and vacuum microbalances. Before the 1960s, a vacuum microbalance typically consisted of a lightweight beam, counterbalanced by an electromagnetic force. As mass is added to one end of the beam, feedback on the beam deflection maintains equilibrium, usually electromagnetically. This feedback signal, proportional to the mass increment, is read as the mass measurement. Although similar microbalances are still in use, microbalances based on quartz-crystal oscillators are more common today, where mass increments translate into resonance frequency shifts. Recent designs of microbalances are described later.

Lever-Arm, or Beam Balances

By far, these are the most common balances in academic laboratories. Beam balance weigh an unknown mass through cancellation of the gravitational torque caused by placing the mass a known distance from the fulcrum of an extended beam. Figure 1 depicts such a balance, in which the canceling torque is provided by a known mass placed a known distance away from the fulcrum.

Because this balance has components found even in more modern automatic beam balances, its operation is discussed further here. The unknown mass is to be placed in pan P_1 , and the balance weights, or standards, are then loaded into pan P_2 until the needle indicator I swings equally about the center of scale S . The center of gravity of the system falls above knife-edge K_2 in equilibrium. Knife-edges are used to lower friction that may cause the swinging motion to stick in a position other than true equilibrium.

Because masses less than 10 g are difficult to handle (and it is undesirable to handle them because any small deposits change the mass), small weights are usually incorporated in a rider system, denoted in Fig. 1 by R . A small mass of 10 g is loaded by the rider onto beam B_2 at any position closer to the fulcrum than the pan. In the balance shown, beams B_1 and B_2 are equal length, so that loading a 10 g mass at the end of B_2 gives a reading of 10 g. Thus, loading the 10 g mass at a position 0.1 of the distance out from knife-edge K_2 gives a reading of 1 g. Multiple-beam analytic balances use multiple rider systems, so that the standard weights are never handled physically.

Beam balances also use an arrestment device, labeled A in Fig. 1. This device allows attaching the weighing pans rigidly to the supporting structure, so that the pans are released slowly near equilibrium, after loading is accomplished. Releasing A sets the balance into swinging motion, so that the position of the indicator may be monitored.

Two other common features are not shown explicitly in this figure: taring and damping. Taring is necessary because inevitable differences in the masses of pans P_1 and P_2 would cause a nonzero reading even with the balance unloaded.

Figure 1. The beam balance. The unknown sample is placed in pan P_1 . Standard weights are added to pan P_2 to return the beam to the null position read from scale S . Masses smaller than 10 g are effectively added to beam B_2 through the rider R .

Taring is often accomplished with a counterweight mounted on one of the beams by an adjustable screw, so that the taring torque can be adjusted. Although a large amount of friction is undesirable in the knife-edge itself, damping the swinging motion of the scale indicator is desirable to reduce the time needed for a reliable measurement. Damping is often incorporated by placing small magnets near the end of one beam and using the eddy-current brake effect to damp the motion.

The sensitivity of the balance is fixed by the length of the indicator needle I , the unit measurement on the scale S , the size of the smallest mass placed in the rider system, and the increments on the rider scale. The balance is also more sensitive if the two beam arms are longer, but this increases the period of swinging caused by an increase in the moment of inertia of the balance. Practical beam balances, such as those manufactured by Mettler, measure from hundreds of grams to less than 0.0001 g.

Cantilever and Spring Balances

Both cantilever and spring balances use the elastic forces produced by a known material to balance an unknown weight. In a spring scale [Fig. 2(a)], loading an unknown mass stretches the spring beyond its unstretched length a distance Δx . The weight of the mass is related linearly to this displacement by Hooke's law:

$$F = k\Delta x$$

where k is the elastic spring constant. This relationship arises from the strain on the spring material, which is [Fig. 3(a)] related to a compressive or stretching force F applied perpendicularly to one end of a wire of cross-sectional area A via

$$\frac{F}{A} = Y \frac{\Delta x}{L}$$

where L is the length of the wire and Y is Young's modulus for the wire material. Spring balances are made of very stiff materials, such as steel, tungsten, or quartz, with elastic

Figure 2. Spring (a) and cantilever (b) balances counter the weight with internal restoring forces. The displacement of the balance is proportional to the load over a wide range, where the constant of proportionality is called the effective spring constant k .

moduli close to 10^{11} N/m². The previous strain relationship indicates that one can make a more sensitive spring balance by increasing the length L of the spring; and by reducing the cross-sectional area A , one can make the deflection of the balance larger for a given applied force.

Figure 3. Two linear material deformations that may be exploited in balances. (a) Strain corresponds to an elongation in a fiber caused by a force applied perpendicularly to a cross section. (b) Stress corresponds to a sideways displacement of the fiber caused by a force applied parallel to a cross section.

In a cantilever balance, mass is loaded onto the end of a flexible rod or bar, mounted horizontally [Fig. 2(b)]. As in a spring scale, the deflection of the end of the rod is proportional to the weight added. This can be deduced by considering the shear force F acting on the fiber end [Fig. 3(b)] in the plane of the rod's cross-sectional area A :

$$\frac{F}{A} = G \frac{\Delta y}{L}$$

where Δy is the vertical deflection of the rod and G is the shear modulus of the material (typically the same order of magnitude as Y). As in spring balances, cantilever balances are made more sensitive by increasing the length of the rod and reducing the cross-sectional area.

Spring and cantilever balances are calibrated by loading standard masses onto the balance, while measuring the corresponding set of displacements. The data set allows determining k , the effective elastic constant of proportionality. When unknown masses are to be determined, they must be within the range of masses used for calibration, because both springs and cantilever beams are linear over only a limited range of loads.

Another method for calibrating spring and cantilever balances requires that they serve as high- Q (i.e., low-friction) mechanical oscillators. For a highly underdamped spring system, the resonant frequency of oscillation is given in Hertz by

$$f = \frac{1}{2\pi} \sqrt{\frac{k}{m}}$$

If frequency difference measurements of 1 ppm are reliably and repeatedly made on an oscillating mass, a mass change of 2 ppm can be detected.

Torsion Balances

Two types of balance are denoted by this title. In one type, similar to a beam balance, a taut wire is used as a fulcrum in place of a knife-edge [Fig. 4(a)]. Like other analytical balances, this balance measures a gravitational torque by a downward angular deflection $\Delta\theta$ of the beam.

A more commonly used torsion balance relies on the elastic properties of a fiber to determine small forces acting to rotate a beam. A beam of arm R is supported from its center of gravity by a wire or fiber w [Fig. 4(b)]. Forces apply a couple simultaneously to both ends of the beam, which rotates through an angle $\Delta\psi$. The total torque Γ and $\Delta\psi$ are related through $\Gamma = \kappa \Delta\psi$, where κ is an elastic constant determined by the shear modulus of the fiber G , the length of the fiber l , and the fiber radius r :

$$\kappa = \frac{r^4}{l} G$$

Thus, one can see that this form of torsion balance is most similar to spring and cantilever systems, in that known material properties of the fiber produce the balancing forces. Also, like these other balances, a torsion balance can be made more sensitive by increasing the fiber length and reducing the wire radius.

Torsion balances are unique in that they are designed to measure forces occurring in a horizontal plane. They are

Figure 4. Two types of balances called torsion balances. (a) This is most similar to a beam balance because a weight added to one end creates a downward deflection of a beam. The torsion wire takes the place of a knife-edge. (b) This torsion balance is most similar to spring and cantilever balances. Material properties of the wire w balance the torque tending to twist the beam in a horizontal plane.

calibrated by using the frequency of oscillation of the beam about its unperturbed equilibrium position. (Practical torsion balances have periods that are several seconds to several minutes long.) The natural torsion frequency is given by

$$f = \frac{1}{2\pi} \sqrt{\frac{\kappa}{I}}$$

where I is the moment of inertia for the beam twisting in a horizontal plane about the fiber point of suspension. This I must be calculated or measured independently to determine κ .

Applications of the torsion balance have been numerous and include determining the Newtonian gravitation of constant G and the magnetic properties of superconductors. Such applications require sensitivities of $10^{-9} \text{ N} \cdot \text{m/rad}$, which are readily achieved in many laboratories.

INSTRUMENTATION

There are two main types of balance in terms of how measurements are acquired: null-detection and deflection type. In deflection-type balances, force or mass measurements are related to how far the balance moves from an equilibrium position. Cantilever and spring balances fall in this category. If such balances are to be automated, a position transducer is needed to convert a deflection into an electrical signal. In null-detection balances, the balance is to be maintained in equilibrium, and the force needed to restore the balance is read as the measurement. Beam balances are of this variety. Automated null-detection balances require a negative feedback loop.

Figure 5. A null-detection microbalance. Position sensing is accomplished optically, and feedback is provided through the energized coil on the beam that attempts to align with the field created by the stationary magnets. Such balances are capable of detecting mass increments as small as 10^{-7} g.

A position transducer converts a displacement into an electrical signal, which is fed back to a force-producing mechanism that restores equilibrium. Figure 5 shows a Cahn beam microbalance, in which an electromagnetic coil energized by an optical position sensor tries to maintain alignment with the field created by static magnets. Because position sensing is central to both deflection and null-detection balances, various transducers are described below.

Optical Detection

One common method for sensing the position of a beam balance uses a light source and split photodiode arrangement [Fig. 6(a)]. The photodiode outputs a voltage signal proportional to the difference in source light intensity S reaching its two separate halves. The beam balance is set so that, at equilibrium, it covers both halves of the split photodiode symmetrically. As the beam moves upward, the lower half of the detector is more illuminated than the upper half, and the photodiode output changes accordingly. Many balance position-detecting systems use a similar split-transducer arrangement. Relatively simple, inexpensive circuits can be developed, such as the one shown, that output a voltage proportional to the difference between the two detector halves. Hence, the transducer output is null at equilibrium and produces a bipolar signal dependent on the direction of displacement.

Reflection is often used with balances that create angular deflections, such as cantilevers, beam balances, and torsion balances. In such systems, a well-collimated intense light source, such as a laser, is reflected from a mirror attached to the pivoting body or movement arm [Fig. 6(b)]. As the balance arm moves through an angle θ , the beam is deflected through 2θ . As the balance pivots, the light beam traverses an arc, the length of which is determined by how far the detector is placed from the balance. The length of this optical lever arm determines the sensitivity of the position transducer.

Two types of sensors are available for measuring the deflected light beam: linear charge-coupled device (CCD) arrays

Figure 6. Optical position sensing. (a) Split photodiode. If all resistors shown have equal value, the output of the second operational amplifier is proportional to the difference in the detector outputs. (b) Reflection, or optical lever-arm device.

and position-sensing devices (PSDs). A CCD array consists of a set of photosensitive elements, typically a few microns in size. Arrays are commercially available with thousands of so-called pixels. The device produces a digital signal that provides information about the light intensity recorded as a function of discrete position along the one-dimensional array. This method is limited in resolution by the number of photosensitive elements in the array and also requires some computer processing to determine the centroid of the laser light spot. Thus, resolution in such devices is gained at the expense of speed. The second type of detector, the PSD, consists of a single photodiode several cm in length. A resistor network built into the device behaves as a voltage divider, so that the device output is related to the position of the laser spot on the photodiode active area. Unlike the CCD array, the signal is continuous, and no centroid determination is required. However, a specialized analog circuit is required to make the voltage output proportional to the beam-spot position on the device. PSDs are available that measure $0.1 \mu\text{m}$ of linear motion.

Capacitive Sensing

Capacitors store electric charge and energy. A capacitor consists of two conductors separated by an air gap or dielectric. How much charge the two conductors store is determined by the shape and size of the conductors and by the geometry of the gap separating them. These features can be used to convert motion into an electrical signal.

The simplest configuration is the parallel-plate capacitor, the capacitance of which is determined by the area of the plates A and gap size d :

$$C = \frac{\epsilon_0 A}{d}$$

where ϵ_0 is the permittivity of free space (8.85×10^{-12} F/m). The small value of ϵ_0 means that position transducers using

Figure 7. Two types of capacitive position sensors. (a) The capacitance decreases as the separation between the two plates increases with balance motion. (b) The area of overlap between the capacitor plate on the beam and the split capacitor sensors changes as the balance rotates.

capacitors must be very sensitive to minute changes in C of the order of nanofarads or picofarads.

Two types of capacitive position sensors can be developed, depending on whether the gap changes [Fig. 7(a)] or the area of the plates changes [Fig. 7(b)] as the balance moves. [Figure 7(b)] indicates that although the movable capacitor plate is single, the stationary plate consists of a split conductor. For the same reason that split photodiodes are used in optical sensors, split capacitor plates allow determining the direction of balance movement.

One also needs a circuit designed to detect changes in C . This is often done by placing the variable position-sensing capacitor in an ac-excited bridge [Fig. 8(a)]. The potential difference between points A and B in the figure remains null, as long as the four capacitors in the bridge have equal values. As the variable C s change because of motion of the balance, the amplitude and phase of the voltage difference ($V_A - V_B$) changes correspondingly. Another common arrangement is to place the capacitive position sensor in a resonant LC circuit [Fig. 8(b)], excited by an ac source driving the circuit near the resonant frequency of the circuit, given by $1/(2\pi\sqrt{LC})$. As the capacitance changes, the amplitude and phase of the voltage drop across C also change.

Strain Gauges

Strain gauges are devices that convert physical elongation or compression into an electrical signal. They are readily incorporated into deflection-type balances, such as the spring scale and beam balance. A strain gauge consists of four metal-film

Figure 8. Two circuits used to change capacitance variations into an electrical signal. (a) Ac capacitance bridge, in which a moving capacitor plate deflects across a split capacitor plate (two variable C s). (b) Resonant LC circuit.

resistors placed in a Wheatstone bridge configuration. As the balance deflects, the resistors deform and destroy the bridge electrical balance. It is difficult to find strain gauges that measure small displacements reliably, so that these devices are more appropriately used in balances designed to measure large loads, hundreds of grams to thousands of kilograms.

Inductive Sensing

A common technique for measuring deflection in balances is a device known as a linear variable differential transformer (LVDT). As all transformers contain a pair of coils coupled with an iron core, so do LVDTs. However, the primary coil, the one to be excited directly with an ac source, is center-tapped. This allows two secondary coils to share a common ground at the center of the transducer (Fig. 9). This configuration is reminiscent of the split photodiode sensor

Figure 9. Linear variable differential transformer (LVDT), an inductive position sensor. The center-tapped primary coil P is flux-coupled to the secondary windings through an iron core C . As the beam B deflects up or down, either S_1 or S_2 becomes more strongly coupled to the primary.

described previously, so it is evident the LVDT is capable of determining the direction of balance motion. The iron core is attached to the balance beam and is centered at equilibrium. As the beam displaces upward, coil S_1 in the secondary is more strongly coupled to the primary than coil S_2 . The voltage signals from the two secondary windings are processed by an electronic circuit that produces a signal proportional to their difference.

MICROBALANCES AND VACUUM MICROBALANCES

A microbalance is a device that either determines a small mass (μg range) or force. Applications are numerous, including measurement of adsorbed chemicals on surfaces, film thicknesses in vacuum deposition systems, minute pressure changes, dehydration and hygroscopic processes, pyrolytic reactions, corrosion, etc. Measurement in vacuo is often necessary, to remove buoyancy or chemical reactions that cannot be controlled. Under these conditions the balance is termed a vacuum microbalance. The main difference between a vacuum microbalance and other such devices is that the balance parts must be capable of being heated to high temperature to circumvent outgassing and appropriate mechanisms for loading and reading must be placed within the vacuum chamber.

As was mentioned in the previous section, most microbalances before 1960 were similar in design to standard automated balances. Differences were required in the small, delicate parts, from which beams, springs, and cantilevers were machined, and the low levels of signals produced by the position transducers. In this section, relatively new forms of the microbalance are presented. Two of these, the quartz crystal microbalance (QCM, described later) and the surface acoustic wave (SAW, described later) microbalance, are based on the piezoelectric nature of quartz. When a quartz crystal is placed in a sufficiently strong electric field, it undergoes a characteristic deformation. Oscillating quartz crystals can be made sensitive to small material deposits on their surfaces.

Atomic-force microscopy is also an unfolding field, in which a miniature cantilever beam records forces on a microscopic scale. If such a device is used to create images of materials, it is a microscope. However, if such a device is used to measure forces absolutely, it is a microbalance.

Atomic Force Balances

An atomic force microscope (AFM) has at its heart a micromachined cantilever beam, which responds to microscopic forces as it is dragged over a surface or through a fluid. Although cantilever fibers and leaves have also been used to measure small forces, currently V-shaped structures of Si_3N_4 are popular because they resist lateral motion and the tendency to twist. These beams are only tens of micrometers thick and hundreds of micrometers long.

Regardless of the shape of the cantilever beam, a remaining challenge for such small devices is calibrating them to determine their effective spring constants. One technique involves calculating the k from the size of the cantilever and its bulk properties (namely, the Young's modulus of the material from which it is made). However, this calculation is unreliable because the thin films may not have the same Young's modulus as large blocks of material. Another problem concerns the fact that many cantilever beams have gold surfaces sputtered on them to make them easier to track via optical reflection. The

gold film also changes the Young's modulus in a way that is difficult to determine.

Another method of calibrating these cantilever beams involves loading the end of the beam with mass and measuring the beam displacement or the shift in the resonant frequency of the beam set into oscillation. Both methods are common to calibrating any spring-type balance. However, for atomic force balances this is a destructive method, as glue is often necessary to attach a μg mass to the beam. It has also been found that the effective spring constant measured by mass loading and frequency shifting is affected by the attachment location. New methods of calibrating these cantilevers to determine microscopic forces will continue to develop, as AFMs become more widely used for absolute force measurements.

Quartz Crystal Microbalances

Quartz crystal microbalances (QCMs) are extensively used in materials research and in chemistry laboratories. Their longest application has been for film-thickness monitoring during vacuum deposition. More recently, they have been adapted for investigating liquid solutions, in which chemical reactions at the liquid-quartz interface leave deposits only one atomic layer thick.

QCMs are an attempt to use frequency measurement as a mass indicator. A thin (several hundred micrometer) wafer is cut from a quartz crystal, and typically gold electrodes are deposited on both faces of the wafer [Fig. 10(a)]. Shear-mode oscillations are set up in the wafer when an oscillating electric field is applied to the electrodes [Fig. 10(b)]. If the thickness of the wafer is one-half the wavelength of the shear-mode fundamental, the antinodes of the oscillation occur at the faces of the wafer. In this case, very little energy loss occurs at the wafer faces, and the acoustic wave essentially becomes trapped inside the wafer. Constructed in such a way, a quartz crystal oscillator

Figure 10. Operation of the quartz crystal microbalance. (a) Quartz wafers showing electrodes. The dark gray region indicates the orientation of the electrode on the opposite side of the wafer. (b) Shear oscillation in the bulk of the quartz crystal. As long as the film deposit is thin compared with the crystal width, the shear wave is damped very little by the film.

Figure 11. Orientation of an AT-cut wafer in a quartz crystal.

can have a very high Q , and thus a narrow resonance frequency of oscillation.

When quartz wafers are prepared, care is taken to minimize the dependence of this natural frequency of oscillation on temperature. Such a dependence causes errors in thickness monitors because mass deposition is usually measured as a change in the resonant frequency. QCMs are manufactured with an AT cut, a particular crystallographic orientation known to minimize temperature dependence of the resonant frequency at room temperature (see Fig. 11).

The resonant frequency of an AT-cut quartz crystal is given as $f = A/d$, where d is the thickness of the wafer and A is a constant, 1.67 MHz-mm. The initial thickness of the wafer is cut to give f near 10 MHz. Smaller cuts produce a higher frequency but reduce both the sensitivity of the crystal and the thickness of foreign material that can be practically deposited.

Mass deposits Δm on the QCM are monitored according to the Sauerbrey relationship:

$$\Delta f = -2.3 \times 10^6 \frac{\text{cm}^2}{\text{Hz} \cdot \text{g}} f_0^2 \frac{\Delta m}{A}$$

where A is the area over which the film has been deposited, and Δf is a measured shift in the quartz oscillation frequency. This relation shows explicitly that the QCM becomes more sensitive to deposits as the natural frequency f_0 of the crystal increases.

Several well-studied problems occur in using QCMs, both in vacuum deposition systems and in electrochemical environments. One difficulty arises from the sensitivity of the QCM to varying environmental conditions other than a change in thickness, especially to temperature changes and variations in liquid viscosity and density. The main difficulty in using QCMs as film-deposition monitors in vacuum is the fact that the evaporated substance conveys thermal energy to the crystal, thereby changing its temperature. Even if it is an AT-cut crystal, the crystal has a frequency dependent to a slight degree on temperature. The way around this problem is to place a shutter close to the crystal surface, so that the film does not cover the entire crystal surface. Also, the shutter is not opened immediately, so that the crystal has time to reach thermal equilibrium before thickness is monitored.

Another well-documented problem is that the crystal's sensitivity to thickness changes is not uniform across the wafer.

The sensitivity is highest in the center and lowest on the periphery. The profile may be made more uniform by polishing the crystal so that it exhibits a convex or plano-convex shape. However, most researchers take care to confine reactions and deposits to the area of the wafer covered by the electrode.

One final challenge to using QCMs concerns the approximation that the nature of the shear wave is not affected by the film deposit but that only the speed of the wave changes. In reality, the film changes the acoustic impedance at the surface, which in turn affects energy loss of the wave.

As a foreign substance is deposited on one face of the crystal, the thickness of the wafer increases, and the resonant frequency drops. As long as the foreign film is thin compared with the wafer thickness, the elastic properties of the foreign substance do not affect the behavior of the shear wave. Thus only the areal mass density affects the frequency. This approximation has been experimentally verified, as long as the foreign film remains thinner than a few percent of the wafer thickness. It is advisable to clean the wafer after a certain amount of deposit has accumulated, although a technique called Z-match, described in the next paragraph, allows larger deposits.

A more careful one-dimensional acoustic analysis of the shear wave propagating through the crystal recognizes the impedance mismatch at the boundary between the film and the quartz. In this instance, a transcendental equation relates the frequency shift of the oscillator to the mass deposited Δm on the crystal:

$$\Delta m/m_0 = -\frac{z_f f_0}{z_Q \pi f} \arctan \left(\frac{z_Q}{z_f} \tan \frac{\pi f}{f_0} \right)$$

where z_f and z_Q represent the acoustic impedances of the film and quartz materials, respectively, and m_0 is the initial mass of the crystal. Third-generation thickness monitors use this relationship, which is valid up to loads of 70% of the quartz mass. A disadvantage to using this Z-match technique is that the ratio of the two impedances must be determined by an independent measurement and entered in the deposition-monitor memory for each type of film deposited. Because this ratio may not accurately be known, the Z-match feature provided in such monitors may not necessarily be accurate up to high loads. Monitors using the Z-match technique must also keep track of which films have been preloaded before a particular deposition and the impedance of these preloaded samples.

For QCMs submerged in liquids, it has been found that the shear wave loses energy exponentially as it enters the liquid solution. The energy loss adds a term to the Sauerbrey equation, so that frequency shifts Δf do not depend solely on the mass added:

$$\Delta f = -f_0^{3/2} \sqrt{\frac{\eta_s \rho_s}{\pi \mu_Q \rho_Q}}$$

where η_s and ρ_s are the viscosity and density of the liquid solution, respectively, μ_Q is the shear modulus of quartz (2.947×10^{11} g/cm-s²), and ρ_Q is the density of quartz (2.648 g/cm³). A second crystal in contact with the fluid may compensate for frequency shifts due to viscosity and density of the solution.

As described above, the thickness of a deposited film can be measured as a change in the resonant frequency of a quartz crystal. Figure 12 shows a block diagram of a common method to extract this frequency change. The quartz crystal forms part

Figure 12. Typical block diagram showing the configuration of a QCM in a film-deposition monitor.

of a positive feedback oscillator circuit. The output of this circuit is mixed with a reference oscillator not subjected to the film deposition and thus having a constant resonant frequency. The mixer creates a signal in the audio frequency range, which may be counted, or may be input into a frequency-to-voltage converter. The f -to- V converter has the advantage that the output signal can be directly fed into a recorder or computer. Commercial QCM systems are available for less than \$10,000. Many detect mass increments less than 1 ng.

As an alternative to placing the QCM in an oscillator circuit, the QCM may be excited with a signal generator. When the generator is shut off, the crystal exhibits a decaying oscillating behavior characteristic of a high- Q mechanical oscillator. The resonant frequency can be determined from the oscillations within the decaying envelope.

The need for measuring z -values for better Z -matching has introduced more techniques in instrumentation. One technique involves placing the quartz/film resonator to be studied in a circuit where multiple resonances of the device are measured by using a vector voltmeter. (This is a specialized instrument that measures both the amplitude and phase of an oscillating electrical signal.)

Surface Acoustic-Wave Devices

At first glance, a SAW device appears related to the QCM [Fig. 13(a)]. Electrodes are deposited on a piezoelectric quartz wafer, and the crystal is set in oscillation electrically. However, the SAW device is excited only on one surface [Fig. 13(b)], and thus the excited waves occur at the surface, unlike the shear waves propagating in the bulk of a QCM.

However, just as in a QCM, changes in frequency of oscillation occur if mass is deposited on the surface. The frequency

Figure 13. Operation of a surface acoustic wave (SAW) device. (a) Two sets of interdigital transducers are deposited on a quartz substrate. The configuration shown corresponds to an RF delay line. (b) Surface acoustic wave energized by the oscillating voltage source shown in (a).

shift created by a mass Δm deposited on a SAW crystal of area A is found from

$$\Delta f = -1.26 \times 10^6 \frac{\text{cm}^2}{\text{Hz} \cdot \text{g}} f_0^2 \frac{\Delta m}{A}$$

where f_0 is the unloaded resonant frequency. The SAW device has two advantages over the QCM. First of all, the SAW is uniformly sensitive to deposits over its entire surface. Secondly, there is no practical limit to the f_0 of the surface waves because the resonant frequency is not determined by crystal thickness. In an SAW device, f_0 is determined by the spacing in the interdigital transducer (IDT) electrodes, which must be smaller and closer together to produce a higher frequency. Thus, the SAW has greater inherent sensitivity than the QCM.

SAWs were initially constructed to serve as delay lines in radio-frequency (RF) circuits, which can be seen in the SAW configuration in [Fig. 13(a)]. One set of electrodes is excited with an RF generator, and the other set receives the signal a short time later. Because the wave speed of surface acoustic waves is far less than the speed of light waves, a short SAW device creates a lengthy delay in the RF signal without appreciable energy loss. SAW devices were soon found impractical for RF applications, however, because they are extremely sensitive to ambient conditions and hence display varying frequency.

SAW devices are incorporated into film-deposition microbalances similarly to QCMs. Typically two separate SAW devices are placed on the same quartz substrate and are excited by a matched pair of RF driver circuits. One of the SAW devices is exposed to the process under study, and the other is a reference. Both signal and reference are mixed, so that the frequency difference is measured in the kilohertz range.

BRIDGE INSTRUMENTS

Bridge instruments have a broad field of applications in metrology and industrial laboratories, not only for the comparison or the determination of electrical quantities but also for the measurement of nonelectrical quantities by electrical methods. The aim of this article is to combine the need to provide an understanding of the principles used in some modern dc and ac bridge instruments without forgetting those involved in the most classical ones. This article is divided in three parts: bridge networks, dc bridge instruments, and ac bridge instruments.

BRIDGE NETWORKS

Elementary Dipoles

Bridge networks are realized by the connection of elementary electrical elements generally fitted with two terminals and called dipoles. An electrical dipole is an electrical element which could be externally connected by means of its two terminals. The current entering by one terminal is identical to the one leaving the other. One electrical dipole can supply or transform electrical energy. Two main categories of dipoles can be distinguished:

- Active dipoles like voltage sources and current sources
- Passive dipoles like resistors, capacitors and inductors

If one dipole is linear, its behavior is governed by a mathematically well-defined linear correspondence between the applied voltage and the flowing current. Then, we can write for each dipole:

- A relationship voltage-current $v = f(i)$
- A relationship current-voltage $i = g(v)$

Sources. The sources are dipoles which are able to modify the electrical state of networks. There are two types of ideal sources: voltage sources and current sources. The ideal voltage source is a hypothetical dipole which maintains a constant voltage at its terminals, independent of the current flowing through it:

$$\frac{dv}{di} \equiv 0 \quad (1)$$

The ideal current source is a dipole for which the current is independent of the voltage at its terminals:

$$\frac{di}{dv} \equiv 0 \quad (2)$$

Figure 1. Representation of the used active dipoles: (a) dc current source. (b) dc voltage source. (c) ac generator.

The symbols used for the dc sources are those indicated in Recommendation No. 117 of the International Electrotechnical Commission (IEC) and represented in Fig. 1(a) and 1(b). To distinguish the ac sources and due to the fact that it is very common in the literature, the symbol used has been abstracted from IEEE Standard 315-1975 and is shown in Fig. 1(c).

Passive Dipoles

Resistor. A resistor of resistance R and of conductance G is a dipole which creates a voltage drop $v(t)$ at its terminals, when flown through by an instantaneous current $i(t)$:

$$v(t) = Ri(t) \quad (3)$$

The inverse relationship current-voltage is

$$i(t) = Gv(t) \quad (4)$$

Capacitor. A perfect capacitor of capacitance C is a dipole which possesses an electrical charge $q(t)$ when the instantaneous voltage at its terminals is $v(t)$:

$$q(t) = Cv(t) \quad (5)$$

The relation of current-voltage can be written

$$i(t) = \frac{dq(t)}{dt} = C \frac{dv(t)}{dt} \quad (6)$$

and the relationship of voltage-current:

$$v(t) = \frac{1}{C} \int_0^t i(t) dt + v(0) \quad (7)$$

where $v(0)$ is the value of v at $t = 0$.

Inductor. A perfect inductor of inductance L is a dipole which embraces a magnetic flux $\Phi(t)$ when flown through by an instantaneous current $i(t)$:

$$\Phi(t) = Li(t) \quad (8)$$

The instantaneous voltage at the terminals of this inductor is

$$v(t) = \frac{d\Phi(t)}{dt} = L \frac{di(t)}{dt} \quad (9)$$

The relationship of current-voltage is

$$i(t) = \frac{1}{L} \int_0^t v(t) dt + i(0) \quad (10)$$

where $i(0)$ is the value of i at $t = 0$.

Passive Dipoles in ac

If we apply an ac voltage to each of the previous passive dipoles, an ac current $i(t) = I_M \cos \omega t$ will flow through them. We will hereafter successively examine each dipole.

Resistor. The voltage difference at the terminals of the resistor is

$$v_R = RI_M \cos \omega t = V_M \cos \omega t \quad (11)$$

The impedance Z and the admittance Y are real numbers:

$$Z = R \quad \text{and} \quad Y = \frac{1}{R} \quad (12)$$

Inductor. The voltage difference at the terminals of the inductor is

$$v_L = L \frac{di}{dt} = -L\omega I_M \sin \omega t = L\omega I_M \cos \left(\omega t + \frac{\pi}{2} \right) \quad (13)$$

The impedance Z and the admittance Y are imaginary numbers:

$$Z = jL\omega \quad \text{and} \quad Y = \frac{1}{j\omega L} \quad (14)$$

Capacitor. The voltage difference at the terminals of the inductor is

$$v_C = \frac{1}{C} \int_0^t i dt + v_C(0) \quad (15)$$

if $v_C(0) = 0$ at $t = 0$
Then, we have

$$v_C = \frac{I_M}{C\omega} \sin \omega t = \frac{I_M}{C\omega} \cos \left(\omega t - \frac{\pi}{2} \right) \quad (16)$$

The impedance Z and admittance Y are also imaginary numbers:

$$Z = \frac{1}{j\omega C} \quad \text{and} \quad Y = j\omega C \quad (17)$$

Symbols. In this document, the symbols used to represent the different passive dipoles are coming from the same IEEE Standard or IEC Recommendation as already indicated previously and are shown in Fig. 2(a–e).

Lumped Networks in ac

A lumped network is realized by the connection of separate passive dipoles like a resistor, an inductor, and a capacitor. This

Figure 2. Representation of the used passive dipoles: (a) Resistor. (b) Inductor. (c) Capacitor. (d) Admittance. (e) Impedance.

concept is very familiar in ac bridges and is used for representation of imperfect dipoles. An imperfect inductor is represented in two ways in Fig. 3(a) and (b). The conversion relationships between the two representations are

$$L_s = L_p(1 + Q^{-2}) \quad \text{and} \quad R_s = \frac{R_p}{1 + Q^2} \quad (18)$$

where

$$Q = \frac{R_p}{\omega L_p} = \frac{\omega L_s}{R_s} = \frac{1}{D} = \frac{1}{\tan \delta} \quad (19)$$

Similarly, for an imperfect capacitor the relationships are

$$C_s = C_p(1 + D^2) \quad \text{and} \quad R_s = \frac{R_p}{1 + D^{-2}} \quad (20)$$

where

$$D = \frac{1}{\omega C_p R_p} = \omega C_s R_s = \tan \delta = \frac{1}{Q} \quad (21)$$

Generally, the series representation is preferred for inductors, and the parallel one is preferred for capacitors.

Kirchhoff's Laws

Two laws due to Kirchhoff form the basis of the electrical network theory.

Kirchhoff's Current Law. The current law is applicable to any node and may be expressed as

$$\sum i(t) = 0 \quad (22)$$

Figure 3. Lumped networks in ac: (a) Inductive (b) Capacitive.

This law may be regarded as a principle of conservation of charge.

Kirchhoff's Voltage Law. The voltage law is applicable to any loop, is made up of a set of electrical dipoles connected end to end in order to form a closed circuit, and may be expressed, in the case of purely resistive dipoles, as:

$$\sum e(t) = \sum Ri(t) \quad (23)$$

That is a generalization of Ohm's law.

General Principles Applicable to Linear Electrical Networks

An electrical network consists of a set of electrical dipoles connected together. If an electrical network is externally accessible by only two terminals, it constitutes by itself a dipole. An electrical network which is accessible from the external by means of four terminals, is considered like a quadripole. The general case is a multipole. We will only examine the principles which are useful for the understanding of the following sections. Indeed, complementary explanations about these principles can also be found in this encyclopedia or in other specialized books.

It is also assumed that the examined networks are linear. This means, in particular, that the current in any branch of a network caused by a source located in the same or any other branch is proportional to the electromotive force of that source. A branch is made up of one electrical dipole or of more electrical dipoles connected in series and flown through by the same current.

Superposition Principle (Helmholtz's Theorem). The current in any branch of a network is the sum of the currents which would be induced in the branch by each source of the network when all other sources are either short-circuited (voltage source) or open (current source).

Duality Principle. The current-voltage relationships for a given network can be deduced from the voltage-current relationships of the reciprocal network by application of the following bijections:

$$v \Leftrightarrow i$$

$$R \Leftrightarrow G$$

$$L \Leftrightarrow C$$

$$\phi \Leftrightarrow q$$

$$\text{series} \Leftrightarrow \text{parallel}$$

$$\text{loop} \Leftrightarrow \text{node}$$

$$\frac{dv}{di} \equiv 0 \Leftrightarrow \frac{di}{dv} \equiv 0$$

$$v \equiv 0 \Leftrightarrow i \equiv 0$$

(24)

This principle is useful when it is requested to solve a problem where the solution of the reciprocal problem is already known. So, in an electrical bridge, by application of this principle, the source and the detector may be interchanged without altering the balance condition. However, this change also modifies the impedance matching between the source and the detector.

Figure 4. An equivalent circuit of a five-terminal resistor.

DC BRIDGE INSTRUMENTS

Definitions for a dc Resistor

The value of the combined standard measurement uncertainty, which accompanies the measurement result of a resistor, is often dependent of the characteristics of the device, itself. The factors contributing to this uncertainty are mainly

- Imperfect design of the resistor
- Connection terminals and the insulation materials
- Influence of the measurement parameters such as the temperature, the relative humidity, the pressure, and the measuring current.

At present, the most completely defined resistor is the one called five-terminal. The schematic diagram of a five-terminal resistor is shown in Fig. 4:

- P_1 and P_2 are the potential terminals
- C_1 and C_2 are the current terminals
- G is the guard terminal and is connected to the metal container surrounding the resistive element
- R is the resistor to be measured. It must respond to the accepted definition of a four-terminal resistor, which is the ratio of

$$R = \frac{U_{12}}{I_{12}} \quad (25)$$

where U_{12} is the open circuit voltage between nodes 1 and 2, and I_{12} is the current flowing through R .

- r_{c1} , r_{c2} , r_{p1} , and r_{p2} represent the lead and terminal resistances, respectively, at the terminals C_1 , C_2 , P_1 , and P_2 .
- R_{L1} and R_{L2} represent the leakage resistances from the same terminals C_1 , C_2 , P_1 , and P_2 .

This type of five-terminal resistor is now commercially available in the range from 1Ω to $10^9 \Omega$.

The four-terminal configuration is the same as in Fig. 4 without the Guard terminal G . The measured resistance differs

from the four terminal definition and is given by:

$$R_{\text{meas}} \cong R \left(1 - \frac{R}{R_{L1} + R_{L2}} \right) \quad (26)$$

From this formula, it can be seen that this design is valid for lower value dc resistors ($< 10^3 \Omega$). Although an old design, this is still used for the most stable dc standard resistors at the 1Ω level (1).

In the three-terminal configuration, there is no distinction made between the potential and the current terminals but the guard terminal is kept. The lead and terminal resistance r_{c1} and r_{c2} for this kind of resistor add to R . The measured resistance is now given by:

$$R_{\text{meas}} = R + r_{c1} + r_{c2} \quad (27)$$

Because r_{c1} and r_{c2} for this kind of resistor are below 1Ω , it is generally accepted that this design can be used for resistors above $10^6 \Omega$.

The two-terminal configuration is a simplified model of the three-terminal one. That was the first configuration used. It is still used in practice when it is compatible with the required measurement uncertainty.

Wheatstone Bridge

The bridge principle was first introduced by S. H. Christie in 1833, but was neglected until 1843, when Sir Charles Wheatstone applied this previously described arrangement of wires to the comparison of resistances (2–4).

In the original form of the Wheatstone bridge, shown in Fig. 5, X is the unknown resistor, A and B are equal resistors, and S is an adjustable resistor. S is varied until the detector deflection is zero. A battery is connected between nodes 1 and 3, and a detector joins the nodes 2 and 4. A node is a connecting point for one or more branches. S is adjusted until no potential difference exists between the junction points 2 and 4, so there is no current through the detector. The magnitude of X is to be

Figure 5. A Wheatstone bridge.

calculated from the equation:

$$X = S \frac{A}{B} \quad (28)$$

In this bridge, four of the six branches of the network containing the resistors A , B , S , and X are also called arms. Due to the fact that the resistors X and S are compared, Wheatstone called this arrangement a resistance balance. The resistors A and B are forming the arms of the balance by analogy with a weighing process.

In practice, the ratio A/B can be 1, 0.1, 0.01, or even lower. Inverse ratios 10, 100, or even higher can also be used. As also indicated in Fig. 5, the polarity of the voltage source is periodically reversed to reduce the effect of thermoelectric voltages. Thermoelectric voltages are mainly generated at the junctions of dissimilar metals at different temperatures. If we consider that the voltage source E has a negligible internal resistance r , and that the null detector has an input resistance g , we can calculate the current I_D in the detector by solving three loop equations in the networks 123E, 143E, and 124 as follows:

$$\begin{bmatrix} X+A & 0 & -X \\ 0 & S+B & S \\ -X & S & S+g+X \end{bmatrix} \cdot \begin{bmatrix} I_1 \\ I_2 \\ I_D \end{bmatrix} = \begin{bmatrix} E \\ E \\ 0 \end{bmatrix}$$

$$I_D = \frac{\begin{vmatrix} X+A & 0 & E \\ 0 & S+B & E \\ -X & S & 0 \end{vmatrix}}{\begin{vmatrix} X+A & 0 & -X \\ 0 & S+B & S \\ -X & S & S+g+X \end{vmatrix}}$$

$$I_D = E \frac{X(S+B) - S(X+A)}{(X+A)(S+B)(S+g+X) - X^2(S+B) - S^2(X+A)} \quad (29)$$

$$I_D = E \frac{XB - SA}{AX(B+S) + BS(A+X) + g(A+X)(B+S)} \quad (29)$$

When the bridge is balanced, $I_D = 0$, and we find the same relation as in the Eq. (28).

The first two products of the denominator may be replaced by

$$AB(S+X) + SX(A+B)$$

or by

$$AS(B+X) + BX(A+S)$$

The relative current sensitivity σ_i of the Wheatstone bridge near the balance condition can be expressed as follows:

$$|\sigma_i| = \left| \frac{\Delta I_D}{\frac{\Delta S}{S}} \right|_{\Delta S \rightarrow 0} \quad (30)$$

The sensitivity σ_i of a bridge can be optimized by selecting the elements of the bridge. If we slightly modify the balance of the

Wheatstone bridge given in Fig. 5 by changing the adjustable resistor S by a small amount ΔS , the corresponding variation ΔI_D indicated by the detector will be given according to Eq. (29):

$$|\Delta I_D| = \left| E \frac{A \Delta S}{AX(B+S) + BS(A+X) + g(A+X)(B+S)} \right| \quad (31)$$

knowing that at balance, we have also

$$\frac{A}{B} = \frac{X}{S} = \frac{A+X}{B+S} \quad (32)$$

Equation (31) can be rewritten:

$$|\Delta I_D| = \left| E \frac{A \Delta S}{AS(A+X) + BS(A+X) + gS(A+X) + gB(A+X)} \right| \quad (33)$$

$$|\Delta I_D| = \left| E \frac{A \Delta S}{(A+X)[AS + BS + gS + gB]} \right| \quad (34)$$

$$|\sigma_i| = \left| \frac{\Delta I_D}{\frac{\Delta S}{S}} \right| = \left| E \frac{A}{(A+X) \left[A + B + g + \frac{gB}{S} \right]} \right| \quad (35)$$

The parameters of the bridge must be chosen so that this current sensitivity is maximum, taking into account that the value of the source voltage E is limited by the admissible power dissipation in each resistor.

The usual Wheatstone bridge is designed for the measurement of two-terminal devices and so is not suitable for accurate resistance measurements below 1 M Ω .

At present, the Wheatstone bridge remains the basic bridge for many industrial applications with sensors like strain-gauge installations for force, torque, or pressure measurements.

Automated Guarded Wheatstone Bridge

At present in metrology laboratories, the main application of the Wheatstone bridge is reserved for the measurement of high value resistors.

In this case, a guarded Wheatstone bridge is used to compare three-terminal resistors. The availability of highly linear and fully computer-controlled dc sources or calibrators based on the pulse width modulation technique has led to the development of a new type of automated guarded Wheatstone bridge represented in Fig. 6 (5–7). In this bridge, the arm resistors A and B are advantageously replaced by two dc calibrators V_A and V_B having a very good linearity, a low temperature coefficient, and low output impedance. This bridge can be balanced automatically. At balance, the value of R_x is given by the following equation:

$$R_x = \frac{V_A}{V_B} R_S \quad (36)$$

This type of bridge can be used to calibrate resistors from 10 M Ω up to 1 T Ω or more in less time and with lower uncertainty than with the conventional guarded Wheatstone bridge. Combined

Figure 6. An automated guarded Wheatstone bridge.

measurement uncertainties of order of 1 part in 10^5 can be obtained at $1 \text{ G}\Omega$ with this bridge.

Kelvin Double Bridge

William Thomson (later Lord Kelvin) first described this bridge in a paper published in 1862. This network became known as the Thomson bridge, the Thomson double bridge, the Kelvin bridge, and the Kelvin double bridge. According to F. Wenner (2), Thomson seems to have been the first to attempt measurements of the highest precision attainable with the apparatus then available and to have an understanding of the factors limiting the precision of measurement. As shown in the schematic diagram of Fig. 7, the circuit contains a second set of ratio arms, labeled a and b . The guard circuit is not represented in Fig. 7. This Kelvin bridge may be transformed into an equivalent Wheatstone bridge. The Δ network formed by arms a and b and by link k can indeed be transformed in the Y network by using the theorem of Kennelly.

The detector indication will be zero when the voltage at node 2 equals the voltage at node 5.

$$U_2 = \frac{A}{A+B} I \left[S + X + \frac{(a+b)k}{a+b+k} \right] \quad (37)$$

Figure 7. A Kelvin double bridge.

$$U_5 = I \left\{ S + \frac{a}{a+b} \left[\frac{(a+b)k}{a+b+k} \right] \right\} \quad (38)$$

We can solve for X by equating U_2 and U_5 and simplifying:

$$S + X + \frac{(a+b)k}{a+b+k} = \frac{A+B}{A} \left\{ S + \frac{a}{a+b} \left[\frac{(a+b)k}{a+b+k} \right] \right\} \quad (39)$$

$$X = S \frac{B}{A} + \frac{ak}{a+b+k} \left(\frac{B}{A} - \frac{b}{a} \right) \quad (40)$$

By making two successive balances using configurations with and without the link k opened, the condition $B/A = b/a$ is fulfilled. The well-known relationship is established:

$$X = S \frac{B}{A} \quad (41)$$

This bridge is suitable for comparing five-terminal and four-terminal resistors. Nevertheless, it does not entirely satisfy the theoretical definition of a four terminal resistor. Indeed, there exists a voltage difference between nodes 1 and 3. This means, in particular, that a current is flowing through one of the potential leads and terminals of each resistor X and S . This bridge is especially useful for the measurement of 4 Terminal resistors below 100Ω .

Warsawsky Bridge

I. Warsawsky described this bridge in 1955 (8). The schematic diagram is given in Fig. 8. The screens of the resistors are not represented on this diagram. This bridge is of the Wheatstone type and is fitted at each of its four corners with a combining network. Each combining network consists of two auxiliary resistors connecting terminals of adjacent main resistor and also consists of one low-resistance link joining the other terminals. At each corner, the ratio of the auxiliary resistors must be the same as that of the main resistors they join. The exact balance equation of this bridge can be calculated by transforming, at

Figure 8. A Warsawsky bridge.

each corner, the Δ network in a T network. The ideal relationship for this bridge is similar to that of the Wheatstone bridge:

$$X = \frac{B}{A} S \quad (42)$$

Departure of less than 1 part in 10^8 from this ideal relationship has been reported if all the resistors of the bridge satisfy the following conditions (9):

- The four main resistors are within 1 part in 10^4 of their mean value.
- The auxiliary resistors are matched pairwise to better than 1 part in 10^4 .
- The low-resistance links are less than 1 part in 10^4 of the main and auxiliary resistances.

These conditions can be achieved in particular when main resistors of 10 k Ω are compared.

Dc Current Comparator Bridge

Originally, the basic design of this bridge comes from the work of N. L. Kusters et al. at the National Research Council of Canada (10,11). The essential feature of the dc current comparator bridge (CCB) is shown in Fig. 9. This CCB consists of

1. Two uniformly distributed ratio windings of N_x and N_s turns, wound on a toroidal magnetic core, are excited in a opposite way by two isolated and reversible direct current sources acting as Master and Slave
2. A zero flux detector and a double core magnetic modulator with a magnetic shield. This magnetic shield has the form of a hollow toroid, made of high permeability material
3. A null detector

The balancing of the bridge is completed when two balance conditions are fulfilled:

Figure 9. A dc current comparator bridge.

- The magnetomotive force balance is achieved automatically by means of the servo circuit operating from the output signal of the zero flux detector. This servo circuit adjusts the current I_s delivered by the slave power supply in order to maintain the difference of the magnetomotive forces of the two windings as close to zero as possible. This gives the first condition:

$$N_s I_s = N_x I_x \quad (43)$$

- The zero voltage condition which is obtained, in the manually operated version of this type of bridge, by changing the turns ratio N_x by rotating switches until the zero indication of the null detector is achieved. This gives the second condition:

$$I_x R_s = I_x R_x \quad (44)$$

From these above-mentioned relations, it can be deduced

$$R_x = R_s \frac{N_s}{N_x} \quad (45)$$

The dc current comparator has several advantages with respect to the previously described dc bridges:

1. The measured ratio depends for the most significant decades only on numbers of turns. This means that this type of bridge are not likely to drift with time or to change with ambient temperature, relative humidity, and atmospheric pressure.
2. The latest available versions of this kind of current comparator bridge is automatic and feature a linearity often better than 3 parts in 10^8 .
3. It is possible to compare resistors according to the four-terminal and five-terminal definitions.
4. The unknown and standard resistors are not connected in series. This means that the current flowing through them can be different.

In addition to the limitations common to other bridges due to the resolution of the null detector and thermal noise, we have two other sources of noise: Barkhausen noise in the magnetic core and electrical noise in the electronic servo circuit. Currently, commercial versions of this type of dc current comparator are automatic. They can be used to measure dc resistors and shunts between 1 m Ω and 1 M Ω . Their sensitivity is about 0.1 μ A for a winding of 1 turn.

Dc Cryogenic Current Comparator Bridge

Similar in its principle to the dc CCB, the dc cryogenic CCB has its ratio windings, toroidal overlapping lead shield, detection winding and flux detector made of superconductors or superconducting devices. As for the dc current comparator bridge, at balance, the ratio of currents I_s and I_x flowing through the windings is also the inverse ratio of the number of turns. The working principle is the Meissner effect. If the magnetomotive forces generated by the windings inside the superconducting shield are not fully equal and in opposition, a current, proportional to this imbalance, will circulate in the outer surface of this toroidal shield. This current will be detected by means of

Figure 10. A dc cryogenic current comparator bridge.

a superconducting flux transformer made of a low inductance superconducting coil. The latter is connected in series with the superconducting input coil of a very sensitive SQUID (Superconducting Quantum Interference Device) magnetometer. This type of magnetometer is presently the most sensitive magnetic field sensor known. A schematic diagram of a cryogenic current comparator bridge (CCCB) is illustrated in Fig. 10. Two reversible isolated and fully floating current sources generate currents I_s and I_x in approximately the inverse ratio of the winding turns N_s and N_x . The SQUID provides the magnetomotive force balance by controlling the Slave current source through the SQUID output and an isolation amplifier. The null detector amplifies the potential difference across the two resistors R_s and R_x . The output of this detector is used to drive a third current source, which provides a feedback current I_f through a feedback winding N_f . This feedback current is known by measuring the voltage across a known resistor with a digital voltmeter or an analogue to digital converter (ADC). At balance, we have again two equations. At zero indication of the null detector, we have

$$R_s I_s = R_x I_x \quad (46)$$

and when the magnetomotive force balance is achieved,

$$N_x I_x + I_f N_f - N_s I_s = 0 \quad (47)$$

If we replace I_s in (46), we obtain

$$\frac{R_x}{R_s} = \frac{N_x}{N_s} \left(1 + \frac{I_f N_f}{I_x N_x} \right) \quad (48)$$

A typical 1σ combined uncertainty of a few parts in 10^9 can be obtained with a commercially available CCCB (12) in the measurement of 1:1 ratios for resistors of 100 Ω . This uncertainty depends mainly on

- Calibration of the bridge and accessories
- Leakage resistances

- Electrical noise in the null detector, the SQUID, and the resistors

A sensitivity of about 1 nA for a winding of one turn can be achieved.

Dc Sources

The balance conditions calculated above for most of the bridges are independent of the values of the voltage sources. To reduce the influence of thermal emf's, the polarity of the source is regularly and often automatically reversed. It is reasonable to think that after these reversal operations, the voltage of the source must be kept reasonably stable.

The advantages of computer controlled dc calibrators have also been demonstrated for the realization of automated guarded Wheatstone bridges. In the past, depending on the value of the measuring current, batteries or lead acid accumulators were generally used as sources in dc bridges. Mercury batteries were also often used in different bridges because of their low drift and low temperature coefficient. However, they are no longer available because of new legislation concerning the environment. Today, the efficiency of shielding and noise reduction techniques has also increased, so those sources operating from the electrical mains are now more often used. Also, thanks to design improvements and automatization, power supplies, sometimes connected in parallel, are now the most convenient solution for the calibration with dc current comparator bridges of large current-carrying resistors or resistive shunts for currents from 1 A to 2000 A or more. For applications involving low power consumption and when it is strictly necessary to avoid noise and leakage paths due to the electrical mains, batteries can provide fully isolated voltage or current sources.

Dc Detectors

Today, electronic null detectors have replaced nearly all the galvanometers and the photogalvanometer amplifiers. Some electronic null detectors, nanovoltmeters, and certainly picovoltmeters exceed the sensitivity of most of the older detectors. Picovoltmeters operating at 4.2 K and based on a SQUID have been developed (13). An increasing number of these electronic instruments are more and more often operated from controlling computers via a parallel or a serial bus despite the problem arising from the additional noise introduced by this type of connection.

Noise coming from the bridge influences the null detector. This includes

- Radiated and conducted electromagnetic interference
- Thermal noise or Johnson noise due to the bridge. This means, in particular, that in some applications, the resistance of the connecting leads must be taken into account
- Barkhausen noise, which can be present with magnetic circuits like those in dc current comparators bridges

In addition to external noise and even when they are operating on internal batteries, electrical noise is also generated inside these electronic null detectors (14):

- Thermal noise or Johnson noise which emanates from all resistive devices. The value of the open-circuit voltage is

given by the following equation:

$$V = \sqrt{4kTRB} \quad (49)$$

where k = Boltzmann's constant (about 1.38×10^{-10} J/K); T = Absolute temperature in Kelvin; R = Resistance in ohm; B = Equivalent noise bandwidth in hertz.

- Shot noise caused by the current flow across a potential barrier
- Popcorn noise mainly due to some manufacturing processes of semiconductors and integrated circuits
- Contact noise due to imperfect contacts in switches or relays

An equivalent circuit of a dc detector can be represented by an ideal noiseless detector of infinite input impedance, shunted by a ideal noise current generator i_n and having an ideal noise voltage source e_n in series with.

Reliable dc nanovoltmeters and picovoltmeters are now commercially available. The most sensitive of them, operating at room temperature, has an equivalent noise resistance of about 30 mΩ, a common mode rejection ratio above 180 dB, and can detect potential differences as small as a few tens of picovolts when connected to a low-impedance circuit.

Checking of dc Bridges Accuracy

To comply with international quality standards, laboratories send, at specified intervals, standard resistors and even bridges to a national metrology service or to a qualified accredited laboratory for calibration. Between such calibrations, it is good practice that each laboratory performs elementary checks on its bridges. Some checks of dc resistance bridges include

1. *Zero Voltage of the Bridge Source.* When possible, it is always useful to disconnect the power source from the bridge and to short the input leads to the bridge or to turn the output voltage down to zero. After doing this, any deflection of the null detector will be an indication of the remaining thermal emfs, external signals, and noise, which are not due to the source.
 2. *Zero Resistance.* Replace the device under test by a short circuit.
 3. *Infinite Resistance.* Replace the device under test by an open circuit.
 4. *Checks of the Bridge Linearity.* Linearity check can be made using individual resistors or resistor networks.
- *With Individual Resistors.* Let us assume that we have two similar resistors A and B to compare and that we make two successive measurements $Rd_1 = A/B$ and $Rd_2 = B/A$. If the bridge under test has no linearity error, the product of these readings must be equal to 1. It is interesting to point out that this check does not require knowing of the exact value of these resistors A and B . The only technical requirement for these resistors is a good short term stability.
 - *With Resistive Networks.* A network of n nominally equal four-terminal resistors connected end to end with ideal zero-resistance junctions. In this case, each resistor of the network is successively compared by means of the bridge

under test with a separate one of the same nominal value. A first approximation of the linearity of the bridge at one point of the string can be obtained if the reading is equal to the sum of the individual readings up to this point:

$$R_i = \sum_{n=1}^i R_n$$

- *A Hamon Resistor Network.* A Hamon network is realized by connecting first in series and then in parallel the same number of n nominally equal four terminal resistors. It can be demonstrated that if all of these resistors are within 1 in 10^4 of their mean value, the ratio of the series/parallel combination R_s/R_p is equal to n^2 within 1 part in 10^8 (15). Accurate 1/100 ratios and even 1/10 ratios can be made with these Hamon build-up resistors.
- Very recently a resistance network, similar to the Hamon's design, was especially built for checking dc resistance bridges. It consists of a network of four main resistors connected to a common carefully engineered four-terminal junction. This produces 35 different resistance values of the four-terminal type and provides a convenient way to verify the accuracy of resistance bridges (16).

AC BRIDGE INSTRUMENTS

Many of the ac bridge instruments described in this section are mainly used in the audio-frequency range. However, some of them are still correctly operating, with higher uncertainties, slightly above the 1 MHz range.

Ac Networks

Most of the existing circuit components and even most of the impedance standards to be measured with ac bridges are neither purely resistive nor purely reactive. This means that unwanted capacitance and inductance are present in resistors, unwanted resistance and inductance in capacitors as well as unwanted resistance and capacitance in inductors. The energy flow at sufficiently low frequencies in these real-world devices must be treated like a flow in a RLC network. When driven with an ac voltage, each RLC network will dissipate heat and store the energy of the generated magnetic and electric fields.

If no precaution is taken in the construction and the use of this RLC network, the magnetic and electric fields generated by this network will be modified by any change with respect to its immediate environment. The final measured value of this RLC network will be altered. As in ac bridges, the comparison is made in the energy flow through two or more sets of impedance standards; special care in order to limit the influence of these fields is the first criterion to be fulfilled in the design of these impedance standards. In theory, for a standard of capacitance, the only energy should be that associated with the electrical field E , and for a standard of inductance that associated with the magnetic field H . For a standard of resistance, the only energy should be dissipated in heat.

Ac Measured Devices

The definitions given for dc resistors are, even for the most sophisticated of them, not satisfactory in low-frequency ac measurements mainly due to the frequency dependence of the

Figure 11. Four terminal-pair definition.

measured value, the series impedances, the shunt admittances, and the stray fields present in each device. Other definitions for the devices to be measured in ac have been developed in order to overcome these problems.

Four Terminal-Pair Definition. Today, it is generally accepted that the four terminal-pair definition is the most accurate. The interest of this definition has been firstly pointed out by R. D. Cutkosky (17) and more recently refined and intensively explained by B. P. Kibble and G. H. Rayner (18). An example of a simplified circuit of a four terminal-pair impedance is shown in Fig. 11. The numbering of the terminal-pairs or ports has been kept similar to that used by the first pioneers in this field. In order to fulfill the astatic condition, the coaxial geometry is intensively used. This means also that the impedance Z is contained in a shielded box, not represented in Fig. 11, and is connected to the measuring bridge by means of suitable coaxial sockets or plugs. In Fig. 11, again by analogy with the convention (9,18), the connections between the inner conductor of each coaxial connector are represented by a fine line and the connections between the outer conductor by a thicker line. This difference points out the low series impedance of this outer conductor per unit length. A generator may be connected to the current terminal-pair 1 to supply the necessary current and a second four terminal-pair impedance to be compared with the first one at the other current terminal-pair 3. The four terminal-pair impedance Z' is defined as

$$Z' = \frac{e_2}{i_3} \quad (50)$$

The required conditions for this definition are the following:

- At port 4: $e_4 = 0$ and $i_4 = 0$
- At port 3: $i_{3 \text{ OUT}} = i_{3 \text{ IN}}$
- At port 2: $i_2 = 0$

From Fig. 11, the impedance Z , including the low series impedance between the nodes a and b, can be expressed as

$$Z = Z'(1 + Z_2 Y_2)(1 + Z_3 Y_3) \quad (51)$$

These first order correcting terms $Z_i Y_i$ are due to the connections, the coaxial connectors, and the connecting cables. These terms may be forgotten if it is accepted that the impedance is

Figure 12. Two terminal-pair definition.

defined at the end of the connecting cables. It can also be calculated that these correcting terms $Z_i Y_i$ are lower than 1×10^{-8} at 1 kHz but nearly reach 1×10^{-3} at 1 MHz for 1 m length of 50 Ω ordinary PTFE isolated coaxial cable. It is also worth mentioning that these correcting terms do not involve the value of the impedance Z . This means that the four terminal-pair definition is valid for all values of the impedance Z and especially as long as the ratio between the length of the connecting leads or coaxial cables and the wavelength of the applied signal remains negligible. In practice, achievement of the definition condition at port 4 is limited by the sensitivity of the used null detector and usually requires the use of a combining network connected to both impedances to be compared. At port 3, the equality of the inward and outward currents at the terminals is obtained by means of a current equalizer. Port 2 is connected to a reference output voltage potential of the bridge, and auxiliary adjustments are necessary until no current flows at port 2. Despite the complexity of bridges designed for the calibration of four terminal-pair impedances, they constitute today the most widely accepted way to achieve the lowest uncertainty.

Two Terminal-Pair Definition. This definition is illustrated in Fig. 12. In comparison with Fig. 11, ports 2 and 4 have been deleted. The two terminal-pair impedance is defined as

$$Z' = \frac{e_1}{i_3} \quad (52)$$

The required condition is the following:

- At port 3: $e_3 = 0$ and $i_{3 \text{ OUT}} = i_{3 \text{ IN}}$

By analogy with the four terminal-pair definition, we have

$$Z' = kZ \quad (53)$$

where k is a correcting factor, the value of which can be found in the literature (17,18). From a practical point of view, it can be seen from Fig. 12 that the values of Y_H and Y_L do not affect this definition. However, Y_H and Y_L enter in the correcting factor k .

Four-Terminal Coaxial Definition. A simplified circuit illustrating this definition is shown in Fig. 13. The leakage resistance, the capacitance, the series resistance, and inductance of the connecting cables and of the input connectors, which are not represented in this figure, are also influencing the measured device. This type of definition is mainly suitable for resistive devices. Several ac resistance thermometer bridges are based on this definition (19).

Figure 13. Four-terminal coaxial definition.

Three-Terminal Definition. Many capacitors manufactured in the past were based on this definition. In some of them, the outer conductor of the high potential connector is not connected to the outer conductor of the low potential one. This is not a fundamental problem when they are properly used.

Four-Arm ac Bridges

In ac, the conventional four-arm resistive bridges (also called Wheatstone bridges) and more complicated multi-arm bridges are used. Generally, these multi-arm bridges are modified four-arm bridges and can, in principle, be reduced to simple Wheatstone bridges through $Y - \Delta$ or $\Delta - Y$ transformations (theorem of Kennelly). The problem becomes more difficult when the arms of these bridges consist of complex impedances as it is the case for the measurement of inductors, and capacitors. A complex impedance can be arranged like a network in which the resistors, the inductors and capacitors can be connected in series or in parallel or both. This means that there exist a great variety of four-arm ac bridges. This multiplicity of possible network arrangements makes the classification of ac bridges somehow difficult taking also into account that some combinations of these networks are impractical and even impossible to balance.

The most general form of a four-arm ac impedance bridge is the generalization in ac of the dc Wheatstone bridge, represented in Fig. 14. The structure is similar but the resistances R_1, R_2, R_3, R_4 are replaced by impedances Z_1, Z_2, Z_3, Z_4 . The generator G and detector D are operating at least partially in a common frequency range. At balance, the general equation of this bridge will be

$$Z_1 Z_3 = Z_2 Z_4 \quad (54)$$

Using the complex notation and substituting in Eq. (54)

$$(R_1 + jX_1)(R_3 + jX_3) = (R_2 + jX_2)(R_4 + jX_4) \quad (55)$$

Figure 14. General form of a four-arm impedance bridge.

By solving the real and imaginary terms separately, we obtain

$$R_1 R_3 - X_1 X_3 = R_2 R_4 - X_2 X_4 \quad (56)$$

$$X_1 R_3 + X_3 R_1 = X_2 R_4 + X_4 R_2 \quad (57)$$

The main difference with the dc version is that the balance condition is given by a system of two equations which must be simultaneously fulfilled. This is rather normal because two unknown quantities, which are the resistive and reactive components of the same complex impedance, have to be measured. The balance calls for the simultaneous adjustment of at least one resistive and one reactive parameter in the network. This becomes clearer if we rewrite the general balance equation in the form:

$$|Z_1 Z_3| e^{j(\varphi_1 + \varphi_3)} = |Z_2 Z_4| e^{j(\varphi_2 + \varphi_4)} \quad (58)$$

The two conditions for the balance of an ac bridge in magnitude and in phase can then be expressed as follows:

$$|Z_1 Z_3| = |Z_2 Z_4| \quad (59)$$

$$\varphi_1 + \varphi_3 = \varphi_2 + \varphi_4 \quad (60)$$

Thus, the balance of an ac bridge is obtained when the products of the magnitudes and the sum of the phase angles of the impedances in the pairwise opposite arms are made equal.

We will only consider the most useful of these bridges. To simplify the study of the different bridges, the balance conditions of each bridge will be determined assuming that perfect two terminal components and connecting leads or connections are used, which is far from the truth in practice.

Wien Capacitance Bridge. This bridge is shown in Fig. 15. Two adjacent arms of this bridge have nonreactive resistors, and the other two arms have capacitors respectively in series and in parallel with resistors. It is used to determine capacitance in terms of resistance and frequency. The balance equation is

$$R_1 \left(\frac{R_x}{1 + j\omega C_x R_x} \right) = R_2 \left(R_3 + \frac{1}{j\omega C_3} \right) \quad (61)$$

By solving this equation, we obtain

$$C_x = \frac{R_1 C_3}{R_2 (1 + \omega^2 R_3^2 C_3^2)} \quad \text{and} \quad R_x = \frac{R_2 (1 + \omega^2 R_3^2 C_3^2)}{\omega^2 C_3^2 R_1 R_3} \quad (62)$$

Figure 15. A Wien capacitance bridge.

Figure 16. A Maxwell-Wien bridge.

This Wien bridge is also widely used in electronics, for example, to realize low distortion RC oscillators. In this case, the balance conditions may be rewritten

$$\frac{C_x}{C_3} = \frac{R_1}{R_2} - \frac{R_3}{R_x} \quad \text{and} \quad \omega^2 = \frac{1}{C_3 C_x R_3 R_x} \quad (63)$$

Maxwell-Wien Bridge. This bridge is normally used for the measurement of inductance in terms of resistance and capacitance. It was originally introduced by Maxwell as a ballistic method and at first used as an ac bridge by Wien (3,4). This bridge is shown in Fig. 16. The balance equation is

$$\frac{R_1(R_x + j\omega L_x)}{(1 + j\omega C_1 R_1)} = R_2 R_3 \quad (64)$$

or if we separate the real and imaginary parts:

$$L_x = C_1 R_2 R_3 \quad \text{and} \quad R_x = \frac{R_2 R_3}{R_1} \quad (65)$$

It can be deduced that the balance is independent of frequency.

Hay Bridge. This bridge is particularly suitable to measure inductances with large time-constants. It differs from the Maxwell-Wien bridge in that in the arm opposite to the inductor, the capacitor is in series with the resistor. The circuit arrangement is given in Fig. 17. At balance,

$$\left(R_1 + \frac{1}{j\omega C_1}\right)(R_x + j\omega L_x) = R_2 R_3$$

Solving for L_x and R_x ,

$$L_x = \frac{R_2 R_3 C_1}{(1 + \omega^2 R_1^2 C_1^2)} \quad \text{and} \quad R_x = \frac{\omega^2 R_1 R_2 R_3 C_1^2}{(1 + \omega^2 R_1^2 C_1^2)} \quad (66)$$

These balance conditions are frequency dependent. The frequency must be well known and very stable. This is obtained nowadays very easily by using frequency synthesizers.

Figure 17. A Hay bridge.

Schering Bridge. Schering first suggested this bridge in 1920. This bridge is used for the measurement of capacitance and dissipation factor. The unknown capacitor C_x and the standard loss-free capacitor C_2 form two adjacent arms, while the opposite arm to the capacitor C_x consists of a resistor R_1 and a capacitor C_1 in parallel. The fourth arm is a nonreactive resistor R_3 . The balance may be written referring to Fig. 18:

$$\left(R_x + \frac{1}{j\omega C_x}\right)\left(\frac{R_1}{1 + j\omega C_1 R_1}\right) = \frac{R_2}{j\omega C_2} \quad (67)$$

By separating the real and the imaginary parts:

$$C_x = \frac{C_2 R_1}{R_2} \quad \text{and} \quad R_x = \frac{C_1 R_2}{C_2} \quad (68)$$

The balance conditions are independent of frequency.

Wagner Principle. Already in many dc bridges but still more in ac bridges, the problem of leakage currents, coming, for example, from the source directly to the detector due to the poor isolation from the conductor of the mains supply called ground or earth or due to stray capacitances, must be under control. In many ac bridges, this is achieved by adding an auxiliary circuit or branch called Wagner earth to the bridge. It can be deduced from Fig. 19 that the admittances of the bridge and

Figure 18. A Schering bridge.

Figure 19. The Wagner principle.

the auxiliary circuit respect the following conditions:

$$\frac{Y_1}{Y_4} = \frac{Y_2}{Y_3} = \frac{(Y_5 + Y_b)}{(Y_6 + Y_d)} \quad (69)$$

then the detector terminals are at the same potential as the earth or ground potential without being connected to the earth or to the ground. The admittances Y_a , Y_c and Y_b , Y_d have, consequently, no effect because they are respectively connected between equipotential points and in parallel with the admittance Y_5 and Y_6 of the auxiliary arms. The condition (69) is fulfilled by balancing successively the bridge constituted by Y_1 , Y_2 , Y_3 and Y_4 and the bridge consisting of Y_1 , Y_4 , Y_5 and Y_6 or of Y_2 , Y_3 , Y_5 and Y_6 . The procedure is iterated until a consistent balance is obtained for the two possible connections of the detector.

Multiple-Arm Bridges

Other ac bridges having six arms and even more rarely seven arms have been described in the technical literature and also used successfully (3). However, it will be shown that several of these networks may be reduced to the basic four-arm configuration by suitable $Y - \Delta$ or $\Delta - Y$ transformations.

Anderson-Type Bridge. The interest of the modification introduced by Anderson has been demonstrated in the Maxwell-Wien bridge to measure inductance in terms of capacitance and resistance. If we apply the theorem of Kennelly to the triangle cde of the network shown in Fig. 20, we have the following equations:

$$Z'_3 = \frac{Z_5 Z_6}{Z_3 + Z_5 + Z_6} \quad (70)$$

Figure 20. An Anderson bridge.

Figure 21. A modified Anderson's type bridge after a $Y - \Delta$ transformation.

$$Z'_5 = \frac{Z_3 Z_6}{Z_3 + Z_5 + Z_6} \quad (71)$$

$$Z'_6 = \frac{Z_3 Z_5}{Z_3 + Z_5 + Z_6} \quad (72)$$

The general balance equation of the network represented in Fig. 21 is

$$Z_2 Z_4 (Z_3 + Z_5 + Z_6) + Z_3 Z_5 Z_4 = Z_1 Z_3 Z_6 \quad (73)$$

Ac Kelvin Double Bridge. The need to characterize four terminal low value resistors and, in particular, to know their time-constants and their residual inductances has led to extend the use of the Kelvin double bridge from dc to low frequency ac. A general form of this bridge is given in Fig. 22. Let us apply again the theorem of Kennelly to the network 456:

$$Z'_a = \frac{Z_b Z_c}{Z_a + Z_b + Z_c} \quad (74)$$

$$Z'_b = \frac{Z_a Z_c}{Z_a + Z_b + Z_c} \quad (75)$$

$$Z'_c = \frac{Z_a Z_b}{Z_a + Z_b + Z_c} \quad (76)$$

The general equation of the network shown in Fig. 23 is

$$(Z_a + Z_b + Z_c)(Z_A Z_X - Z_B Z_S) = Z_c(Z_B Z_a - Z_A Z_b) \quad (77)$$

Figure 22. An ac Kelvin double bridge.

Figure 23. A modified ac Kelvin double bridge after a $Y - \Delta$ transformation.

Therefore, the double condition as follows permits the achievement of balance:

$$\frac{Z_S}{Z_X} = \frac{Z_A}{Z_B} \quad \text{and} \quad \frac{Z_A}{Z_B} = \frac{Z_a}{Z_b} \quad (78)$$

Twin-T Networks. Networks other than the four-arm bridges have been developed to compare impedances. An important one among them is the Twin-T network. This circuit illustrated in Fig. 24 may be regarded as a parallel-T network. The direct impedances Z'_6 and Z'_3 between nodes 1 and 2 can be calculated after $Y - \Delta$ transformations (Fig. 25). If these direct impedances Z'_6 and Z'_3 are equal in magnitude and have phase angles differing by π radians, the currents through these impedances cancel one another at the input of the detector. The other admittances obtained after these transformations do not affect the balance condition because they shunt either the source or the detector. The balance condition of this parallel-T network is given by the following equation:

$$Z_1 + Z_2 + Z_1 Z_2 Z_3 + Y_4 + Z_5 + Z_4 Z_5 Y_6 = 0 \quad (79)$$

Therefore the null at the detector is only possible if the impedances contain reactances. This type of bridge is particularly suitable for use at high frequencies. An interesting feature of this type of network is the fact that the source and the detector have a common point. Therefore, the bridge balance is not disturbed by stray capacitances.

Figure 24. A Twin-T network.

Figure 25. $Y - \Delta$ transformations applied to a Twin-T network.

Transformer-Ratio Arm Bridges

In the four-arm or the multi-arm ac bridges, which have been examined before, the ratio arms are generally realized by fixed nonreactive resistances in a definite numerical ratio. For forty years, ac bridges have been designed where the impedance ratios in adjacent arms are advantageously replaced by voltage ratios from inductive voltage dividers (IVDs). An IVD is an accurate autotransformer provided with a variable tapping point.

At present, 8- or 9-decade IVDs with a departure from the nominal ratio of the number of turns of the windings lower than one part in ten million in the audio-frequency range are commercially available. Some of them are also correctly operating up to 1 MHz. Applications using 30 bits binary voltage dividers have also been described (20). The automatization of the IVDs seems also to be a promising feature for these devices.

Ratios defined by IVDs are very stable as a function of time, temperature, humidity, and even frequency. At 1 kHz, uncertainties lower than 3 parts in 10^8 for the ratio and less than $1 \mu\text{rad}$ for the phase are currently achieved for IVDs manufactured by qualified specialists in the field.

In transformers especially designed for ratio measurements, the departure from the ideal transformer has mainly the following origins:

- Power losses due to the magnetization and eddy currents in the core
- Power losses due to Joule effect, skin effect, and eddy currents in the windings
- Flux leakages
- Leakage inductances and capacitances

Potential Transformer-Ratio Arm Bridge. A simple example of a bridge, which might be called potential transformer bridge, is shown in Fig. 26. The balancing condition is easily obtained. Indeed, at node 1,

$$I_1 = I_2 \quad (80)$$

$$\frac{V_1}{Z_1} = \frac{V_2}{Z_2} \quad (81)$$

If the potential transformer is ideal,

$$\frac{V_1}{V_2} = \frac{n_1}{n_2} \quad (82)$$

$$\frac{Z_1}{Z_2} = \frac{n_1}{n_2} \quad (83)$$

Figure 26. A potential transformer-ratio arm bridge.

In the potential transformer-ratio bridge, the ratio of the number of turns of the windings n_1 and n_2 determines the ratio of the voltage across the other arms. It can also be observed from the same diagram that, if the variable tapping point P is grounded, the stray capacitances associated with Z_1 and Z_2 are in parallel with the internal impedances of the two parts of the potential transformer. As these impedances are in general rather low, the admittances of these stray capacitances do not affect the balance of this simple bridge. If a lower uncertainty is requested, the generator must at least be isolated; a Wagner branch and an injection network have to be added to correctly balance this bridge.

Current Transformer-Ratio Bridge. This bridge, represented in Fig. 27, is the dual bridge of the potential transformer-ratio bridge. This bridge is a three-winding type where the extra winding detects the magnetomotive force balance. The magnetic and electrostatic screens between the toroidal windings and the detector winding are not represented. These screens are often necessary to improve the accuracy of this type of bridge. Contrary to the potential transformer-ratio bridge, which operates with a finite magnetic flux in the magnetic core, the flux in the magnetic core of a current transformer ratio bridge is theoretically zero.

When the bridge is balanced, the magnetomotive forces created by the currents flowing through the two impedances and the two windings nullify each other. At balance, we have

$$n_1 I_1 - n_2 I_2 = 0 \quad (84)$$

or

$$\frac{n_1}{Z_1} = \frac{n_2}{Z_2} \quad (85)$$

Figure 27. A current transformer-ratio bridge.

Figure 28. An ac current comparator bridge.

Ac Current Comparator Bridge

Many applications of the ac current comparator have been described for low as well as for high voltage and current applications (10). In low voltage applications, an ac current comparator is used in the development of many useful instruments like current transformers, active capacitor/quadrature current references, transconductance amplifiers, resistance-ratio ac bridges (21), and power comparators. We will describe this last one, which is also known as power bridge due to its use for the measurement of power and energy. The basic circuit, shown in Fig. 28, offers the possibility to provide a power standard (22). This bridge compares the magnetomotive forces created by the current I in the winding N_x with the magnetomotive forces in the winding N_r due to the in-phase current flowing through the resistance R and that in the winding N_c due to the quadrature current through the capacitor C . The balance condition is

$$IN_x = \frac{V}{R} N_r \pm j\omega C V N_c \quad (86)$$

By rewriting Eq. (86),

$$VI = \frac{1}{N_x} \left(\frac{V^2}{R} N_r \pm j\omega C V^2 N_c \right) \quad (87)$$

This bridge measures the apparent power VI that has one active component proportional to V^2/R and one reactive component proportional to $\omega C V^2$.

Coaxial ac Bridges

This is the latest refinement in the field of ac bridges. Measurement uncertainties as low as 1 part in 10^9 for impedance comparison can be achieved from about 200 Hz to 2 kHz with these kinds of coaxial ac bridges. However, the technique can be extended from 10 Hz to slightly above 1 MHz. The technique of the coaxial ac bridges is based on some of the following

Figure 29. A two terminal-pair bridge based on IVDs [From (18) with the consent of Dr. B. P. Kibble and the permission of IOP].

features:

1. Complete equality in magnitude and opposition in sign between the currents flowing in the inner and the outer conductor of the coaxial cable. By this means, no external field is created, and no electromagnetic interference is influencing the bridge.
2. Low impedance of the outer conductor of the cable and of the screens of the measuring devices
3. Fully screened or shielded measuring devices provided with terminal-pairs

Coaxial ac bridges are used to realize the link between the farad and the ohm and vice versa. A simple example of a coaxial ac bridge is shown in Fig. 29, with the permission of one of the authors (18). This bridge built around a calibrated IVD can be used to compare two terminal-pair measuring devices of similar admittance with a measurement uncertainty lower than 1 part in 10^6 .

Automatic RLC Bridges

Many of the ac bridges described in the previous chapters are not very widespread in industrial laboratories and not very practical for component manufacturers. In many sectors of activities, the preference is mainly given to automatic *RLC* bridges, which are more easily available due to the fact that several manufacturers commercialize them. These *RLC* bridges offer several advantages:

- Automatic and quick measurement of the real and imaginary parts of the impedance vector and conversion of them into the desired parameters like $|Z|$, $|Y|$, Θ , R , X , G and B
- Computer control by means of an IEEE 488 interface
- Frequency range from a few hertz up to several megahertz

A schematic diagram of an HP 4284A Precision *LCR* Meter is represented in Fig. 30 with the permission of the manufacturer (23). As indicated in this figure, the structure of this bridge allows the measurement of 4TP devices. Coaxial cables are used to isolate the voltage sensing cables from the signal current path. Since the same current flows, but in an opposite direction through the outer conductor of the same coaxial cable, the magnetic field generated by the inner conductor is canceled. The outer conductor of the coaxial cable is also connected at the system ground.

This bridge uses the auto balancing method, where the current flowing through the device under test is balanced by the range resistor current in order to maintain a zero potential at the low terminal of the device under test. A null detector in amplitude and in phase measures the zero potential at this point. If the zero potential is not achieved, the null detector adjusts the amplitude and/or the phase of the second oscillator in order to maintain this balance condition. This bridge, operating up to 1 MHz, allows the measurement of devices with a basic accuracy of 0.05% at 1 kHz. Better performances could be achieved when using a substitution method and standards calibrated with lower uncertainties. Before using this type of bridge, it is also needed to proceed to an OPEN/SHORT/LOAD compensation technique. The length of the cables must be taken into account, especially if the frequency is above the kilohertz band.

Figure 30. A schematic diagram of HP 4284A Precision *LCR* Meter (copyright Hewlett-Packard).

Ac Sources

From the balance conditions, it can be deduced that the first two requirements for an ac bridge source are the frequency stability and an output voltage sine waveform with very low distortion, especially if the balance condition is frequency dependent. The output power delivered by the ac bridge source may be insufficient, and the need for an additional power amplifier possibly associated with a matching transformer may perhaps be necessary. The addition of these devices will increase the total harmonic distortion of the source.

Modern *RC* audio-frequency sinewave generators usually present output voltages with a total harmonic distortion lower than 0.01% and generally offer the possibility to be phase-locked by a frequency synthesizer. Up to several kilohertz, as long as the total harmonic distortion of the output can be kept lower than 0.1%, it is also possible to work directly with a frequency synthesizer. Indeed, several of the commercially available frequency synthesizers in the audio frequency range have a frequency resolution higher than 1 part in 10^{10} . If necessary, the reference signal generated by the internal crystal oscillator may be replaced by the one produced by a higher stability oscillator like an atomic frequency standard. Digital signal generators may also be found useful due to their frequency and amplitude stability. However, the possible presence of glitches at the output of some of them may be a source of problems in the balancing process (24).

Ac Detectors

Passive detectors like the telephone receiver and the vibration galvanometer, which were very common at the beginning of ac bridge measurements, are no longer used. At present, nearly all detectors used in ac bridge measurements are fed from the mains supply or more rarely from batteries. The most important technical requirements for ac detectors are

- Amplitude sensitivity in current or in voltage
- Frequency selectivity and the ability to reject harmonics
- Phase sensitivity

It is to be noted that in ac, the experimenter can often use a matching amplifier between the network and the available detector.

The most common types of detectors are described below.

Wideband Detectors. Wideband detectors like oscilloscopes and ac millivoltmeters can be used. The wideband operation of these instruments can lead to the necessity of reducing the bandwidth by placing a band-pass filter or tuned preamplifier at the input of these detectors in order to achieve a better selectivity or signal-to-noise ratio.

Narrowband Detectors. Frequency-selective detectors, which are tuned to respond to the fundamental frequency of the in-phase and quadrature components of the out-of-balance signal, are also helpful. Their deflection will correspond to the sum-of-square of these components. Some commercially available detectors of this type also have the advantage of being battery operated. Nevertheless, their principle of operation can make the balancing of some bridges with poor convergence more difficult.

Phase-Sensitive Detectors. This type of detector is also known as a synchronous or lock-in detector. A phase-sensitive detector requires an auxiliary reference signal taken directly from the bridge source. It uses this signal to operate an electronic switch or a modulator. The most suitable detector of this type multiplies the incoming signal with the reference signal. The resulting signal is then passed through an integrating low-pass filter. Dual phase-sensitive detectors incorporated in the same instrument are also very convenient: one detector can be adjusted to respond to a signal with the same phase as the source, and the other to the quadrature component. In this way, the bridge convergence can be made more efficiently. This type of phase-sensitive detectors has the advantage of optimizing the recovery of the bridge out-of-balance signal from random noise. However, the direct connection from the source to the detector could be a source of problems if appropriate precautions, like the right use of an isolation transformer, are not taken.

Convergence of ac Bridges

The ability of a bridge to approach the balance is known as convergence. In ac bridges, this concept also includes the rate at which this balance is achieved. As seen previously, the balance condition is given by a system of two equations, which must be satisfied simultaneously. This indicates that in such bridges, at least two parameters, one reactive and one resistive, must be adjusted. The solution to this problem requires one to choose the adjusting devices and to determine the way to obtain the balance of the bridge in a minimum number of adjustments. As the best solution generally differs from one bridge to another, it is recommended to refer for this point to the bibliography (3,4).

Sensitivity of ac Bridges

As for the dc bridges we can define, at balance, the sensitivity of the detector as the ratio of the small deflection from zero resulting from a small change of the measured impedance to the value of the change. In this way, we can define the relative current sensitivity S_i as

$$S_i = \left| \frac{\frac{\Delta I}{\Delta Z}}{\frac{I}{Z}} \right|_{\Delta Z \rightarrow 0} \quad (88)$$

and the relative voltage sensitivity S_v as

$$S_v = \left| \frac{\frac{\Delta V}{\Delta Z}}{\frac{V}{Z}} \right|_{\Delta Z \rightarrow 0} \quad (89)$$

In theory, these values can be calculated from the parameters of the bridges including those of the detector (3,4). In practice, these parameters are easily measured by changing Z of a small amount from the balance and observing the small deflection ΔI or ΔV on the null detector.

Checking of ac Bridge Accuracy

Several principles explained for checking dc bridges could be applied for ac bridges if we take into account that we compare impedances and not pure resistors:

1. *Zero Voltage of the Bridge Source.* The same procedure as for dc bridges.

2. *Zero Impedance*. A suitable short circuit replaces also the device under test.
3. *Infinite Impedance*. An open circuit replaces the device under test. In this case, care must be taken in order to prevent the flow of capacitive currents.
4. *Checks of the Bridge Linearity*.

- *With Individual Resistors or Impedances*. Depending on the type of instrument, the substitution method or the transposition method can be used. These methods can be applied with all types of resistors or impedances. The used devices do not need to be calibrated. They must have only good short-term stability if the other influencing parameters can be kept constant.
- *With Resistance or Capacitance Networks*. Linearity checks of low frequency ac resistance bridges can be estimated using a string of equal value resistors connected in series. At present, a resistance network close to Hamon's design offers a convenient solution for the calibration of the ac resistance bridges from dc to 10^4 rad/s with an accuracy of about 1 part in 10^8 for 100 Ω (25).

Linearity checks of capacitance bridges can be executed by a set of capacitors successively connected in series and in parallel. Usually, the calibration of IVDs and voltage transformers can be made using an auxiliary transformer or set of capacitors (18).

ACKNOWLEDGMENTS

The author wishes to thank Mr. R. De Vré and Dr. T. J. Witt for the improvements brought to one part of this document. He is also grateful to his son Cedric and to Mr. G. Bairy for their patience in reviewing several drafts of the manuscript and to Mr. P. D'Hainaut for the realization of the figures.

OSCILLOSCOPES

The oscilloscope, or *scope*, is an important tool in engineering. The oscilloscope displays a graph of an electrical signal on a screen. In its basic operational mode, the oscilloscope graphs instantaneous signal values versus time. Displayed waveforms have three basic components: Y, the vertical or amplitude component; X, the horizontal or time component; Z, the signal brightness or intensity. Single-channel and multichannel oscilloscopes are available. The most popular is a two-channel instrument in which a single trace display with channel multiplexing is available. In this case not only instantaneous signal values versus time, but also one amplitude waveform component versus the other, can be observed.

Oscilloscopes are used in physics, electronics, instrumentation and measurements, communications, control, mechanical

Figure 1. Internal structure of a CRT.

engineering, and many other areas where nonelectrical signals can be converted into electrical signals. The graphical display allows a user to determine many signal parameters, such as:

- Voltage and time values
- Frequency, period, and rise and fall times
- Phase shift
- Noise level, jitter
- Frequency ratio of two signals
- Calculated Fourier spectrum
- Calculated statistical parameters
- Calculated mathematical functions of signals, such as the integral, derivative, sum, difference, and product

Two major types of oscilloscopes have emerged over the last decade: analog and digital. Within these two categories, a number of operational modes can be distinguished. There are real-time data acquisition and display scopes, real-time acquisition and equivalent- or transformed-time display scopes, equivalent-time acquisition and display scopes, and random data acquisition and random display scopes. A typical analog scope directly acquires signals and displays them on the screen in real time. An analog sampling scope can operate in real time at low signal frequencies, and in equivalent time at high frequencies. A digital scope can operate in real-time or equivalent-time mode to acquire signals, but the display shows the reconstructed signals in the equivalent-time mode, which allows for great reduction of the display unit speed, which in turn achieves great reduction of the scope's cost. Currently, the major oscilloscope producers, such as Hewlett-Packard, Tektronix, and LeCroy, do not list analog scopes in their catalogs, but many analog oscilloscopes have been used and will be used in the near future. The digital scopes, also called digitizing or digital storage oscilloscopes, are considerably more powerful and flexible for signal inspection and analysis. Signal digitization has opened unlimited possibilities for signal storage and processing.

ANALOG SCOPES

Analog scopes without sampling acquire and display waves in real time. The most critical part of the analog oscilloscope is a cathode ray tube (CRT), whose maximum speed of wave tracing limits the speed of the entire scope. Figure 1 shows the simplified structure of a CRT. The beam of electrons generated by the cathode is directed towards the fluorescent screen by a set of electrodes. The beam makes a bright spot on the screen at a position controlled by the voltages applied to the vertical and horizontal deflection plates. The tube can have a single or a double beam system. The latter has two separate beam-forming and deflection structures. The tube shown in Fig. 1 employs a two-stage electron acceleration process. The electrons emitted from the cathode are formed into the beam, whose density is controlled by the cylindrical electrode. Later, the beam is focused and deflected, passing through the vertical and horizontal deflection plates. Final acceleration, called postdeflection acceleration (which is necessary to produce a visible spot on the screen), is achieved by applying very high voltage, at least several kilovolts, to a distributed electrode located inside the tube between the deflection plates and the screen. The inner surface of the tube screen is covered with a *phosphor*, which emits visual radiation on being bombarded by electrons. The length of time during which the phosphor emits radiation until its level decays to 10% of the initial value is called the *persistence*. Several types of phosphor inner coatings are applied in CRTs. The most popular phosphor, P 31, exhibiting high luminance and reasonable persistence of about 32 ms (1,2), is found in most CRTs.

In analog scopes, an image of a nonrepetitive signal fades quickly or slowly, depending upon the tube persistence. Fast single-shot events may not be registered by a classical CRT whose screen directly reacts to the electron current delivered to it. In order to enhance the quality of writing, microchannel plate CRTs are used in some analog scopes (3,4). Inside the tube, an array of hollow glass fibers is located. The fibers, internally coated with a semiconductor, multiply the number of electrons through secondary emission when activated by an adequately accelerated electron beam. The beam deflection can be

Figure 2. General diagram of an analog oscilloscope.

affected by interfering magnetic and electric signals produced within the oscilloscopes by the proximity of power supplies, especially transformers, chokes, and high voltage. To avoid interference, the tubes and potentially interfering components are well shielded.

The scheme of a typical analog scope is shown in Fig. 2. The vertical channels, A and B, include input coupling circuits, attenuators, preamplifiers, delay line, and differential output amplifiers driving the vertical plates of the CRT, as shown in Fig. 3. Quite often, voltage or current probes are connected to the inputs to provide better interfacing with the tested circuits. The horizontal section of the oscilloscope is composed of a triggering unit with its coupling, trigger shaping unit, trigger level control, and trigger holdoff units; a sweep generator, which defines the main time base of the scope; and a differential output amplifier driving the horizontal deflection plates of the tube (Fig. 4). The main sweep generator can be supported by a fast time-base unit triggered at a preselected level to expand desired parts of the tested waves. Figure 5 illustrates typical waveforms of analog scopes. Two time bases are activated to show distinguished sections of the signals under test with the help of the fast ramp, which is called the delayed time base. The waves observed on the tube screen are delayed in relation to the input signals due to the action of the delay lines forming parts of the vertical amplifier. In this way the trigger and time-base circuit delays and nonlinearities are compensated to create good conditions for tests of the wave leading edges without distortions. Figure 5 also shows internally generated triggering pulses initiated by the input signal of channel 1 or 2.

To stabilize the horizontal wave position on the screen, the trigger level is selected within the frame of the vertical span

of the incoming waves. At the same time an auxiliary system called the *holdoff* has to be adjusted to make the time-base generator insensitive to excessively frequent triggering. If more than one channel is used and a single-trace tube is applied, then a channel switch can direct only one channel to the screen at a time for the duration of the time base at high rates of the time base (alternating mode), or small segments of the individual channel signals can be displayed one by one at lower rates of the time base (chopped mode). The waves for both modes of the display are shown in Fig. 6. Multichannel data acquisition allows one to perform basic hardware arithmetic operations on signals, such as addition and subtraction. The process of subtraction, which can disclose a differential signal component, is corrupted by interchannel interference due to the common ground pathways and nonideal channel isolation of the channel switch. Many analog oscilloscopes have internal amplitude calibrators, which help check the scope amplitude calibration and verify or adjust the compensation of the voltage probes.

ANALOG SAMPLING SCOPES

Typical real-time analog oscilloscopes have operating bandwidths up to several hundred megahertz. The limits are mainly imposed by the CRT's writing speed. One of the means used to reduce the speed of observed wave has been time transformation by means of coherent sampling. The method can only be applied to repetitive waveforms. A basic set of waveforms for a sampling scope is shown in Fig. 7; the scope block diagram is depicted in Fig. 8. The signal under test applied to the input is delayed by a broadband transmission line, then sampled

Figure 3. Vertical channel of an analog oscilloscope.

Figure 5. Waveforms in an analog oscilloscope.

Figure 6. Modes of display of an analog oscilloscope.

Figure 7. Time transformation in an analog sampling scope.

by very narrow pulses in a sampling gate. If the repetition frequency is less than several hundred kilohertz, which is the maximum repetition frequency of the trigger circuitry, a single sample is taken from each pulse of a frame defined by the time base. For higher repetition rates the trigger circuits divide the frequency so that every n th period one sample is taken from a single pulse of a repetitive wave. When the samples are taken, they are stretched, amplified, and memorized in a sample-and-hold circuit. Later, the samples are applied to low-frequency vertical amplifiers driving the tube. The sampling scope system uses a track-and-hold feature that enables the scope to process very small samples formed by the differences between the pairs of consecutive samples. Generation of subsequent sampling pulses is achieved by comparison of two fully synchronized time bases. One of them is a fast time base, and the other is a staircase signal. The horizontal channel provides the timing of all samples. It also delivers trigger signals to the sampling pulse generator and to the time bases. Analog sampling oscilloscopes are often applied in time-domain reflectometers (TDRs), and they can operate covering an equivalent

bandwidth up to 50 GHz, which corresponds to 7 ps for the rise-time without the delay line. The delay lines available for such scopes have their bandwidth limited to 5 GHz.

DIGITAL SCOPES

Digital oscilloscopes overcome many disadvantages of analog oscilloscopes, such as the necessity for delay lines and for fast and long-persistence CRTs. A digital scope display can be adjusted after wave acquisition. The input circuitry of a typical digital scope does not differ from that of analog scopes. After preliminary attenuation or amplification, analog signals are sampled and digitized. The digitized samples are stored in a memory. The tube receives the reconstructed analog samples of vertical and horizontal information through digital-to-analog converters. The process of data display is delayed and stretched in time, so the tube that displays the samples can operate much slower than the fast data-acquisition parts. Three major types of digitizers are applied in digital scopes:

- Real-time digitizers operating at high sampling and conversion rates can capture nonperiodic short transient processes.
- Coherent sampling digitizers work in the same way as the sampling oscilloscopes with time transformation described above. The analog-to-digital conversion is applied to much slower waves after the sampling and time transformation. In this approach, a pretrigger pulse is required; it is obtained either from the tested signal before the delay line and the sampler, or from a separate source whose output wave follows the trigger.
- Random interleaved sampling digitizers sample repetitive signals in a pseudorandom manner. The amplitude and timing data are digitized and memorized in corresponding memories.

All three digitizers can equally well acquire periodic signals. In the last two approaches, only a single sample can be taken

Figure 8. Vertical system of a coherent sampling oscilloscope.

Figure 9. General block diagram of a digital oscilloscope.

during the input signal cycle, especially at low frequency of the input signal. Only real-time digitizers can acquire single short transient events. In some scopes, such as the HP 54600A, the random interleaved sampling digitizer can capture low-speed single events. The real-time signal capture capability of most digital scopes is limited by the maximum sampling rate, which is directly associated with the maximum speed of the analog-to-digital converters. The inherent storage capability of digital scopes, especially the possibility of storing long records of several channels, allows one to process the signals with complex mathematical operations, including statistical functions (5–7). When the oscilloscope calculates the fast Fourier transform (FFT) of the input signal, the frequency spectrum of the signal can be displayed versus frequency separately from the time-domain signal image. A typical block diagram of a two-channel digital storage scope (DSO) is shown in Fig. 9. The channels acquire and digitize the signals independently, and then the digital signals are accumulated and processed according to the chosen function. In the simplest case, the digitized signals are retrieved from the memory, converted back into their analog forms by the digital-to-analog converters, and displayed. The reduced speed of the signal display processes eliminates the need for high-frequency CRTs. Some scope displays utilize liquid crystal display (LCD) tubes, which are directly controlled by addressing the picture elements (pixels) of a display matrix. Analog scopes of this kind can update their pictures about 10^5 times per second. Time changes in the signals are then recorded immediately. The display of a typical digital storage scope is usually a memory reconstruction of the acquired samples taken from many periods, so the entire image can be acquired only 5 to 100 times per second. High quality of the picture display of analog scopes requires rather high frequency of image updates. Such update frequencies are not available when the signal is not repeated frequently. Some digital storage scopes with high-speed digitizers and processors, and with smart display algorithms, update their displays by creating high-quality *analog persistence* images over a broad range of signal frequencies (6). The number of samples displayed on the screen is fixed independently of the time-base settings, which leads to changes of the sampling rates for different time bases. In order to reproduce periodic waves, taking five to ten samples per period of the highest harmonic is regarded as the minimum for sufficient signal detail. The Nyquist sampling rate is too low to reconstruct periodic signals in all cases, especially when the signals are sampled near the zero crossings. Major features of the digital storage scopes can be summarized as follows:

- Large amounts of pretrigger information can be acquired without using delay lines.
- Single or repetitive waves can be stored permanently.
- Computer or printer interfacing to store or print more data can be easily achieved.
- One may reliably capture unpredictable events.
- One may reliably capture glitches shorter than the resolution time by means of peak detectors.
- Within the memory capacity, there is no dead time between acquired events.
- Measurements can be automated.

- Currently acquired waves can be compared with reference waves.
- Wave tolerance tests are possible, including go–no-go tests.
- Acquired waves can be processed mathematically, including statistical operations.
- Finite resolution and a small number of display sweeps per second can mask the time distribution of waveforms.
- The limited number of samples and the constant sample intensity commonly used in displaying simple repetitive waves can distort composite repetitive signals, including waves of various speeds.

TECHNICAL PARAMETERS AND LIMITATIONS

This section describes basic parameters of the oscilloscopes to help select the right one for an application. In the selection process, the scope parameters must be related to the waves under test. The major specifications of analog scopes are number of channels, bandwidth, voltage sensitivity, maximum time-base speed, amplitude noise, time jitter, and overall accuracy. From these parameters other scope features can be derived. For digital scopes, the basic parameters also include maximum sampling rate, vertical and horizontal resolution, and memory length.

Number of Channels

Common-purpose single-channel scopes are not very popular in measurement laboratories. If the number of channels is greater than one, the interchannel interference becomes important and a high common-mode rejection ratio (CMRR) is desired. For example, if $\text{CMRR} = 40 \text{ dB}$, then with one channel receiving a signal of 1 V and the other channel receiving a signal of 10 mV, the lower-amplitude channel will measure the amplitude with an error of about 10%, which is well above scope error specifications.

Bandwidth

The bandwidth (BW) is usually defined as the frequency range between dc and the frequency at which a sinusoidal signal amplitude observed on the screen is reduced 3 dB in relation to the value at dc or low frequencies. The input sinusoidal signal is supplied from a source having very low internal resistance, perhaps 50Ω . The bandwidth of an analog scope is primarily determined by the frequency response parameters of its vertical amplification channel, including attenuators and the tube. The magnitude response error introduced by the frequency limitations is shown in Table 1. The frequency response bandwidth relates to an equivalent time-domain parameter, namely, the rise-time, usually considered as the time the step response changes between 10% and 90% of the steady-state level. For the simplest frequency response approximation, the relationship between

Table 1.

Signal Freq. for -3 dB BW (MHz)	Error (%)
0.1	1
0.2	2
0.5	11
1.0	29

Table 2.

T_R^a (ns)	T_T (ns)	T_0 (ns)	Error (%)
3.5	1	3.6	260
3.5	2	4	100
3.5	5	6.1	22
3.5	10	10.6	6
3.5	20	20.3	1.5

^a BW 100 MHz.

the risetime and the bandwidth is as follows:

$$T_R = \frac{0.35}{BW} \quad (1)$$

For instance, for a 100 MHz scope the response time is 3.5 ns. This leads to time-domain measurement error, whose effects can be corrected for using the following expression:

$$T_T = \sqrt{T_0^2 - T_R^2} \quad (2)$$

where

T_T = actual risetime

T_0 = measured risetime

T_R = scope's own risetime

Table 2 shows the time-domain error calculated without correction.

Both tables suggest that in order to maintain reasonable measurement accuracy, the scope should be at least several times faster than the fastest tested wave. Frequency-domain or time-domain speed limitations of digital scopes are additionally imposed by the sampler sampling speed and the analog-to-digital (ADC) converter speed. The sampler includes the sample-and-hold unit, whose sampling pulse width determines the fastest change that can be captured and later converted in the ADC. Faster digital scopes using flash or parallel analog-to-digital converters have their sample and hold function performed by the sample clock after conversion. In this way,

the changes of the input signal continuously translated into the digital representation do not affect the sample position on the scope screen, so the sample is observed as a dot. With ideal sampling pulses, the sampling rate should be several times larger than the expected maximum frequency of the tested signals. The sampling rate also determines the scope horizontal resolution.

Vertical Sensitivity

This parameter expresses the scope's ability to accommodate small signals as well as large signals within the same space on the screen. Typical ranges of scope sensitivities are between several millivolts per division and 20 V per division. The sensitivity range is a compromise between the user's desired values and the technical limitations imposed by the noise level of the scope amplifiers and the maximum available attenuation of high-frequency compensated attenuators.

Amplitude Noise Level

The scope noise mainly includes the broadband noise generated by the input stages of the scope and by the source resistance. The observed noise levels are usually on the order of 1 mV. Bandwidth reduction decreases the noise level and allows one to increase the scope sensitivity. In digital scopes, the input analog amplifiers introduce their noise, thus degrading the resolution of the ADC conversion process. For example, 1 mV noise on a 1 V signal limits the resolution of the conversion to less than 12 bits.

Time Jitter

Time jitter is caused by threshold instabilities in triggering and time-base circuits. The jitter is observed on the screen as a spread of vertical parts of the tested signals. In digital scopes, the clock jitter is also added. The levels of jitter are on the order of picoseconds for fast sampling scopes, and on the order of nanoseconds for low-frequency scopes.

Accuracy

The inaccuracy of a scope comprises mainly vertical and horizontal calibration and reading errors. The reading errors of digital scopes, with built-in digital amplitude and time meters, are negligible in comparison with calibration errors of amplifiers, voltage attenuators, and input resistors. The total amplitude error can reach several percent, but the dc voltage error can be as low as one percent. The time-base errors in digital scopes are comparable with the errors of digital

Figure 14. High-input-resistance high-voltage probe.

counters, which are below 0.1% (7), while the time base errors in analog scopes are usually 2% to 5%. The process of selecting a scope is primarily determined by information about the waves under test: their shapes, repetitivity, frequency and amplitude, drift, and speed. Additional conditions that should be considered are the length of the record, possibility of test automation, signal statistics, and wave storage. The scope's capabilities and parameters should be also chosen with regard to future applications and affordability.

OSCILLOSCOPE PROBES

Almost all standard oscilloscopes use different voltage probes to connect to a circuit or a device under test, chosen to minimize the effects of the scope input impedance and electromagnetic interference. Some probes convert a nonelectrical quantity or another electrical quantity, such as current, into a voltage, which is measured by the scope. Two major types of voltage probes are used. The first type is a passive probe, which yields high input resistance and low input capacitance but introduces significant signal attenuation, usually ten times. The second type is an active probe, which does not attenuate the signal but provides high input resistance and low capacitance. Unfortunately, the supply voltage required for active probe devices also introduces undesired noise and offset. Active probes usually employ field effect transistors and operational amplifiers (8). A typical voltage probe has two terminals: a signal terminal and a ground terminal. In many cases, tests of differential signals cannot be done by means of two-channel differential measurement, due to the limitations of the CMRR. For these tests, differential active probes, which have very high CMRR, are recommended.

Passive Probes

Passive probes include low-impedance resistive voltage-divider probes and compensated high-impedance voltage-divider probes. There are also high-impedance probes with

Figure 15. Diagram of an active probe.

a very large voltage division factor, which are used in high-voltage measurements. Figure 10 shows a low-impedance passive probe. This type of probe has very low capacitance loading and wide bandwidth. It can be used in testing low-impedance circuits. High-impedance passive probes are shown in Figs. 11 and 12. In both cases, the probes require compensation before the measurement processes start. The compensation is performed by observing a standard square wave signal generated by the scope calibrator. The effects of the pulse compensation on the square wave and the sine wave are shown in Fig. 13. High-voltage probes have similar structure to that in Fig. 13. The series resistor is of much higher value and larger physical size, to withstand voltages higher than 500 V. A high-voltage probe circuit is shown in Fig. 14.

The parameters of passive probes are

- Voltage attenuation (e.g., 10× or 1×)
- Bandwidth for 50 Ω source resistance
- Maximum input voltage (e.g., 500 V)
- Input resistance (e.g., 1 MΩ)
- Input capacitance (e.g., 2 pF)

Active Probes

Figure 15 is a diagram of an active probe with a single input. A differential probe is shown in Fig. 16. Both probes have very large input resistance, broad band, and no attenuation. The differential probe also has high CMRR, greater than 60 dB.

OSCILLOSCOPE MEASUREMENTS

Scopes can measure the following basic quantities:

- Voltage
- Current (with a current probe)
- Frequency and time, including period, time delay, pulse width, and duty factor
- Phase shift
- Rise and fall times
- Amplitude modulation index
- Jitter

Voltage

Voltage measurements are elementary tests done with oscilloscopes. Dc voltages are measured by observing the level shift

Figure 16. Differential probe.

of the horizontal line on the screen. The screen graticule and the vertical sensitivity setting indicate the amount of the shift. Some scopes have internal digital voltmeters indicating numerical values of the beam position and the positions of the different markers. Ac voltages, in older analog scopes, are measured in terms of the voltage differences, which are calculated with the aid of the graticule. In modern scopes, the marked levels are measured digitally and displayed numerically on the screen.

Current

Current measurements require the use of current-to-voltage converting devices, such as Hall effect sensors for dc currents, current transformer clamping sensors for ac currents, or combinations of both. The Hall effect current sensors are supplied from the scope or from a separate power supply, which also incorporates additional amplifiers.

Frequency and Time

With older scopes, the time-domain parameters can be measured using the screen reading in relation to the current time-base setting. Modern scopes, especially digital, have digital readout and display the time-domain parameters with reference markers. Rise and fall times are measured with the help of horizontal levels marked at 10% and 90%. Figure 17 illustrates the way the risetime is evaluated.

Figure 17. Measurement of the risetime.

Phase Shift

The phase shift between two waves is the amount of time, expressed in degrees, that passes between the beginnings or other selected points of the two waves. The phase shift is thus obtained from two time measurements in which the waves' relative position and period are found, followed by computations.

Another method, which can be used only for coherent sinusoidal signals, involves the XY display mode. One signal is applied to the horizontal channel, the other to the vertical channel. The XY figures displayed on the screen are called Lissajous patterns, and from the shape of the pattern the phase shift and frequency can be determined. Figure 18 shows different Lissajous patterns.

Amplitude Modulation Index

Figure 19 shows a time-domain AM wave displayed on the screen while the external triggering of the scope is synchronized by means of a modulated lower-frequency wave. The modulation index is calculated as a ratio of M to C . It is also possible to display an XY pattern in which the modulated wave is

Figure 18. Phase measurement applying XY display.

Figure 19. Time-domain measurement of the AM modulation depth (index).

applied to the scope vertical system, and the modulating signal is applied to the horizontal system. Figure 20 shows a typical AM wave pattern for this method.

Jitter

Jitter measurements are based on repeated readings of the time between the two repeated signal edges. The oscilloscope trigger jitter contributes to the jitter value observed on the screen. Analog scopes, even with long persistence, do not display repetitive waves with jitter in such a way that meaningful jitter evaluation is possible. Digital storage scopes with computer processors and statistical packages display waves with their intensity or colors related to the number of repetitions, thus revealing the frequency of occurrence of different cycles of the same wave. Some scopes (3) can display histograms computed from the samples. Statistical parameters, such as the

Figure 20. Measurement of the modulation depth (index) applying XY display.

standard deviation of the sample histogram or other time-domain and amplitude-domain statistical measures, can be computed.

PROGRAMMABILITY OF OSCILLOSCOPES

Most modern digital scopes can be controlled by computers. The computer provides more flexibility in storing data and programming experiments. Advanced interfacing techniques involve applications of GPIB (GPIB, IEEE-488) cards and connections controlled by the dedicated software, like HPVVEE of Hewlett Packard, or LAB VIEW of National Instruments (9,10).

ELECTRICAL VARIABLES

CHARGE MEASUREMENT

A charge is one of the fundamental quantities of electricity for which the unit is C (coulomb). One C is the total charge delivered by a current of one A for one second. Although it is generally difficult to measure the quantity and distribution of charges, they are measured by converting the charge quantity into voltage, current, light, or sound. The movement of a charge generates current and electromagnetic waves. This section, however, describes how to measure a static charge.

Here is a simple example of a parallel plate. When x is the position in the depth direction of the sample, the internal static charge $\rho(x)$, electric field $E(x)$, and potential $V(x)$ have the following relationships:

$$E(x) = \int \rho(x) dx / \epsilon_0 \epsilon_r \quad (1)$$

$$V(x) = - \int E(x) dx \quad (2)$$

Thus electric field and potential distributions are calculated by obtaining the charge distribution. For a capacitor whose capacitance is C (F), a simple example, the unknown charge quantity is obtained by measuring the potential difference as

$$Q = CV \quad (3)$$

TOTAL CHARGE MEASUREMENT

The Faraday cage is useful for measuring the total charge of an electrified material. As shown in Fig. 1, the cage has two baskets insulated from each other, and the sample is put in the internal basket. An integrated circuit with an operational amplifier is connected to both baskets. The capacitor of the integrated circuit stores the same amount of charge as the sample. The total charge quantity is measured by Eq. (3), where C is the capacitance and V is the output voltage of the integrated circuit.

Figure 1. Total charge measurement by a Faraday cage.

SURFACE-CHARGE MEASUREMENT

Potential Probe Measurement

The surface charge of a triboelectrified sample is measured by detecting the surface potential. When the sample is a uniform plate, such as a plastic film, the capacitance per unit area should be constant, and the surface potential is proportional to the surface-charge, based on Eq. (3). The surface charge distribution is observed by detecting the surface potential. This is done by scanning the surface with a probe of a surface potential meter, as shown in Fig. 2.

Electro-Optical Surface-Charge Measurement

Figure 3 shows direct surface-charge measurement without scanning the surface. This optical measuring system uses a crystal in which an electro-optical effect occurs, for example, BSO:Bi₁₂SiO₂₀ or BGO:Bi₁₂GeO₂₀. When a charge accumulates on the surface of the crystal, an electric field is generated inside it. Because of the electric field, the crystal has birefringence, and so the linearly polarized light incident on the crystal becomes elliptically polarized light with retardation θ and permeates an analyzer. The intensity of the incident light I_0 and permeated light ΔI have the following relationship:

$$\theta = K\sigma \quad (4)$$

$$\Delta I / I_0 = \sin^2(\theta/2) \quad (5)$$

where K is the Pockels constant of the crystal, which is determined by the thickness, dielectric constant, and wavelength of the light and σ is the surface-charge density on the crystal. Thus, surface charge distribution is obtained by measuring the distribution of ΔI with a photodetector. When θ is small, however, it is difficult to measure the real surface charge because

Figure 2. Surface-charge measurement. The charge distribution can be observed by detecting the surface potential with a potential meter probe.

Figure 3. Direct surface-charge measurement without scanning the surface. This optical measuring system uses a crystal which produces an electro-optical effect.

insignificant leakage light generates an output signal even if there is no surface charge. In this case, a two-dimensional lock-in amplifier is used to measure the real surface charge (1). The lock-in amplifier modulates the signal to be measured and detects the synchronized component with the modulation period. Because this equipment detects very small signals, it is widely used in scientific research. The two-dimensional lock-in amplifier is an example of its application for detecting two-dimensional signals, such as images. Figure 4 shows a measurement system. The incident light is phase-modulated by applying a square voltage to an optical phase modulator made of BSO or other crystals that produce an electro-optical effect. Then, retardation θ becomes one of the following two values, alternatively:

$$\theta = K\sigma + \Delta\theta \text{ and } K\sigma - \Delta\theta \quad (6)$$

Then we calculate the difference between light intensity $\Delta I'$ in the case of $\theta = K\sigma + \Delta\theta$ and $K\sigma - \Delta\theta$. Because the same amount of leakage light exists in each case, the difference is independent of the leakage light and is given by

$$\Delta I' / I_0 = \sin(K\sigma) \sin(\Delta\theta) \quad (7)$$

Assuming that $\Delta\theta$ equals $\pi/2$, then $\Delta I'$ indicates the surface-charge distribution directly when the charge density σ is low. A two-dimensional lock-in amplifier is used to store the difference of two synchronized images in a computer. Averaging a lot of images results in a high signal-to-noise (S/N) measurement.

Figure 5 shows the surface-charge distribution on a BSO crystal. It displays the surface discharge obtained by applying an impulse voltage to a needle electrode on the surface of the crystal. This figure shows that a treelike charge pattern remains on the surface in the case of a positive discharge. In the case of a negative discharge, on the other hand, the charge pattern is round. In this way, the electro-optical measurement system with a two-dimensional lock-in amplifier directly observes the accumulation of charge changing with time.

SPACE-CHARGE MEASUREMENT

Pressure-Wave Propagation Method

In general, there are two ways to obtain a pressure wave: a piezoelectric device and a pulse laser. This section introduces the laser-induced, pressure-wave propagation method,

Figure 4. Two-dimensional lock-in amplifier system for surface-charge measurement.

Figure 5. The surface-charge distribution on a BSO crystal. This figure shows that a treelike charge pattern remains on the surface after a positive discharge. With a negative discharge, on the other hand, the charge pattern becomes round.

which has better spatial resolution of the charge distribution and signal-to-noise ratio (2). A plate sample is placed between two electrodes, as shown in Fig. 6. When an extremely narrow-pulse laser (<1 ns) is used to irradiate the grounded electrode on the left, the electrode surface rapidly expands by being heated and then generates a pressure wave. The pressure wave passes through the left electrode and propagates in the sample at the velocity of sound v (typical polymers have sound velocities of 2000 to 3000 m/s). The pressure wave compresses a limited part of the sample. When this pressure wave passes through the position where an internal charge exists, the charge is forced to move right and left, resulting in a current pulse flowing through the conductor connected to both electrodes. The magnitude and direction of the current pulse represent the charge quantity and polarity, respectively. The

Figure 6. Laser-induced pressure-wave propagation method for space-charge measurement.

Figure 7. Space-charge distributions in an XLPE sheet measured by the laser-induced, pressure-wave propagation method.

delay from the application of the pressure wave to the current pulse generation indicates the position of the internal charge. These relationships are shown in convolution as the following equation:

$$i(t) = A \int \rho(\tau) p(t - \tau) d\tau \quad (8)$$

where $p(t)$ is the pressure wave generated by the pulse laser, $\rho(t)$ is the space-charge distribution, and $i(t)$ is the current between both electrodes. Here, $p(t)$ is an extremely narrow independent pulse, so that the pulse is regarded as the delta function, and Eq. (8) is simplified as

$$i(t) = A' \rho(t) \quad (9)$$

where A and A' are sensitivity constants depending on the strength of the laser-induced pulse. Thus the waveform of the current shows the charge distribution directly. When the width of the laser-induced pulse is 100 ps, the spatial resolution of the internal space charge becomes less than 1 μm . The disadvantage of the pressure-wave propagation method is that the amplifier in the measurement system is destroyed when surface discharge on the sample or sample breakdown occurs during radiative exposure or high voltage applications.

Figure 7 shows the space-charge distribution in cross-linked polyethylene (XLPE) measured by the laser-induced, pressure-wave propagation method (3). Because XLPE has higher thermal endurance than polyethylene, it is widely used for insulating power cables. The space charge was measured in the 150- μm XLPE film at 60°C under a 120 kV/mm dc electric field. Negative charge appeared near the anode just after the voltage was applied.

Pulsed Electroacoustic Method

The pulsed electroacoustic (PEA) method detects the space-charge distribution by a process opposite to that of the pressure-wave propagation method mentioned previously. A schematic diagram of the PEA method is shown in Fig. 8. When a narrow-pulse voltage is applied to the sample between the two electrodes, a pulse electric field is generated in the sample. This electric field $e_p(t)$ makes the space charge $\rho(x)$ generate a pressure wave because of its electrostatic force. The pressure wave propagates in the sample and the grounded electrode, and then the piezoelectric device under the grounded electrode changes it into an electric signal $v(t)$. The magnitude and direction of the pressure wave determine the quantity and the polarity of the charge. Because the delay appears when the pressure wave

Figure 8. Pulsed electroacoustic (PEA) method for space-charge measurement.

propagates from the position of the charge to the piezoelectric device, as in the pressure-wave propagation method, the space-charge distribution $\rho(x)$ can be observed by using the sound velocity of the sample as follows.

The pressure wave $p(t)$ generated in the sample due to the applied electric field is given by

$$p(t) = A \int \rho(\tau) e_p(t - \tau) d\tau \quad (10)$$

where $\rho(t)$ is the space-charge distribution, $e_p(t)$ is the pulse electric field applied to the sample, and A is a constant depending on the dielectric constant, the sound velocity, and the density of the sample. Then the output voltage of the piezoelectric device $v(t)$ is given by

$$v(t) = \int k(\tau) p(t - \tau) d\tau \quad (11)$$

where $k(t)$ is a specific function of the piezoelectric device and is a square function whose height and width depend on the sensitivity and thickness of the device. When the piezoelectric device is so thin that the width of $e_p(t)$ is narrow enough, both $e_p(t)$ and $k(t)$ are regarded as individual pulses similar to delta functions. In this case, $p(t)$ equals $A\rho(t)$, and Eq. (11) is simplified as

$$v(t) = A'\rho(t) \quad (12)$$

Thus, the waveform of the output signal indicates the space-charge distribution. Although this method has slightly poor spatial resolution, it has the advantage that the measurement system is never destroyed when a discharge occurs at any place because the detection circuit is electrically insulated from the other parts of the electrode system, such as the high-voltage bias circuit. In particular, a system with an optical fiber for the output signal cable can carry out the space-charge measurement even during a dc breakdown test at 500 kV.

Figure 9 shows the time dependence of the space-charge distribution of XLPE (100 μm) under 10 kV. A packet charge is injected from the anode just after the voltage application, and it moves toward the cathode. Because the charge injection decreased the interface electric field at the anode, the next injection did not occur.

Figure 9. The time dependence of the space-charge distribution of an XLPE (0.1 mm) sheet under 10 kV. A packet charge is injected from the anode just after the voltage application, and it moves toward the cathode.

Deconvolution Signal Processing

As shown in Eqs. (8) and (11), the space-charge measuring methods mentioned previously detect a signal that includes a lot of factors, such as the waveform of the laser pulse, the waveform of the applied pulsive voltage, the frequency characteristics of the piezoelectric device and amplifiers, and so on. These unknown factors should be compensated for to avoid errors with a deconvolution technique by using a reference signal (5). In general, when the measurement system keeps its linearity, the input and output signals have the following relationship of convolution,

$$Y(f) = H(f) * X(f) \quad (13)$$

where $Y(f)$ and $X(f)$ are the Fourier-transformed signals of $y(t)$ and $x(t)$. In the measurements described, $y(t)$ is the output voltage of the amplifier observed by the oscilloscope, and $x(t)$ is the space-charge distribution $\rho(x)$. The sign $*$ is the function to multiply those components whose frequencies are the same. $H(f)$ is the transfer function of the measurement system obtained by Fourier transformation from the impulse response of the system. Here the impulse response is obtained as follows.

When a dc voltage is applied to a sample without internal charge, such as a PET film, the charge distribution becomes the same as the sheet charge on both electrodes of a parallel plate capacitance. The signal due to the accumulated charge on the one side can be regarded as an impulse (delta function) with no width in the depth direction, resulting in the impulse response itself. Because the accumulated charge q_0 is calculated easily, the Fourier-transformed Q_0 becomes a constant, independent of the frequency. When the first peak included in the output signal is described as $v_0(t)$, the Fourier-transformed $V_0(f)$ becomes

$$V_0(f) = H(f) * Q_0 \quad (14)$$

$$V(f) = V_0(f)/Q_0 * R(f) \quad (15)$$

Then, in general,

$$R(f) = Q_0 V(f)/V_0(f) \quad (16)$$

This equation, a division at the frequency region that is deconvolution, represents the Fourier-transformed, space-charge distribution. Thus, the real charge distribution is calculated by inverse Fourier transformation of $R(f)$. In practical analysis, a low-pass filter is needed to reduce the noise and division by zero in the high frequency region.

ELECTRIC CURRENT MEASUREMENT

Current measurements are used to monitor, control, and protect relaying. Current measurements are often the basis for estimating many other physical quantities. Electric current is measured in amperes. It is a measure of the rate of flow of electrons. Traditional direct measurement methods are based on passing the current through a measuring device. Although the device is not supposed to alter the current, direct measurement methods are generally intrusive by their very nature. The indirect measurement methods are based on measuring an effect of the current flow.

The galvanometer is an electromechanical device invented around A.D. 1794. It is based on measuring a magnetic field caused by a current flow. A sensitive magnetic needle deflects in response to the current through a coil. The galvanometer is the basis for many modern display meters.

Electric current measurement techniques have evolved through the years. The developments have addressed the need for better current transducers, for measurement of very large, very small, very fast, and very high voltage currents, and for measurement of current in unapproachable areas, like the human body and inside motors.

Maintenance of a current standard is not as straightforward as that for a resistance, mass, length, and the like. This is due to the fact that current measurement is intrusive by the very nature of the quantity. The earlier current standard was based on the Kelvin current balance (1). The balance is based on four fixed coils and two suspended coils all carrying the same current. The torque produced on the moving coils is

balanced by precise weights. An indirect current standard based on the voltage standard and the resistance standard has better acceptance.

CLASSICAL MEASUREMENT METHODS

Techniques (1,2) based on magnetic field, electric field, and heat have been in existence almost since electricity was discovered. They were basically designed for steady currents. The devices could also measure current variations slowly enough to be visible to the human eye. The dc (direct current) measurement was the standard. When ac (alternating current) was introduced, many of the dc instruments were adapted to measure equivalent dc currents.

Magnetic Field

Current flow in a conductor creates a magnetic field around it. This is called the Hall effect. The magnetic field is concentrated by allowing the current to pass through a coil. A ferromagnetic material experiences a mechanical force when placed in a magnetic field. This force is converted to a torque, and an indicator is allowed to move. This movement is used to measure the current flowing through the coil. This principle is the basis of a galvanometer. The galvanometer is still a common method for current measurement.

The wire resistance, wire inductance, and induced currents in other metal parts cause a burden on the measuring circuit. The burden can alter the current being measured. Several refinements have been made to increase sensitivity and reduce the current being diverted through the measuring circuits. Refinements include delicate balancing, use of springs for damping, and use of permanent magnets to amplify the response. If the current is alternating or varying very fast, the indication is the mean value. This method is suited for measuring the steady or average direct current. A common way of measuring alternating current is to use a rectifying bridge to measure the mean value of each half cycle. The mean value of half cycle of a pure sine wave is about 0.9 times the root mean square of the full cycle.

Electric Field

An electric potential creates an electric field around it. At normal voltages, the electric field is too small to be measured accurately by an electromechanical method. Instruments to measure the electric field have usually been very costly. Traditional voltage-measuring techniques have relied on measuring a current proportional to the voltage. At very high voltages, the electric field can be high enough to permit reliable measurements. The principle used is that there is a force of attraction between surfaces charged at a high voltage and surfaces at ground potential. This force is used to actuate sensitively balanced needles or mirrors. The resulting motion gives a measure of the voltage. This is an expensive method of very low intrusion and suitable for very high voltages.

Heat

The flow of current through a resistance results in part of the electric energy being converted to heat. The amount of energy

Figure 1. Current shunt.

converted is proportional to the square of current. If the current to be measured is made to flow through a thin wire, the heat expands the wire. The expansion can be made to actuate a needle or some other mechanical position indicator. The indication is a measure of the mean square of the current. Instruments based on heat is immune to ambient electromagnetic fields. However, their accuracy is affected by the ambient temperature and will need recalibration to account for this.

CURRENT TRANSDUCERS

It is often not practical to allow the current to be measured to flow through the measurement circuit. Two common methods to divert a small current proportional to the current to be measured are resistive shunts and current transformers. Rogowski coils and optical and wireless methods are some of the novel transducing techniques. A combination of these techniques is often proposed as the optimized solution offering advantages in special situations.

Resistive Shunts

A shunt is used to divert a small portion of the current into a measuring circuit. See Fig. 1. The diverted current is proportional to the unknown current. The effect on the unknown current is thus minimized. The resistive shunts are simple in concept and are widely used for steady direct current and steady alternating current as well as transient currents. The shunts should have very low resistance to minimize dissipated power. Their inductance should be negligible while measuring ac and transients. Typical values of shunt resistors are from 1.0 Ω to 0.01 Ω .

Current Transformers

Current transformers (CT) are the most versatile transducers for use in alternating current measurement. See Fig. 2. They are based on the existence of a magnetic field around any current-carrying conductor, which is called the Hall effect. They are used with currents up to 5000 A and 1000 Hz. frequency in power systems. These provide acceptable performance up to 1000 A. At higher levels, they suffer from drift problems and core saturation. They may need compensation methods while measuring harmonic currents much higher than 1000 Hz. An acceptable level of electrical insulation is required between the

Figure 2. Current transformer.

Figure 3. Rogowski coil.

CT and the high-voltage connection. Any measuring device connected to the secondary of the CT causes a burden on the main current flow. The burden should be as small as possible to avoid altering the current. For a given primary current, the burden is proportional to the core flux. Large lead distances increase the burden. High voltages require thick insulation and a large distance. Thus the use of conventional CT becomes very difficult at high voltages.

A current transformer cannot be used in direct current measurement. However, a proposed method (3) uses the effect of direct current and the magnetization curve of a transformer on its inductance characteristics. An *RL* multivibrator circuit with a nonlinear transformer is used to produce a voltage representing the current to be measured.

Rogowski Coils

The principle of Rogowski coils (4) has been well known since 1912. The Rogowski coil is a solenoidal air core winding of a small cross section looped around a conductor carrying the large transient current. The voltage induced across the terminals of the coil is proportional to the derivative of the current. The induced voltage is also proportional to the number of turns. See Fig. 3. The principle of using a Rogowski coil for current measurement is illustrated in Ref. 5. If the Rogowski coil is connected to a passive *RC* network (6), integrated effect of the voltage induced can be measured. That gives a measure of the current in the main conductor.

Rogowski coils can respond to rise times of a few nanoseconds. They have a decay time of several microseconds. They usually have been used for the measurement of very large currents such as hundreds of kiloamperes, which last for a very short duration, such as less than a microsecond. Such currents occur in electron beam accelerators and transient plasmas. They have the advantages of having a very fast response time and being free from nonlinearity and saturation effects.

Rogowski coils are not preferred for small currents because the voltage induced is small. Another disadvantage is the loss of an initial value caused by the integration process. The cost of Rogowski-coil-based current measurement is very high. A Rogowski coil with an operational amplifier integrator (7) has been shown to measure power system currents of the order of 500 kA.

Optical Transducers

The optical measurement of current (8,9) is recognized as a viable option in power systems. It has the following advantages:

Figure 4. Pockels effect.

- Better immunity to ambient electromagnetic and electrostatic fields. They may be the only option in high electromagnetic field areas.
- Better linearity than iron core transformers. The accuracy can be substantially better.
- A high degree of isolation for safety of instruments and personnel. They are suitable for very high voltages.
- Suitable for very frequency and fast current changes.

There are various ways of implementing the optical transducer–decoder functions.

- A polarized light beam changes its plane of polarization when it passes through a magnetic field. This is called the Pockels effect. See Fig. 4. Several measurement methods based on Pockels effect have been developed (10). Optical elements like crystals, glass blocks, and fibers (11) have been used for sensing the polarizing effect of the magnetic field surrounding the electric current flow. A fiber-optic cable transmits the optical signal from the transducer to a decoder. The detection at the decoder end requires a polarization decoder.
- A polarized light beam changes its plane of polarization when it passes through an electric field. This effect was reported by Michael Faraday in 1845. This has generally been used for measuring high voltages (12,13). A method for measuring small dc currents on the order of nanoamperes to milliamperes at high voltages is presented in Ref. 14.
- In magnetostriction, the sizes of certain materials change as a result of magnetic field. A light beam reflected by or passing through such a material can produce light interference patterns caused by the phase difference. The interference will depend on the magnetic field, which in turn depends on the current. The interference pattern will give a measure of the current. A fiber-optic cable transmits the optical signal from the transducer to a decoder, which analyzes the interference pattern of the light received.
- Another method modulates the frequency of an inexpensive light emitting diode (15) and transmits that signal via an optical fiber. This approach avoids sensitive and expensive polarization coding and decoding process. An active electronic circuit, placed at the site of the high-voltage conductor, generates a voltage signal of several hundred kilohertz. The frequency deviation of the signal is proportional to the amplitude of the current. This voltage is used to activate a light emitting diode (LED). The optical fibers carry the signal to a ground station. A

photodiode responds to the optical signal and reproduces the signal at the same frequency. Another active electronic circuit at the ground station produces a voltage proportional to the frequency deviation. This voltage gives a measure of the current in the high-voltage conductor.

- Chromatic modulation (16) produced using a liquid crystal is the basis for another method. A current transformer placed on the high-voltage line and a current-to-voltage converter provides a voltage proportional to the line current. A broad band light source illuminates the liquid crystal elements of a modulator. The liquid crystal modulator attenuates a portion of the light source spectrum by an amount depending on the voltage. This light is picked up an optical fiber and brought to a ground station. The decoder consists of a double layer photodiode, with different but overlapping spectral sensitivities. The ratio of the currents produced by the photodiodes is measured with an analog-to-digital converter. This gives a measure of the current in the power line.

Transducers with No Physical Connection

Measurement of current with absolutely no physical connection has enormous advantages in cost and safety. The following methods are still being studied.

- A novel optical method eliminates (17) the use of the fiber optic connection itself. It proposes the use of a laser beam and the Faraday/Pockels effect. The reflected laser beam is used to estimate the current.
- Another method is to locate an active current-measuring device at the high-voltage level and transmit the measurement via radio frequency to a base station several meters away. There are several variations of the transmitted signal and the method of transmission. Recent developments in digital communications area have created new opportunities for investigating this approach.

CURRENT MEASUREMENTS IN SPECIAL SITUATIONS

Different measurement techniques offer different advantages and disadvantages under special circumstances. The costs can vary enormously. Some of the special situations and the preferred techniques for current measurement follow.

Currents Measurement Inside the Human Body

Human sensation of current is the combined effect of the duration, intensity, and frequency. Guidelines for limiting currents induced in the body for the frequency range of 3 kHz to 300 GHz are available (18). Electromagnetic pulses of 10 A may cause no sensation, and 100 A produces only a tingling sensation. However, steady current threshold of human body is much lower. The effect of induced currents at power frequencies is a matter of ongoing study. The steady currents induced in human body are on the order of milliamperes. The measurement techniques are less disturbing to the person and cause minimal change in the value being measured. Such techniques (19) have been developed for measurement of current in the 1 MHz to 200 MHz range.

Harmonic Current Measurement

The harmonics give a measure of the deviation from a pure sinusoidal waveform. Harmonic voltage measurements have been used as a measure of the quality of voltage in power systems. Harmonic current measurements are essential for apportioning the responsibility (20) for harmonic distortion. Conventional current transformers may not offer a sufficiently wide frequency range. An electronic technique (21) for reducing the flux in the magnetic core, thereby increasing the frequency response, has been developed. Another technique (22) reduces the flux by using two toroidal coils with opposing fluxes to have a similar increase in performance.

High-frequency currents tend to flow near the surface of conductors. Thus the resistance of the conductor varies with the frequency. Methods to compensate for the effect by analytical means (23) as well as by mechanical design (24) have been proposed.

Post Arc Current Measurement

There are arcs during circuit breaker operation, and the currents are usually high. Yet there is a current activity of milliamperes range around the zero crossing immediately following an arc. These currents provide valuable insight regarding the condition of the switchgear. The measurement sensor under these conditions must measure milliamperes with a megahertz bandwidth, without being damaged during high currents. A technique (25) automatically inserts and disconnects a measurement shunt very close to the zero crossing and measures such currents.

Motor Windings Current Measurement

There is no direct means of measuring the current in windings with no brushes. These currents are useful for control and monitoring purposes. They are estimated (26,27) using other measurable currents.

Lightning Current Measurement

Lightning-induced currents are a source of damage in electrical power lines and other conducting structures. Measuring the wave crest value and wave front duration is of interest in order to assess the damaging effects. The amplitude ranges up to thousands of amperes and the duration is on the order of a few microseconds. Some measurement results and techniques are reported in Ref. 28.

Measurement of Currents at High Voltage

The power line voltage necessitates isolation for safety purposes. Optical couplers are available for voltages up to 1000 V. These can be integrated in a circuit board along with other current-conditioning interfaces. High-voltage lines up to 1000 kV need additional levels of safety isolation interfaces. Highly insulated current transformers are commonly used in substations. They are bulky and expensive. Copper winding, iron core CT has been in successful use for 100 years. During that time, several refinements to the design have been made to improve safety and reduce failures (29). The optical (12) and wireless methods offer a great advantage at very high voltages.

Measurement of Large Currents

It is sometimes inconvenient or impossible to dismantle a bus bar for insertion of a current transformer. For these situations there are clamp-on current transformers in which a clip opens the winding for manual insertion. After insertion, the clamp firmly closes the gaps in the winding. The reclosed gap affects the permeability of the magnetic core as well as the resistance of the copper winding. However, the error introduced might not be acceptable at high currents. An electronic technique to increase the permeability of the gap and thus reduce the error has been demonstrated (30). Direct currents up to 25,000 A are measured using permalloy magnetic modulation comparators (31,32). Another design to measure currents up to 100,000 A is discussed in Ref. 33.

Measurement of Small Currents

The currents in the femtoampere range occur often as leakage currents in microelectronics. A method for implementing an in situ amplifier to amplify the small current to measurable levels is illustrated in Ref. 34.

Measurement of Fast Varying Currents

Fast varying currents occur in electron beam accelerators and transient plasmas. Rogowski coils have usually been used for measuring very large currents such as hundreds of kiloamperes, which last for a very short duration, such as less than a microsecond.

K. SRINIVASAN

INDUCTANCE MEASUREMENT

Along with resistors and capacitors, inductors which are basically components with the property of inductance, are commonly used for building circuits for operating a wide range of electrical and electronic apparatus and instruments. The inductance parameter also inevitably enters the equivalent circuits of various electromagnetic devices and machines. Consequently, the need for inductance measurement arises in the characterization, design evaluation, and production tests of the relevant components and in the circuit modeling of electrical apparatus. Inductance measurement is also important in instrumentation systems where a physical quantity is sensed through its effect on the inductance of a transducer.

BASIC CONCEPTS, DEFINITIONS, AND UNITS

The Inductance Parameter

Inductance is the property whereby an electrical device sets up magnetic flux when current passes through it. In principle, any conductor of current has this property. However it is more pronounced in a coil of wire or any electrical device whose construction is akin to a coil. Taking the solenoid of N turns shown in Fig. 1(a) as representing a general situation, let a current of i amperes through it produce a magnetic flux of ϕ webers. For simplicity, if we assume that the closed path of every flux line is interlinked with all N turns, then the coil has flux linkages of $N\phi$ weber-turns. The inductance L of the coil, defined as the flux linkages produced in it per unit current, is measured in *henrys*. One henry corresponds to one weber-turn per ampere.

$$L = \frac{N\phi}{i} \quad (1)$$

Any physical device, such as the coil considered, which has the property of inductance, is called an *inductor*. It may also have other properties such as resistance and capacitance to a less

Figure 1. An inductor. (a) Physical configuration of a typical inductor. (b) Representation of a pure inductor as a circuit element.

consequential degree. If these other parasitic properties are absent, the device is referred to as an *ideal* or *pure inductor*. If the current i in an inductor and the flux ϕ produced by it are proportionally related, then the value of inductance as defined by Eq. (1) is constant and the inductor is *linear*. A *non-linear* inductor does not have a linear $N\phi$ versus i relationship and its inductance L , defined by Eq. (1), is a function of the current i .

An inductor is built in the form of a coil of good conducting material, usually copper, wound around a core of a nonmagnetic medium like air or a magnetic material such as iron. For the same core geometry, the inductance of a linear inductor is proportional to the square of the number of turns in the coil. Use of iron core permits larger values of inductance for a given inductor size but makes the inductor nonlinear because of the nonlinear magnetization characteristic of iron.

When the current i in an inductor varies, there is an induced voltage e in the inductor, which, according to Faraday's law of induction, is equal to the rate of change of its flux linkages, that is, $d(N\phi)/dt = [d(N\phi)/di](di/dt)$. This voltage acts in a direction opposing the change in i . For the coil in Fig. 1(a), if di/dt were positive, the induced voltage makes the coil behave like a voltage source driving a current in the local circuit in a direction opposite to that of i , that is, in a sense so as to arrest the growth in i . Terminal a then acquires positive polarity with respect to terminal b . For a decreasing i and hence a negative di/dt , the polarity is reversed. In either event, with the reference polarity shown in Fig. 1(a), the induced voltage in the inductor is given by

$$e = \frac{d(N\phi)}{di} \frac{di}{dt} = L \frac{di}{dt} \quad (2)$$

For a linear inductor, the value of L in the foregoing equation is the constant value of inductance given by Eq. (1). If the inductor is nonlinear, the value of L in Eq. (2) is the incremental inductance, that is, the slope of the $N\phi$ versus i characteristic at the particular operating current.

Inductor as a Circuit Element

Figure 1(b) is a representation of a pure inductor as a circuit element. In a pure inductor free from resistive and capacitive parasitic effects, the terminal voltage v equals the induced voltage e and the same current i passes through every section of the conductor. As a consequence, its terminal v - i relationship is given by

$$v = L \frac{di}{dt} \quad (3)$$

where L is the incremental inductance if the inductor is nonlinear. In the sequel, we take all inductors as linear, unless specifically stated otherwise.

As seen from Eq. (3), the inductance parameter quantifies the opposition offered by an inductive device to a change in its current. The higher the rate of change of current, the more the applied voltage needed to support this change. The relation between v and i in Eq. (3) is a statement of the cardinal property of an ideal inductor from the circuit viewpoint and is applicable to general time-varying current and voltage. In ac circuits at steady state, where all currents and voltages are sinusoids of the same frequency, the phasors of v and i are related by the

algebraic expression,

$$\mathbf{V} = j(2\pi fL)\mathbf{I} = j\omega L\mathbf{I} = jX_L\mathbf{I} = \mathbf{Z}_L\mathbf{I} \quad (4)$$

where f is the frequency in Hz and $\omega = 2\pi f$ is the angular frequency in radians/sec, $X_L = \omega L$ and $\mathbf{Z}_L = jX_L$ are the reactance and complex impedance of the inductor, both expressed in ohms. Equation (4) embodies two important properties of an ideal inductor in an ac circuit. First, the impedance (opposition) offered to a sinusoidal current varies proportionately with frequency. Secondly, the voltage has a phase angle of $\pi/2$ radians more than the current.

Practical inductors do not occur in pure form. They include incidental resistive and capacitive properties to a degree which depends on their design. These impurities arise from the resistance of the conductor used to wind the inductor, the distributed capacitance between turns and between layers of the winding, and the imperfection of the insulation used. With dc and low frequencies, the effects of the latter two factors are negligible, and an inductor can be represented by the simple series circuit of Fig. 2(a), where L is the inductance and R the dc resistance of its winding. A more accurate representation valid over a wide range of frequencies is the circuit of Fig. 2(b). Here, C_d is the lumped-element approximation of the distributed capacitance of the winding. The shunt resistance R_s accounts for the dielectric power losses in the insulating material of the winding and the eddy-current power losses caused in the neighbouring conductors and the shield if any, by an ac current in the inductor. For iron-cored inductors, R_s also includes the effects of eddy-current and hysteresis power losses in the core and consequently has a lower value than the corresponding air-cored inductor. Furthermore, with magnetic cores, R_s and L are

$$R_e \approx R \left(1 + 2\omega^2 L C_d + \frac{\omega^2 L^2}{R R_s} \right)$$

$$L_e \approx L (1 + \omega^2 L C_d)$$

(c)

Figure 2. Circuit representations of a practical inductor. (a) Equivalent circuit suitable for an air-cored inductor at dc and low frequencies. (b) Equivalent circuit valid for a wide range of frequencies. (c) Simplified equivalent circuit valid for $R < \omega L < R_s$ and $\omega^2 L C_d < 1$.

nonlinear. Their values depend on the applied voltage at any given frequency.

In ac circuit applications of an inductor, the parasitic elements R , C_d , R_s restrict the useful frequency range over which the device has a predominantly inductive character. This range extends over frequencies which are well below the self-resonant frequency of the inductor ($\omega^2 LC_d < 1$) and at which the inductive reactance ωL is much larger than the series resistance R and much smaller than the shunt resistance R_s . Under these conditions, the equivalent circuit of Fig. 2(b) is approximated by the simpler series equivalent circuit of Fig. 2(c), where the effective inductance L_e and series resistance R_e are functions of frequency given by

$$L_e = L(1 + \omega^2 LC_d) \quad (5)$$

and

$$R_e = R \left(1 + 2\omega^2 LC_d + \frac{\omega^2 L^2}{RR_s} \right) \quad (6)$$

In the frequency range under consideration, the effect of self-capacitance C_d , thus, is increased effective inductance and series resistance over their dc values. A larger C_d leads to larger increases. The dielectric and other losses represented by R_s contribute to an increased R_e with negligible effect on L_e . A further contributing factor to the dependence of R_e on frequency is that the winding resistance R is a function of frequency which increases above its dc value at higher frequencies because of skin and proximity effects. The resulting modified current distribution over the cross section of the conductors also lowers the value of L at higher frequencies.

The quality factor Q is commonly used as a figure of merit for a practical inductor in ac applications. A measure of the effectiveness of an energy storage device in performing its role with small power dissipation, it has the general definition

$$Q = 2\pi \frac{\text{peak value of energy stored}}{\text{energy dissipated per cycle}} \quad (7)$$

For the series equivalent circuit of Fig. 2(c), its value is equal to the ratio of its reactance to resistance, that is,

$$Q_e = \frac{\omega L_e}{R_e} \quad (8)$$

The Q -factor of a practical inductor exhibits a characteristic variation. Increasing linearly with frequency at first, then more gradually, it attains a peak in middle range of frequencies before it tapers off to low values at higher frequencies well below the self-resonant frequency. The self-capacitance of the winding, the skin and proximity effects on the conductor resistance, and the various power losses represented by R_s all contribute to reducing Q at high frequencies. The midrange of frequencies over which Q is fairly large and nearly constant is important in applications of the inductor as a circuit element in filter circuits. Inductors with iron cores have larger values of Q but a smaller usable frequency range. The maximum attainable value of Q with practical inductors is limited to a few hundred.

The important parameters of an inductor in circuit design are L_e and Q_e . The latter is preferred to R_e because it shows a smaller variation over the frequency band of interest. Because

the theoretical deduction of the values of these parameters at any specified frequency has limited scope, it becomes necessary to measure them experimentally. Measurements on inductors imply the measurement of L_e and Q_e (or alternatively R_e) at different frequencies over a specified range.

The Mutual Inductance Parameter

The inductance of a single isolated coil discussed so far is called its self-inductance. The property of mutual inductance arises when two inductors are in proximity so that some or all the flux lines set up by the current in one inductor also link with the other inductor. Because of this magnetic coupling, when the current in the first inductor varies, its self-flux linkages and also the flux linkages created by it in the other inductor (called mutual flux linkages) vary, thereby inducing voltage in the latter.

To illustrate the concept of magnetic coupling, we consider two ideal linear inductors constituted by coils of N_1 and N_2 turns, as shown in Fig. 3(a), and with self-inductances of L_1 and L_2 . As a simplified description, let current i_1 passing through coil 1 establish a self-flux of ϕ_{11} webers which links with all of

Figure 3. Mutual inductance between two coils. (a) Voltages induced when coil 1 alone carries a current. ϕ_{11} and ϕ_{21} represent the self and mutual fluxes. (b) Voltages induced when coil 2 alone carries a current. ϕ_{22} and ϕ_{12} represent the self and mutual fluxes. (c) Circuit representation of two coupled coils.

its N_1 turns and let ϕ_{21} , a part of this flux, link with all the N_2 turns of coil 2. The mutual inductance M between the coils is defined as the flux linkages in coil 2 per unit current in coil 1, that is, $M = N_2\phi_{21}/i_1$ and is measured in henrys, the same units adopted for self-inductances. It is also defined as the induced voltage in coil 2 per unit rate of change of current in coil 1. The self- and mutually induced voltages in the two coils, when only one of them carries a current, are specified in Figs. 3(a) and (b). The equality of $\phi_{21}N_2/i_1$ in Fig. 3(a) and $\phi_{12}N_1/i_2$ in Fig. 3(b) is established from energy considerations and is termed the reciprocity property of mutual inductances. The circuit representation of two coupled ideal inductors is given in Fig. 3(c). When they carry currents i_1 and i_2 simultaneously, their terminal voltages are given by Eqs. 9(a) and 9(b):

$$v_1 = L_1 \frac{di_1}{dt} + M \frac{di_2}{dt} \quad (9a)$$

$$v_2 = M \frac{di_1}{dt} + L_2 \frac{di_2}{dt} \quad (9b)$$

One terminal of each inductor is specially marked, often with a *dot*, as in Fig. 3(c). If the two currents, in their reference directions, both enter (or both leave) their respective inductors through the dotted terminals, then the self- and mutual fluxes are in the same direction in each coil. In this event, the signs of both the self- and mutually induced voltages in each terminal equation are the same. They are opposite otherwise. In Fig. 3(c), the reference directions for i_1 and i_2 both enter the inductors through dotted terminals and hence Eqs. 9(a) and (b) have the same signs for both self- and mutually induced voltages. The dot notation avoids the necessity of indicating explicitly the winding sense of each coil as done in Figs. 3(a) and (b).

In steady-state ac circuits with sinusoidal currents and voltages of angular frequency ω , the terminal equations of the coupled inductors in terms of the respective phasors take the form

$$\bar{V}_1 = (j\omega L_1)\bar{I}_1 + (j\omega M)\bar{I}_2 \quad (10a)$$

and

$$\bar{V}_2 = (j\omega M)\bar{I}_1 + (j\omega L_2)\bar{I}_2 \quad (10b)$$

The quantity ωM measured in ohms is the mutual reactance between the inductors.

STANDARD INDUCTORS

The term “standard” refers to an object built to realize a physical quantity or parameter very accurately. Inductance is the parameter of concern in this section, and we deal with two groups of standards, namely, standards of self-inductance and those of mutual inductance. Either type is further classified as fixed or variable, depending on whether the standard has a single definite value of the inductance parameter or whether it permits a continuous variation of the value over a certain range through an appropriate adjustment.

Another classification of standards is absolute or secondary. An absolute standard of inductance is one whose inductance is computed from accurately measured dimensions of the device. Such standards serve as the basis for calibrating secondary standards. The latter are either reference standards (which are

directly compared with absolute standards) or laboratory working standards (which are calibrated with respect to the reference standards). Both the reference and working standards of inductance have essentially the same constructional features. These are discussed after the following section on absolute standards.

Absolute Standards

Attaining the highest possible accuracy rather than economy is the chief concern in designing absolute standards. These standards of inductance incorporate coil configurations that permit applying the relevant formula for inductance with negligible error. The choice of materials and details of construction ensure precise and permanent positioning of the conductor on the coil former. The coil configuration generally adopted is a single layer solenoid of copper wire uniformly wound on a truly cylindrical former made of glass, ceramic, or marble and with a precisely machined helical groove to accommodate the conductor. The cost involved in their construction and maintenance and the sophisticated optical methods used to measure their dimensions render these standards unsuitable for use in a general laboratory. The tasks of maintaining absolute standards and of employing them to calibrate secondary standards are undertaken only at the national standards laboratories in each country. Even here, absolute standards of mutual inductance are preferred to absolute standards of self-inductance because formulas of higher theoretical accuracy are available for mutual inductance than for self-inductance and because skin effect and self-capacitance of windings are of smaller consequence. Details of representative absolute standards of mutual inductance are available in Refs. 1,2,3.

The cylindrical cross-capacitor, whose capacitance is determined by a single length measurement has become a fundamental electrical standard of choice in national laboratories, because of its extremely high accuracy. As an analog, a calculable mutual inductance standard in the form of a cage of five parallel wires is proposed by Page (4) for calibrating mutual inductor reference standards. The mutual inductance of this calculable standard is given by

$$\frac{1}{10} \ln \frac{3 + \sqrt{5}}{2} \mu\text{H/m}$$

Fixed Inductance Standards

As a rule, standard inductors are made without iron cores to obtain an inductance value independent of current. Marble, glass, porcelain or wood impregnated with paraffin are some of the materials used to construct the coil former. They are nonmagnetic and provide good insulation and adequate dimensional stability. Litz wire is employed for the coil to reduce the consequences of skin effect in the conductor.

There are two basic coil forms, illustrated in Fig. 4, in common use for self-inductance standards. The flat cylindrical coil of square winding cross section shown in Fig. 4(a) provides larger inductance values for a given length and diameter of the conductor than the toroidal configuration of Fig. 4(b). The maximum inductance is obtained when $d = 3a$. However, the arrangement is significantly affected by external magnetic fields from other sources and produces a large interfering field of its own. The uniformly wound toroidal inductor, on the other hand,

Figure 4. Windings for standard self-inductors. (a) Solenoidal coil provides larger Q values. Optimum design requires $d = 3a$. (b) Toroidal coil provides a nearly astatic arrangement.

has smaller Q values but provides a nearly astatic arrangement. As far as generation of and coupling with external fields is concerned, the toroidal winding is equivalent to a single turn with the mean radius of the torus. Figure 5 illustrates two ways by which this “single-turn effect” is effectively overcome. An auxiliary circular turn carrying a current in the opposite direction is provided on the surface of the toroid in the arrangement of Fig. 5(a). In the duplex winding of Fig. 5(b), the current from a lead does not take a path around the complete toroid, but splits equally into two parallel paths, each around half the toroid, and recombines at the diametrically opposite point. The currents in the two parallel paths have a cumulative action in establishing the magnetic flux around the toroid but act in opposite directions in setting up an interfering field in the axial direction.

Due attention is necessary in designing and constructing standard inductors to the size and placement of terminals and to the effects of temperature on the inductance value. See Refs. 1,2, and 5. The manufacturer of a standard inductor certifies its effective inductance at a particular frequency and suitable corrections are needed for use at other frequencies. In any

Figure 5. Methods of compensation for “single-turn effect.” (a) An additional circular turn carries current in the opposite direction. (b) In the duplex winding, current flows clockwise in one-half of the effective single turn and anticlockwise in the other half.

event, the operating frequency must be well below the self-resonant frequency of the inductor. The typical accuracy of a standard inductor is 0.1%.

Fixed mutual-inductance standards have design features similar to those of self-inductance standards except that they consist of two windings instead of one. Two circular coils of the same radius are fixed on the same bobbin axially displaced from one another, or they are concentric coils of different radii.

Variable Inductance Standards

Decade units of self- and mutual inductances are realized by an appropriate series connection of uncoupled fixed self-inductors or of sections of the secondary winding of a mutual inductor. The stepwise variation available with such units may not be sufficiently fine in several applications. Furthermore, in bridge measurements, the need exists for an inductor whose inductance value can be continuously changed without changing its resistance. Such a variable inductor is called a variometer or an inductometer. As a rule, these devices are less accurate than fixed standards. A typical value is 1%.

An inductometer consists of two coils, which are rotatable with respect to each other, so that the mutual inductance between them can be varied continuously, say from $-M_0$ to $+M_0$. If the two coils are connected in series, then the self-inductance of the combination can be varied from $L_1 + L_2 - 2M_0$ to $L_1 + L_2 + 2M_0$ where L_1 and L_2 are the individual self-inductances. Thus the inductometer is used as a variable self-inductor or as a variable mutual inductor.

Figure 6 illustrates two forms of the inductometer. The Ayrton–Perry arrangement, in which the fixed and rotatable coils are wound on sections of spherical surfaces, has the disadvantages of lack of astaticism and a nonlinear variation of M

Figure 6. Two forms of inductometer. (a) The Ayrton–Perry inductometer has a nonlinear scale and is not astatic. (b) The Brooks–Weaver inductometer provides a linear scale and is astatic.

with angular rotation. The Brooks–Weaver inductometer has a disk-shaped structure with two pairs of fixed coils and a rotatable third pair sandwiched between them. The left and right groups of fixed coils are connected to form an astatic arrangement. When the flux direction is upward in one group, it is downward in the other group, and one side serves as the return path for the flux of the other group. The coils are shaped to provide a fairly linear variation of M with the angle of rotation. An advantage of the arrangement is that small axial displacements of the rotor with respect to the stator caused by mechanical wear of the bearings do not significantly alter the value of M at any angular position.

METHODS OF MEASUREMENT OF SELF-INDUCTANCE

The salient schemes of measurement, grouped under four heads, are detailed in the following. All measurements are made under sinusoidal steady-state conditions and the values of L_e and R_e (or equivalently Q_e) of the inductor at the test frequency are determined. The inductor current (voltage) in the measuring circuit should be kept at the same level as in the actual application of the device to obtain reliable results for nonlinear inductors.

Methods Employing Indicating Instruments

These methods are easy and convenient in implementation and yield results of moderate accuracy. Figure 7 illustrates two commonly adopted schemes.

In the three-voltmeter method of Fig. 7(a), a known standard resistance R_s is connected in series with the test inductor. The values of R_e and L_e are computed from the three voltmeter readings V_s , V_1 , and V_2 , as indicated in the figure. The large number of algebraic operations involved render the final results prone to gross accumulation of errors.

The wattmeter method of Fig. 7(b) yields the values of L_e and R_e from the readings V , I , and P of the voltmeter, ammeter, and wattmeter. This method is particularly suitable at power frequencies. Its frequency range is limited by that of the dynamometer wattmeter.

Figure 7. Inductance measurement using indicating instruments. (a) Three voltmeter method. (b) Wattmeter method.

Figure 8. Standard form of a four-arm bridge network.

ac Bridge Measurements

The ac bridge method is one of the most accurate and sensitive means of determining the parameters of a circuit component such as an inductor. The accuracy stems from the fact that the unknown impedance is measured purely in terms of standard circuit components, which can be built to a much higher degree of accuracy than the best indicating instruments and are also less susceptible to deterioration in accuracy from ageing and environmental influences.

The Four-Arm ac Bridge. The four-arm ac bridge network has the general form shown in Fig. 8. The voltage source is typically a sinusoidal oscillator whose frequency is adjusted to the desired value. $\bar{CIZ}_4$ is the impedance to be measured, and the other three arms contain fixed and variable standard elements. The variable elements are adjusted until the detector D senses zero voltage across it. The bridge is then balanced, and $\bar{CIZ}_4$ is given by $\bar{CIZ}_4 = \bar{CIZ}_1 \bar{CIZ}_3 / \bar{CIZ}_2$.

The previous equation in complex numbers yields two real equations in terms of the bridge elements, which are called the balance conditions of the bridge. At least two variable elements should be provided to force bridge balance. Variable resistors are usually preferred for this purpose. If each variable element enters only one of the balance equations exclusively, then the balance adjustments are independent and the balancing process is faster. Furthermore, the balance conditions should preferably be independent of frequency to achieve a sharper balance detection when the source voltage contains harmonics. Detectors include vibration galvanometers, telephone receivers, tuned-amplifier detectors, oscilloscopes and radio receivers. References 1, 2, 6 give a comprehensive account of their relative characteristics and useful frequency ranges.

With the background of the foregoing general remarks, let us now look at a few popular ac bridge networks used for measuring inductors. Table 1 gives the configurations and balance equations of these networks. For measuring high- Q inductors, impractically large values of R_2 are needed in the Maxwell–Wien configuration. This difficulty is overcome by reconnecting R_2 and C_2 in series in arm 2. The resulting configuration, known as the Hay bridge, is quite suitable for use with high- Q inductors. The Owen bridge yields good accuracy but needs a large-valued adjustable capacitor C_1 for high- Q inductors. The Anderson bridge, a modification of the four-arm configuration, is quite suitable for a wide range of inductances and Q -values. A merit of this network is that preliminary balance is obtained with dc excitation and a suitable dc detector by adjusting r and the final balance with ac excitation effected essentially with R_5 accompanied by a slight readjustment of r .

Several important issues common to all bridge measurements are the rapidity with which balance adjustments converge, the sensitivity of detection, the effects of residuals (impurities) in the bridge elements, and the adoption of screening

Table 1. Bridge Networks for Measurements on Self-Inductors

Type	Configuration	Balance Equations	Remarks
Maxwell		$L_e = L_3 \frac{R_1}{R_2}$ $R_e = R_3 \frac{R_1}{R_2}$	Requires an inductometer.
Maxwell±Wien		$L_e = C_2 R_1 R_3$ $R_e = R_3 \frac{R_1}{R_2}$ $Q_e = \omega C_2 R_2$	For measurement of L_e and Q_e , the adjustable elements are R_1 (or R_3) and R_2 . Suitable for low Q ($Q < 10$) inductors.
Owen		$L_e = C_2 R_1 R_3$ $R_e = \frac{C_2}{C_1} R_3$	Suitable for a wide range of inductance values. Determination of L_e in terms of a fixed capacitor is an advantage.
Anderson		$L_e = C_5 R_1 \left[R_3 + R_5 + \frac{R_3 R_5}{R_2} \right]$ $R_e = R_1 \frac{R_3}{R_2} - r$	Suitable for a wide range of inductance. Only resistors are used as balancing elements.

and other strategies to combat the effects of stray admittances and parasitic coupling between elements. The reader may consult Refs. 1, 2, and 5–11 for good coverage of these topics.

Typical commercial bridges for inductance measurements have accuracies ranging from 0.05% to 1%. Besides measurements on conventional coils used as circuit components, inductance bridges are also employed for such purposes as determining inductive output impedances of amplifiers, inductance and Q -values of loudspeaker voice coils and television deflection yokes.

T-networks for RF Measurements. To combat the effects of stray capacitances, which are more pronounced at higher frequencies, it is desirable to ground one end of both the voltage

source and the detector. The four-arm bridge does not permit this without using isolating transformers. Two networks that permit this condition are the bridged-T and the twin-T measuring networks, which are useful for measuring inductances, especially at radio frequencies. These have three-terminal, two-port configurations, and the balance equations necessarily involve the frequency. References 2, 5, 6, and 8 may be consulted for further details.

Transformer Ratio Bridges. A very precise and stable voltage or current ratio standard is established by a suitably designed transformer. The voltage or current ratio is determined by the ratio of the number of turns in two windings of a transformer and is unaffected by temperature, ageing and other

Figure 9. The double-ratio, transformer-bridge circuit measures the admittance $\overline{CY}_e$ of the inductor in terms of fixed standards C_s and R_s and transformer ratios n_1 , n_2 , k_1 , and k_2 .

influences. The imperfections of the materials used for the core and conductor and in the magnetic coupling between the various turns cause only second-order effects, which can be minimized by careful design and choice of materials. Transformer ratio bridges that take advantage of this property have been developed over the last four decades, which incorporate variable-ratio standards of extraordinarily fine resolution (typically 1 in 10^7) and compatible accuracy. The transformer ratio bridges effectively solve the problem of stray admittances in measuring impedances and have the further advantage of needing only fixed-value standard R and C elements. The principle of a transformer ratio bridge scheme of inductor measurement is shown in Fig. 9. The transformer ratios n_1 , n_2 , k_1 , and k_2 are adjusted to secure a null response in the detector D . The flux in the core of T_2 is zero under these conditions. Hence, the primary winding of T_2 presents only a very small impedance equal to its resistance and the currents in C_s and R_s are controlled by $n_1 \overline{CIV}_s$ and $n_2 \overline{CIV}_2$, respectively. The ampere-turn balance at this condition is given by

$$N(\overline{Y}_e \overline{V}_s) + k_1 N(j\omega C_s n_1 \overline{V}_s) - k_2 N(n_2 \overline{V}_s / R_s) = 0$$

or

$$\overline{Y}_e = \frac{k_2 n_2}{R_s} - j\omega k_1 n_1 C_s \quad (11)$$

In practice, T_1 consists of six to eight decade dividers connected in cascade, and hence the ratios n_1 and n_2 can be fixed in steps of 10^{-6} to 10^{-8} . The details are omitted in Fig. 9 for simplicity. Transformer ratio bridges have been made for use at frequencies up to 200 MHz. References 2, 8, 10, and 11 may be consulted for additional details on transformer ratio bridges.

Resonance Methods

If a variable capacitor is employed to resonate with the inductor under test, then the inductance value is deduced from the values of the capacitance at resonance and source frequency. A bridge method and a meter method using this principle are illustrated in Fig. 10. Both methods are particularly suited to measurements in the RF range, which permits the use of small capacitors.

In the resonance bridge of Fig. 10(a), C_4 and a resistor in one of the other three arms is varied to secure the balance. At balance, arm 4 of the bridge is equivalent to a pure resistance, and an accurate value of R_e can be deduced. The frequency f must be known accurately, because it enters the balance equation for L_e . Furthermore, the waveform of the source must be pure for sharp detection of balance.

The Q -meter is a versatile and useful instrument for measuring inductors and capacitors at radio frequencies. Referring to the circuit of Fig. 10(b), a small voltage V_s of fixed value (of the order of 20 mV) is introduced into the series-resonant circuit formed by the test inductor and a variable standard capacitor C . R_s is a small, fixed, noninductive resistance (of the order of 40 mΩ) and the current I through it is sensibly equal to I , which is read by an RF ammeter and adjusted to a predetermined value to yield the required value of V_s . Now the capacitance of C is adjusted to result in the maximum value $(V_0)_m$ of the voltage across it read by the high impedance voltmeter V . For all practical purposes, this is also the resonant condition of the circuit and the voltage magnification $(V_0)_m / V_s$ is equal to the Q -factor of the coil. Accordingly, we deduce L_e and Q_e at frequency f from

$$L_e = 1 / (4\pi^2 f^2 C_0)$$

and

$$Q_e = (V_0)_m / V_s \quad (12)$$

where C_0 is the value of the capacitance for maximum V_0 .

Because V_s has a predetermined value, the output voltmeter is calibrated directly in terms of Q_e . By repeating the above measurement at a revised frequency of $2f$, the self-capacitance C_d of the inductor is deduced as $(C_0 - 4C'_0)/3$, where C'_0 is the value of the variable capacitor needed for resonance at the frequency $2f$.

Digital Methods

Modern electronics has brought a variety of instruments to the art of impedance measurement which provide the convenience of a direct digital readout and accuracies comparable to commercial measuring bridges. The underlying principle of measurement in most of these instruments is based on one or the other of the two schemes shown in Fig. 11.

The inductor under test and a standard resistor R_s of known value are connected in series in the scheme of Fig. 11(a). The

Figure 10. Resonance methods employ a variable capacitor to resonate with the inductor at the test frequency. (a) Resonance bridge. (b) Q-meter.

components of the phasor of the inductor voltage in phase and in quadrature with the phasor of the resistor voltage are measured by suitable analog and digital electronics. The second scheme shown in Fig. 11(b) employs an automatic balancing arrangement to null the detector voltage $\overline{CIV}_d$. This is effected by varying the in-phase and quadrature components of the controlled voltage $\overline{CIV}_z$. In both schemes, the parameters α and β are given by

$$\alpha = R_e/R_s \quad (13a)$$

$$\beta = \omega L_e/R_s \quad (13b)$$

and form the basis of the digital display of the values of R_e and L_e . The details of the circuit implementation in a few representative designs are given in Refs. 11–13.

Modern digital *RLC* meters measure a wide range of impedances at frequencies from a few hertz to megahertz with

a basic accuracy of 0.1% to 1.0%. They are being increasingly used for routine measurements in the laboratory and for production and inspection tests.

MEASUREMENT OF MUTUAL INDUCTANCE

The measurement of mutual inductance is called for in testing mutual inductors and when dealing with mutual inductance transducers for measuring nonelectrical quantities. We shall look at a few representative methods.

Voltmeter-Ammeter Method

In the voltmeter-ammeter method, Fig. 12(a), the current in the primary winding and the induced emf in the secondary are measured by an ammeter and a high-resistance voltmeter, such as an electrostatic voltmeter or an electronic voltmeter. M is calculated as $V_2/\omega I_1$. The value of the supply frequency is needed for this measurement.

Measurement in Terms of Self-Inductances

This is a popular method of measuring mutual inductance. If two coils whose mutual inductance is to be measured are connected in series, the self-inductance of the combination is given by $L_1 + L_2 \pm 2M$, depending on whether the magnetic fluxes set up by a common current in the two coils are additive or not [Fig. 12(b)]. Thus, M is deduced from the measurement of the two resulting values of self-inductance. Any one of the methods of measurement of self-inductance can be used to determine L_a and L_b . If $M < L_1 + L_2$, the method suffers from inaccuracy because then the value of M is deduced from the difference between two nearly equal measured values.

Mutual Inductance Bridges

There are several bridge methods for measuring M (1,2,6,7,9). The Carey-Foster bridge shown in Fig. 12(c) is representative. It measures M in terms of a fixed capacitor. At balance,

Figure 11. Schemes adopted for digital measurement of impedances. (a) The measurement of α and β enables the determination of R_e and L_e . (b) Feedback forces the controlled voltage $\overline{CIV}_z$ to a value that makes $\overline{CIV}_d = 0$.

Figure 12. Methods of measuring mutual inductance. (a) The voltmeter-ammeter method is direct and simple but requires the frequency value. (b) M is deduced from the measured self-inductance values L_a and L_b . (c) The Carey-Foster bridge measures M in terms of a capacitance and two resistances.

$(R_1 - j/\omega C_1)\overline{CII}_1 = R_2\overline{CII}_2$, and $(R_4 + j\omega L_4)\overline{CII}_1 - j\omega M(\overline{CII}_1 + \overline{CII}_2) = 0$. Solution of these equations yields

$$M = C_1 R_2 R_4$$

and

$$L_4 = C_1 R_4 (R_1 + R_2) \quad (14)$$

L_4 must be larger than M . Further, the resistance R_4 associated with L_4 must be known accurately.

If m and n are the required values of the potentiometer setting x in the two adjustments, then R_e and L_e are computed from the equations

$$R_e = \frac{(1-m)}{m} R_s \quad (15a)$$

and

$$L_e = \frac{\sqrt{m-n}}{\omega m \sqrt{n}} R_s \quad (15b)$$

SPECIAL TECHNIQUES AND MEASUREMENTS

Quasi-Balanced Bridges

Unlike in a conventional bridge measurement where the repetitive adjustment of two elements in succession is needed, the quasi-balanced bridge requires adjusting only one element, leading to a rapid convergence to what is termed the *quasi-balance* condition. This condition is the detection of the minimum or maximum value of a voltage or even null detection in some forms. The quasi-balance, in principle, yields only one component of an unknown complex impedance. The second component, if needed, is obtained by adjusting another variable element for a different quasi-balance condition. The principles and some examples of quasi-balanced bridges are given in Ref. 9.

The microcontroller-based bridge described in Ref. 14 illustrates the application of the quasi-balance technique in conjunction with modern electronic hardware. Two independent quasi-balance conditions are obtained in succession in the bridge circuit of Fig. 13. The phasor $\overline{CIV}_d$ is brought into quadrature with the phasor $\overline{CIV}_R$ in the first adjustment and with the phasor $\overline{CIV}_s$ in the second. Both adjustments are effected by the potentiometer setting x . The quadrature condition is sensed by the zero output of a phase-sensitive detector (PSD).

A multiplying digital-to-analog converter (MDAC) is used to implement the potential divider action. A microcontroller senses the PSD output, adjusts the inputs to MDAC to secure quasi-balance conditions, measures the source frequency, and

Figure 13. A quasi-balanced bridge measurement of the unknown impedance $R_e + j\omega L_e$. (a) Circuit configuration. The potentiometer setting x is used to obtain quasi-balance. (b) Phasor diagram. $\overline{CIV}_d$ is brought into quadrature with $\overline{CIV}_R$ and $\overline{CIV}_s$ for $x = m$ and $x = n$, respectively.

Figure 14. Hay's bridge circuit adapted for the measurement of incremental inductance.

finally displays digital values of R_e and L_e computed from the measurement.

Measurement of Incremental Inductance

A measurement of practical importance is the effective resistance and incremental inductance of iron-cored inductors when they carry a comparatively large direct current with a small superimposed alternating current, such as occurs with filter chokes and transformer windings in electronic circuits. The variation of incremental inductance as a function of the dc bias current needs to be determined. The Owen and Hay bridge circuits are well suited to introduce the dc current into the inductor branch, because the capacitors block the dc in two of the branches. Figure 14 shows the Hay bridge adapted to measure incremental inductance. The resistor in series with the dc supply is first varied to set up the required dc current in the inductor, as read by the dc ammeter A. This bias current also flows through R_1 , whose power rating should be appropriately chosen. The detector responds only to the ac signal because of the blocking capacitor in series with it. Now the bridge is balanced for ac signals by adjusting R_2 and C_2 . The following balance equations, which yield the values of incremental parameters, are the same as for the conventional Hay bridge:

$$L_i = \frac{C_2}{1 + \omega^2 C_2^2 R_2^2} R_1 R_3 \quad (16a)$$

and

$$R_i = \frac{\omega^2 C_2^2 R_2}{1 + \omega^2 C_2^2 R_2^2} R_1 R_3 \quad (16b)$$

where L_i is the incremental inductance and R_i the effective ac resistance at the chosen dc bias current. See Ref. 2 for further details.

Residual Inductance and Its Measurement

The balance equations of the bridge circuits in Table 1 are derived on the assumption that the standard elements used therein are pure. The impurities in these elements, called residuals, are no doubt small in practice, but must nevertheless be considered in high-precision measurements. Although the residuals of standard capacitors normally used can be ignored as negligibly small, the residual inductances associated with

resistors have to be considered, particularly when low-valued inductances are to be measured.

As an illustration of the methods used to tackle the problem of residuals, we consider the Maxwell–Wien bridge of Table I, modified by including a variable standard resistance R_4 in series with the test inductor. Let l_1 , l_2 , l_3 and l_4 be the residual inductance values of the resistors R_1 , R_2 , R_3 and R_4 and let C_2 be considered pure. Reworking the equations of the bridge and making appropriate approximations valid at medium frequencies, we obtain the following balance equation for L_e :

$$L_e = C_2 R_1 R_3 + \frac{1}{R_2} \left[l_1 R_3 + l_3 R_1 - l_2 \frac{R_1 R_3}{R_2} \right] - l_4 \quad (17)$$

Now let the test inductor be removed from the bridge and replaced by a resistor with a resistance value approximately equal to R_e and with a calculable inductance L_s . Such resistors are readily constructed as a loop of two, parallel, high-resistance wires (see pp. 147–153 of Ref. 2). Now the bridge is rebalanced by adjusting C_2 to C'_2 and R_4 to R'_4 . Because all other elements and their residuals remain unchanged,

$$L_s = C'_2 R_1 R_3 + \frac{1}{R_2} \left[l_1 R_3 + l_3 R_1 - l_2 \frac{R_1 R_3}{R_2} \right] - l'_4 \quad (18)$$

where l'_4 is the residual inductance of R'_4 . From Eqs. (17) and (18),

$$L_e = L_s + (C_2 - C'_2) R_1 R_3 + (l'_4 - l_4) \quad (19)$$

Because the substituted resistor has approximately the same resistance as the test inductor, the resistance values R_4 and R'_4 should be approximately equal, and the quantity $(l'_4 - l_4)$ can be neglected. Thus the value L_e is given, independently of the residuals of the bridge elements, by

$$L_e = L_s + (C_2 - C'_2) R_1 R_3 \quad (20)$$

For a detailed treatment of the solution of problem of residuals, consult Refs. 1, 2, and 6.

The substitution principle, which forms the basis of the foregoing procedure, is one of the most effective and accurate tools available, when the original measurement is beset by influencing factors of unknown magnitude. The method outlined in this section is also used to evaluate the residual inductance of a resistor, by treating the given resistor itself as the test inductor.

In-Circuit Measurement

It is useful to measure impedance values of elements already connected in a network without dismantling them. Such measurements, termed *in-circuit* or *in-situ* measurements, are called for in identifying, testing, and trouble-shooting electronic circuits. The shunting effect of other elements in the network has to be avoided in this evaluation.

In one approach (15), a current is injected into the element from an external sinusoidal voltage source. One of the leads to the element carrying this current and another wire carrying an adjustable opposing current derived from the same source through an auxiliary circuit are passed through a clamp-on type

Figure 15. In-circuit measurement of an inductor. (a) The active bridge circuit employed. $R_e = R_1 R_3 / R_2$ and $L_e = R_1 R_3 C_2$ at balance. (b) Network modifications for the in-circuit measurement of an inductor connected between nodes a and b in a network.

current probe. The circuit constants of the auxiliary circuit, adjusted to obtain a null output from the probe, are used to evaluate the parameters of the element under test.

A second approach is to block the currents in the disturbing network elements by forcing zero voltage on them or to make these currents inconsequential and then measure the desired impedance by a suitable method (16,17). The active bridge circuit of Fig. 15, discussed in Ref. 17, apart from other advantages, enables the in-circuit measurement of an inductor at any specified voltage. To this end, the source v_s is adjusted to the desired voltage and the test inductor is connected into the bridge with all nodes in the network adjacent to one terminal of the test inductor lumped together and connected to the source as shown in Fig. 15(b). This method is applicable only when no other element exists in the network, which is connected directly in parallel with the test inductor.

CAPACITANCE MEASUREMENT

Capacitance is the property that exists between two charged bodies separated by a dielectric material. The capacitance C is equal to the ratio of the absolute value of the charge Q to the absolute value of the voltage between charged bodies as

$$C = Q/V \quad (1)$$

where C is the capacitance in farads (F), Q is charge in Coulombs (C) and V is voltage (V).

The unit of capacitance is the Farad, which is a very large unit; therefore, practical capacitors have capacitances of microfarads (μF or 10^{-6} F), nanofarads (nF or 10^{-9} F), and picofarads (pF or 10^{-12} F).

In general, the capacitance can be determined by using Laplace's equations $\nabla^2 V(x, y, z) = 0$ with appropriate boundary conditions. The boundary conditions specify the electrode voltages V_1 and V_2 of the plates. For two electrodes, Laplace's equation yields the voltage $V(x, y, z)$ and the electric field $E(x, y, z) = -\nabla V(x, y, z)$. The charge of each electrode can also be obtained by integration of the flux density over each electrode surface as

$$Q = \int \epsilon(x, y, z) \mathbf{E}(x, y, z) \cdot d\mathbf{A} \quad (2)$$

If the capacitor is made from two parallel plates, as shown in Fig. 1, the capacitance value in terms of dimensions may be

Figure 1. A typical capacitor made from two parallel plates. The capacitance between two charged bodies depends on the permittivity of the medium, distance between the bodies, and the effective area. It can also be expressed in terms of the absolute values of the charge and the absolute values of the voltages between bodies.

expressed by

$$C = \epsilon A/d = \epsilon_r \epsilon_0 A/d \quad (3)$$

where ϵ is the dielectric constant or permittivity, ϵ_r is the relative dielectric constant (in air $\epsilon_r = 1$), ϵ_0 is the dielectric constant of vacuum (8.854188×10^{-12} F/m or $10^{-9}/36\pi$ F/m), d is the distance between the plates in m, and A is the effective area of the plates in m^2 .

As can be seen in Eq. (3), the value of the capacitance is largely dependent on the permittivity of the dielectric material used. The permittivity of commonly used materials in the construction of capacitors, is listed in Table 1.

The capacitance C depends on the size and shape of charged bodies and their positioning relative to each other as shown in Table 2. In many electric and electronic systems, it is necessary to deal with the useful capacitances as well unwanted components. In many circuits, stray capacitances are introduced externally or internally at various stages. Cables and other external components introduce additional capacitances that need to be dealt with for desirable performance of the system. In these cases, Table 1 is useful to identify and analyze possible sources of additional capacitances where charged bodies are involved.

Characteristics of Capacitors

Capacitors are characterized by dielectric properties, breakdown voltages, temperature coefficients, insulation resistances, frequency and impedances, power dissipation, and quality factors: reliability, aging, etc.

The dielectrics of capacitors can be made from polar or non-polar materials. Polar materials have dipolar characteristics; that is they consist of molecules whose ends are oppositely charged. This polarization causes oscillations at certain frequencies resulting in high losses at those frequencies.

Table 1. Permittivity (Dielectric Constants) of Materials Used in Capacitors

Material	Permittivity
Vacuum	1.0
Air	1.0006
Polythene etc.	2.0 to 3.0
Impregnated paper	4.0 to 6.0
Glass and Mica	4.0 to 7.0
Ceramic (low K)	to 20.0
Ceramic (medium K)	80.0 to 100.0
Ceramic (high K)	1000.0 up

Dielectric absorption and leakage currents occur due to properties of dielectric materials. Absorption introduces a time lag during the charging and discharging of capacitors, thus reducing the capacitance values at high frequencies and causing unwanted time delays, particularly in pulse circuits. The leakage current, on the other hand, prevents indefinite storage of energy in the capacitor. An associated parameter of leakage currents is leakage resistance, which is measured in megohms but is usually expressed in megohm-microfarads or ohms-farads. The leakage resistance and capacitance introduce time constants which can vary from a few days for polystyrene to several seconds in some electrolytic capacitors. The leakage current is not only dependent on the properties of the dielectric materials but also on the construction and structure of the capacitors, and this is particularly true for capacitors having values less than $0.1 \mu\text{F}$ with very thin dielectric material between the electrodes.

If the capacitor is subjected to high operating voltages, the electric field in the dielectric exceeds the breakdown value and damages the dielectric permanently. The dielectric strength depends on the temperature, the frequency, and the applied voltage. An example of this dependence on the applied voltage is given in Fig. 2. It is commonly known that the use of capacitors below their rated values increases the reliability and their expected life time. The standard voltage ratings of most capacitors are quoted by the manufacturers as 50, 100, 200, 400, and 600 V. Tantalum and electrolytic capacitors have ratings of 6, 10, 12, 15, 20, 25, 35, 50, 75, 100 V, and higher.

Usually, values of surge voltages are given to indicate the ability of capacitors to withstand high transients. Typically, the surge voltages for electrolytic capacitors are 10% above the rated voltage, 50% for aluminum capacitors, and about 250% for ceramic and mica capacitors. The rated reverse voltages of electrolytic capacitors are limited to 1.5 V and, in some cases, to 15% of the rated forward voltages.

The temperature characteristics of capacitors are largely dependent on the temperature properties of the dielectric materials used, as given in Fig. 3. The temperature coefficients of

Figure 2. Changes in relative permittivity against field strength. The dielectric strength depends on the temperature, frequency, and applied voltage. Increases in the applied voltage cause higher changes in the dielectric strength. If the capacitor is subjected to higher operating voltages, the electric field in the dielectric exceeds the breakdown value which can damage the dielectric permanently.

Table 2. Capacitances of Various Electrode Systems

 Parallel plates with homogeneous dielectric $C = \frac{\epsilon A}{d}$	 $C = \frac{\pi \epsilon \ell}{\ln \left[\frac{d}{r} + \sqrt{\left(\frac{d}{r} \right)^2 - 1} \right]} = \frac{2\pi \epsilon \ell}{\cosh^{-1} \left(\frac{d}{r} \right)}$
 Parallel plates with two constituent dielectrics $C = \frac{(\epsilon_1 r + \epsilon_2) A}{(1 + r) d}$ where r value is the volumetric ratio	
 Parallel plates with two different dielectrics $C = \frac{\epsilon A}{\frac{d_1}{\epsilon_1} + \frac{d_2}{\epsilon_2}}$	 Parallel cylinders with equal radius $C = \frac{\pi \epsilon \ell}{\ln \left[\frac{d}{r} + \sqrt{\left(\frac{d}{r} \right)^2 - 1} \right]} = \frac{2\pi \epsilon \ell}{\cosh^{-1} \left(\frac{d}{r} \right)}$
 Coaxial cylinders with single dielectric $C = \frac{4\pi \epsilon \ell}{\ln(r_2/r_1)}$	 Mutual capacitance $C_{11} = \frac{\pi \epsilon \ell}{\ln(d_1/r)} + \frac{\pi \epsilon}{2} \frac{\ln(b/a)}{[\ln(a/r)] \ln(b/r)}$ $C_{21} = C_{12} = \frac{\pi \epsilon \ell}{2} \frac{\ln(b/a)}{[\ln(a/r)] \ln(b/r)}$
 Coaxial cylinders with three dielectrics $C = \frac{2\pi \epsilon_0 \ell}{\ln \left[\left(\frac{r_2}{r_1} \right)^{\frac{\epsilon_3}{\epsilon_1}} \times \left(\frac{r_3}{r_2} \right)^{\frac{\epsilon_2}{\epsilon_2}} \times \left(\frac{r_4}{r_3} \right)^{\frac{\epsilon_3}{\epsilon_3}} \right]}$ $= \left(\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} \right)^{-1}$	 Concentric spheres $C = \frac{4\pi \epsilon r_1 r_2}{r_2 - r_1}$

glass, teflon, mica, polycarbonate, etc. are very small, whereas in ceramic capacitors, they can be very high.

The insulation resistance of capacitors is important in many circuits. The insulation resistance is susceptible to temperature and humidity. Particularly, unsealed capacitors show

large and rapid changes against temperature and humidity. For most capacitors, at high temperatures, the change in insulation resistance is an exponential function of temperature ($R_{T1} = R_{T2} e^{K(T1-T2)}$). The temperature dependence of insulation resistance of common capacitors is shown in Fig. 4.

Figure 3. Temperature dependence of capacitors. The temperature characteristics of capacitors are largely dependent on the temperature properties of the dielectric materials used. The variations in capacitance due to temperature also depend on the type of capacitor and the operational voltage. The temperature coefficients of glass, teflon, mica and polycarbonate are very small, whereas in ceramic capacitors, they are relatively high.

Figure 4. Temperature dependence of insulation resistance. The insulation resistance of many capacitors is not affected at low temperatures. However, under high temperature conditions, the change in insulation resistance may be approximated by an exponential relation. The insulation resistance is also susceptible to variations in humidity.

Figure 5. Frequency and impedance relation of capacitors. The losses and inherent inductance affect the ideal operation of capacitors, and the capacitance impedance becomes a function of frequency. Depending on their construction, all capacitors will resonate at a certain frequency.

Power Dissipation and Quality Factors. An ideal capacitor should have entirely negative reactance, but losses and inherent inductances prevent ideal operation. Depending on the construction, every capacitor resonates at certain frequencies due to equivalent resistance and inductances. A typical impedance characteristic of a capacitor is depicted in Fig. 5.

The electric equivalent circuit of a capacitor consists of a pure capacitance (C_p), plate inductances (L_1, L_2), plate resistances (R_1, R_2), and a parallel resistance R_p which represents the resistance of the dielectric called leakage resistance as shown in Fig. 6. The capacitors that have high leakage currents flowing through the dielectric have relatively low values for R_p . Very low leakage currents are represented by extremely large values of R_p . Examples of these two extremes are electrolytic capacitors that have high leakage current (low R_p), and plastic film capacitors which have very low leakage current (high R_p). Typically, an electrolytic capacitor might easily have $R_p < 1 \text{ M}\Omega$, giving several microamperes of leakage current, while a plastic film capacitor could have a resistance greater than $100,000 \text{ M}\Omega$.

In some cases, it is usual to represent a low leakage capacitor (high R_p) by a series RC circuit, while those with high leakage (low R_p) are represented by a parallel RC circuit. However, when the capacitor is measured in terms of the series C and R quantities, it is usually desirable to convert them into the parallel equivalent circuit quantities. This is because the (parallel) leakage resistance best represents the quality of the capacitor dielectric.

An ideal capacitor stores energy without dissipating any power. However, due to equivalent resistances, R_{eq} , some power will be dissipated. The power factor of a capacitor may be

Figure 6. Capacitor equivalent circuit. A practical capacitor has resistances and inductances. Often, the electrical equivalent circuit of a capacitor can be simplified by a pure capacitance C_p and a parallel resistance R_p by neglecting resistances R_1, R_2 and inductances L_1, L_2 . In low leakage capacitors where R_p is high, the equivalent circuit may be represented by a series RC circuit.

Figure 7. Power dissipation factors. In ideal operation, capacitors should store energy without dissipating power. Nevertheless, due to resistances, some power will be dissipated. The dissipation depends on frequency. The standard measurement of the dissipation factor δ is determined by applying 1.0 Vrms at 1 kHz .

expressed as

$$\text{PF} = \cos \theta = R_{eq} / |Z_{eq}| \quad (4)$$

where θ is the phase angle, and Z_{eq} is the equivalent total impedance.

One important characteristic, the dissipation factor of capacitors, is expressed as

$$\text{DF} = \tan \delta = R_{eq} / X_{eq} \quad (5)$$

where δ is the angle of loss, and X_{eq} is the equivalent reactance.

The dissipation factor is dependent on the frequency. Capacitors are designed such that this dependence is minimal. The measurement of the dissipation factor δ is made at 1 kHz and 1.0 Vrms applied to the capacitor. A typical dissipation factor curve is depicted in Fig. 7.

CAPACITIVE REACTANCE

Capacitors are used as two terminal elements, shown in Fig. 8(a), with the current voltage relationship given by

$$i(t) = C dv(t)/dt \quad (6)$$

From the $v(t), i(t)$ relationship, the instantaneous power of this element is then

$$p(t) = v(t)i(t) \quad (7)$$

The stored energy in the capacitor at time t seconds may be calculated as

$$\begin{aligned} w(t) &= \int C v(t) \{dv(t)/dt\} dt \\ &= [C v^2(t)]/2 \end{aligned} \quad (8)$$

Hence, the energy stored in the capacitor in the time interval t_1, t_2 will be equal to

$$W = (1/2)C[v^2(t_2) - v^2(t_1)] \quad (9)$$

If $v(t_2) = v(t_1)$, the energy stored in the capacitor in this time interval is equal to zero. This implies that the energy stored

Figure 8. A capacitor as a two-terminal circuit element: (a) connection of a capacitor in electrical circuits, (b) current voltage relationship under sinusoidal operations, and (c) the power, voltage, and current relationships. The power has positive and negative values with twice the frequency of applied voltage.

in the capacitor is returned to the circuit during the time interval; that is, the capacitor transforms the energy without dissipation.

In circuits, capacitors form passive components. That is, if the voltage is known, the currents can immediately be determined by differentiation of the voltages. The Laplace transform gives the relationship

$$I(s) = sC V(s) \quad (10)$$

From this, the input-output relationship yields the impedance of the capacitor as

$$Z(s) = 1/sC$$

or

$$Y(s) = sC \quad (11)$$

In the stationary condition, $s \rightarrow 0$, $Z \rightarrow \infty$, and $Y \rightarrow 0$.

In the sinusoidal condition, $s = j\omega = 2\pi f$, where f = frequency, and hence,

$$\begin{aligned} Z(j\omega) &= 1/(j\omega C) \\ &= -j/(\omega C) \end{aligned} \quad (12)$$

and

$$Y(j\omega) = j\omega C \quad (13)$$

The capacitor can then be characterized, under the sinusoidal condition, by a reactance of $X_c = 1/\omega C$, measured in ohms. The current leads the voltage by 90° as shown in the phasor diagram in Fig. 8(b).

In sinusoidal operations, the instantaneous power $p(t) = v(t)i(t)$ can be calculated as

$$v(t) = V_{\max} \cos \omega t = \sqrt{2}V \cos \omega t \quad (14)$$

By using the relationship given by Eq. (6), the current can be written as

$$i(t) = C dv/dt = -\omega C \sqrt{2}V \sin \omega t \quad (15)$$

giving

$$p(t) = v(t)i(t) = -2\omega C V^2 \sin \omega t \cos \omega t = V^2 \sin 2\omega t / X_c \quad (16)$$

This indicates that the average power is zero because of the $\sin 2\omega t$ term, but there is a periodic storage and return of energy, and the amplitude of that power is V^2/X_c . The power, voltage, and current relationship in a capacitor is shown in Fig. 8(c).

Series and Parallel Connection of Capacitors

The formulas for series and parallel connections of capacitors, as shown in Fig. 9(a) and 9(b), respectively, can be obtained from a general consideration of series and parallel connections of impedances. For the series connection, the impedances are added such that

$$1/sC = 1/sC_1 + 1/sC_2 + \dots + 1/sC_n \quad (17)$$

where $C_1, C_2, \dots, C_n$ are the capacitances of the capacitors connected in series as in Figure 9(a). The equivalent capacitance is then given by

$$C = \{1/C_1 + 1/C_2 + \dots + 1/C_n\}^{-1} \quad (18)$$

That is, in series connection, the final capacitance value will always be smaller than the smallest value of the capacitance in the circuit.

In a similar way, the equivalent capacitance of parallel connected capacitors is

$$C = C_1 + C_2 + \dots + C_n \quad (19)$$

Figure 9. Series and parallel connection of capacitors: (a) series connection, and (b) parallel connection. In series connection, the final capacitance value will always be smaller than the smallest value of the capacitor as the circuit element, whereas in parallel connection, the final value is greater than the largest capacitance.

Figure 10. Construction of a typical capacitor. Dielectric sheets are placed between electrode foils and convolutely wound. The moisture of the dielectric material is removed at high temperatures by vacuum drying before the capacitor is impregnated with oil, paraffin, or wax.

and the final value of C is always larger than the largest capacitance in the circuit.

STANDARD CAPACITORS

Commonly used fixed capacitors are constructed with paper, mica, polymeric, and ceramic dielectric materials. Variable capacitors are generally made of air or ceramic dielectric materials. Capacitors can broadly be classified as electrolytic, ceramic, polymer, mica, variable, and integrated circuit capacitors.

Paper Capacitors

Usually, paper capacitors are made with thin ($5\ \mu\text{m}$ to $50\ \mu\text{m}$ thickness) wood pulp. A number of sheets are used together to eliminate possible chemical and fibrous defects that may exist in each sheet. The paper sheets are placed between thin aluminum foils and convolutely wound, as shown in Fig. 10. The moisture of the paper is removed by high temperature vacuum drying before the capacitor is vacuum impregnated with oil, paraffin, or wax. When impregnated with silicon oil, they can withstand voltages up to 300 kV.

Electrolytic Capacitors

This implies any capacitors in which the dielectric layer is formed by an electrolytic method. Electrolytic capacitors in dry foil form may be similar in construction to paper film capacitors; that is, two foil layers separated by an impregnated electrolyte paper spacer are rolled together. In this case, one of the plates is formed by metallization of one side of a flexible dielectric film. A foil, for example aluminum, is used as the other plate. The

Figure 11. Construction of an electrolytic capacitor. The two foil layer electrodes are separated by an impregnated electrolyte paper spacer and rolled together on a plastic core. Usually, a flexible metallized dielectric film is used as one of the plates and an ordinary foil is used for the other. The capacitor is then hermetically sealed in an aluminum or plastic can.

capacitor is then hermetically sealed in an aluminum or plastic can, as shown in Fig. 11. These capacitors can be divided into two main subgroups:

Tantalum Electrolytic. The anode consists of sintered tantalum-powder, and the dielectric is Ta_2O_5 , which has a high value of ϵ_r . A semiconductor layer MnO_2 surrounds the dielectric. The cathode made from graphite is deposited around the MnO_2 before the capacitor is sealed. These capacitors are highly stable and reliable with good temperature ranges, and they are suitable in high frequency applications.

Aluminum Electrolytic Capacitors. Aluminum-foil is oxidized on one side as Al_2O_3 . The oxide layer is the dielectric, having a thickness of about $0.1\ \mu\text{m}$ and a high electric field strength ($7 \times 10^5\ \text{Vmm}^{-1}$). A second layer acting as a cathode made from etched Al-foil is inserted. The two layers are separated by a spacer; then, the layers are rolled and mounted.

Electrolytic capacitors must be handled with caution, since in these capacitors, the electrolyte is polarized. That is, the anode should always be positive with respect to the cathode. If not connected correctly, hydrogen gas will form, which damages the dielectric layer causing a high leakage current or blow-up. These capacitors may be manufactured to values up to $10,000\ \mu\text{F}$.

Ceramic and Glass Capacitors

The dielectric is a ceramic material with deposited metals. They are usually rod or disk shaped. They have good temperature characteristics and are suitable in many high frequency applications. There are many different types, such as

1. *Low K ceramic:* These capacitors are made with materials that contain a large fraction of titanium dioxide (TiO_2). The relative permittivity of these materials varies from 10 to 500, with negative temperature coefficients. The dielectric is $\text{TiO}_2 + \text{MgO} + \text{SiO}_2$, suitable in high frequency applications in filters, tuned circuits, coupling and bypass circuits, etc.
2. *High K ceramic:* The dielectric contains a large fraction of barium titanate, BaTiO_3 , mixed with PbTiO_3 or PbZrO_3 giving relative permeabilities of 250 to 10,000. They have high losses and also have high voltage time dependence with poor stability.
3. *Miniature ceramic capacitors:* These are used in critical high-frequency applications. They are made in the ranges of 0.25 pF to 1 nF.
4. *Dielectric ceramic capacitors:* The material is a semiconducting ceramic with deposited metals on both sides. This arrangement results in two depletion layers which make up the very thin dielectric. In this way, high capacitances can be obtained (22 nF to 100 nF). Due to thin depletion layers, only small dc voltages are allowed. They are used in small and lightweight equipment such as hearing aids.

Glass capacitors are made with dielectric glass materials. The properties of dielectric glass are similar to ceramic materials.

Polymer Capacitors

Various polymers such as polycarbonate, polystyrol, polystyrene, polyethylene, polypropylene, etc. are used as the dielectric. The construction is similar to that of paper

capacitors. Polystyrene capacitors, in particular, are very stable and are virtually frequency independent. They have low voltage rating and are used in transistorized applications as tuning capacitors.

Mica Capacitors

A thin layer of mica, usually muscovite mica (≥ 0.003 mm), is stapled with Cu-foil or coated with a layer of deposited silver. It is then vacuum impregnated and coated with epoxy. The field strength of these capacitors is very high (10^5 Vmm $^{-1}$), and their resistivity is $\rho = 10^6$ to 10^{15} Ω m. These capacitors are available in values from 1.0 pF to several microfarad for high voltage (from 100 V to 2000 V) and high frequency applications. They have tolerances between ± 20 to $\pm 0.5\%$.

Variable Capacitors

These capacitors usually have air as the dielectric and consist of two assemblies of space plates positioned together by insulation members, such that one set of plates can be rotated, as shown in Fig. 12. Their main use is in adjustment of the resonance frequency of tuned circuits in receivers and transmitters, filters, etc. By shaping the plates, various types of capacitances can be obtained, such as linear capacitance, in which capacitance changes as a linear function of rotation, and logarithmic capacitance.

Variable capacitors may be grouped as precision types, general-purpose types, transmitter types, trimmer types, and special types such as phase shifters.

Precision type variable capacitors are used in bridges, resonant circuits, and many other instrumentation systems. The capacitance swing can be from 100 pF to 5000 pF. They have good long term stability with very tight tolerances.

General-purpose type variable capacitors are used as tuning capacitors in radio and other broadcasting devices. They are available in many laws such as straight line frequency, straight line wavelength, etc. The normal capacitance swing is from 400 pF to 500 pF. In some cases, a swing of 10 to 600 pF is available.

Transmitter type variable capacitors are similar to general-purpose variable capacitors, but they are specially designed for high voltage operations. The swing of these capacitors can go from as few picofarads up to 1000 pF. The most common laws are liner frequency and straight line capacitances. In some

Figure 12. A variable capacitor. It consists of two assemblies of spaced plates positioned together by insulation members such that one set of plates can be rotated. The majority of variable capacitors have air as the dielectric. They are used mainly in adjustment of resonance frequency of tuned circuits in receivers and transmitters. By shaping the plates suitably, they can be made to be linear or logarithmic.

cases, oil filling or compressed gases are used to increase operating voltages.

Trimmer capacitors are used for coil trimming at intermediate radio frequencies. They can be air spaced rotary types (2 pF to 100 pF), compression types (1.5 pF to 2000 pF), ceramic-dielectric rotary types (5 pF to 100 pF), and tubular types (up to 3 pF).

INTEGRATED CIRCUIT CAPACITORS

There are many types of capacitors in IC technology. The most commonly used are depletion capacitors and thin-film capacitors. Junction capacitors are the easiest to form in integrated circuits and are primarily used as decoupling and bypass capacitors. The typical value of a junction capacitor is about 300 pF/mm ^{2} . Capacitors of the order of picofarads occupy large areas.

The thin-film capacitors are made mostly within MOS integrated circuits, as monolayer capacitors containing tantalum or other suitable deposits. The plates of integrated circuit capacitors are generally formed by two heavily doped polysilicon layers formed on a thick layer of oxide. The dielectric is usually made from a thin layer of silicon oxide. Important parameters for IC capacitors are the tolerances, voltage coefficients, temperature coefficients, and capacitance values. These capacitors are largely temperature stable with a temperature coefficient of about 20 ppm/ $^{\circ}$ C. The voltage coefficients are usually less than 50 ppm/V. Integrated circuit capacitive sensors are achieved by incorporating a dielectric sensitive to physical variables. Typical values of these capacitors are 1 pF to 27 nF for temperature compensating ceramic, 100 pF to 3000 pF for tantalum oxide, 390 pF to 0.47 μ F for general purpose ceramic, and 0.1 μ F to 10 μ F for tantalum electrolyte. Operating voltages range from 25 V to 200 V for ceramic, 12 V to 35 V for tantalum electrolyte, and 12 V to 25 V for tantalum oxide.

Integrated circuit capacitors are adapted for use in micro-electronic circuits. They include some miniature ceramic capacitors, tantalum oxide solid capacitors, and tantalum electrolyte solid capacitors. The ceramic and tantalum oxide chips are not encapsulated and are fitted with end caps for direct surface mounting onto the circuit board. Ceramic chip capacitors are most suitable for RF applications. Many different types of high- Q , multi-layer ceramic chip capacitors are offered by different manufacturers. They are available from 0.5 pF to 1000 pF, with voltage ratings from 100 V to 500V dc, depending on capacitance value.

The thin film integrated circuit computable capacitor may contain many capacitors with typical values of up to 1, 2, 4, 8, and 16 pF capacitance. Binary ratios starting at 0.25 pF are also available. In many designs, a common back metallization layer forms one plate of the capacitor, individual contacts form the other plate, and silicon dioxide dielectric features high Q over a wide temperature range. These capacitors are commonly used in circuits involving active filters, such as the Chebyshev or Butterworth filter (multiple feedback design) for high pass, low pass, stopband, or band pass applications.

CAPACITIVE MEASUREMENTS

Capacitive measurement techniques are extensively used in industrial and scientific applications. They are based on changes

in capacitances in response to physical property variations. These sensors find many diverse applications from humidity and moisture to displacement measurements.

Capacitive Displacement Measurements

The measurement of distances or displacements is an important aspect of many industrial, scientific, and engineering systems. Capacitive displacement sensors have high linearity and have wide ranges from a few centimeters to a few nanometers.

The basic sensing element of a typical displacement sensor consists of two simple electrodes with capacitance C . The capacitance is a function of the distance d (cm) between the electrodes of a structure, the effective surface area A (cm²) of the electrodes, and the permittivity ϵ ($=8.85$ pF/m for air) of the dielectric between the electrodes; therefore

$$C = f(d, A, \epsilon) \quad (20)$$

There are three basic methods for realizing a capacitive displacement sensor, that is, by varying d , A , or ϵ as discussed below.

Variable Area Displacement Measurements

The displacements may be sensed by varying the surface area of the electrodes of a flat plate capacitor, as illustrated in Fig. 13. In this case, the capacitance is

$$C = \epsilon_r \epsilon_0 (A - wx)/d \quad (21)$$

and the transducer output is linear with displacement x . This type of sensor is normally implemented as a rotating capacitor for measuring angular displacement. The rotating capacitor structures are also used as output transducers for measuring electric voltages as capacitive voltmeters.

Variable Distance Displacement Measurements

If a capacitor is made from two flat coplanar plates separated by a variable distance x , ignoring fringe effects, the capacitance can be found by

$$C(x) = \epsilon A/x = \epsilon_r \epsilon_0 A/x \quad (22)$$

where ϵ is the dielectric constant or permittivity, ϵ_r is the relative dielectric constant (in air and vacuum, $\epsilon_r \approx 1$), $\epsilon_0 =$

Figure 13. A variable area capacitive displacement sensor. The sensor operates on the variation in the effective area between the plates of a flat plate capacitor. The transducer output is linear with displacement x . This type of sensor is normally implemented as a rotating capacitor for measuring angular displacement.

8.854188×10^{-12} F/m ($10^{-9}/36 \pi$ F/m) is the dielectric constant of vacuum, x is the distance of the plates in m, and A is the effective area of the plates in m².

The capacitance is a nonlinear function of the distance x , and has the characteristics of a hyperbolic transfer function. The sensitivity of capacitance to changes in plate separation may be found as

$$dC/dx = -\epsilon_r \epsilon_0 A/x^2 \quad (23)$$

Equation (23) indicates that the sensitivity increases as x decreases. Nevertheless, using Eqs. (22) and (23), it can be proved that the percent changes in C are proportional to the percent changes in x which can be expressed as

$$dC/C = -dx/x \quad (24)$$

This type of sensor is often used for measuring small incremental displacements without making contact with the displaced object.

Differential Capacitive Measurements

These sensors are basically three terminal capacitors, as shown in Fig. 14. Slight variations of these sensors find many applications, including differential pressure measurements. In some versions, the central plate moves in response to physical variables with respect to the fixed plates. In others the central plate is fixed, and the outer plates are allowed to move. The output from the center plate is zero at the central position and increases as it moves left or right. The range is equal to twice the separation d . For a displacement d , we have

$$\begin{aligned} 2\delta C &= C_1 - C_2 = \epsilon_r \epsilon_0 lw/(d - \delta d) - \epsilon_r \epsilon_0 lw/(d + \delta d) \\ &= 2\epsilon_r \epsilon_0 lw \delta d / (d^2 + \delta d^2) \end{aligned} \quad (25)$$

Figure 14. A differential capacitive sensor. This is a three-terminal capacitor with one fixed center plate and two outer plates. Its response to physical variables is linear. In some versions, the central plate moves in response to physical variables with respect to two outer plates; in the others, the central plate is fixed, and the outer plates are allowed to move.

Figure 15. A typical smart capacitive position sensor. These types of microstructure position sensors contain three electrodes, two of which are fixed, and the third electrode moves infinitesimally relative to the others. Although the response is highly nonlinear, the integrated chip contains linearization circuits. They have a 0 to 1 mm measuring range with 1 μm accuracy.

and

$$\begin{aligned} C_1 + C_2 = 2C &= \epsilon_r \epsilon_0 l w / (d - \delta d) + \epsilon_r \epsilon_0 l w / (d + \delta d) \\ &= 2\epsilon_r \epsilon_0 l w d / (d^2 + \delta d^2) \end{aligned} \quad (26)$$

giving

$$\delta C / C = \delta d / d \quad (27)$$

This indicates that the device is inherently linear in contrast to the nonlinear response of the two-plate types. However, some nonlinearity can still be observed in practice due to defects in the structure.

Integrated Circuit Smart Capacitive Position Sensor

Figure 15 shows a typical microstructure capacitive displacement sensor. It has a 1 mm measuring range, 1 micron accuracy, and 0.1 s total measuring time. The specification corresponds to a possible range of 1 pF to 50 pF to displacement.

The relative deviation in the capacitance C_x between the two electrodes caused by the finite guard electrode can be expressed as

$$d < \epsilon^{-P} \frac{x}{d} \quad (28)$$

where x is the width of the guard, while d is the distance between the electrodes. Nonlinearity characteristics are exhibited in this deviation. Therefore, d is required to be less than 100 ppm.

In some special cases, the sensor capacitance C_x can be expressed as

$$C_x = \frac{\epsilon A_x}{d_0 + \Delta d} \quad (29)$$

where A_x is the area of the electrode, d_0 is the initial distance between them, ϵ is the dielectric constant, and Δd is the displacement to be measured.

Capacitive Pressure Sensors

A commonly used two-plate capacitive pressure sensor is made from one fixed metal plate and one flexible circular diaphragm as shown in Fig. 16. The flat circular diaphragm is clamped around its circumference, and is bent into a curve by an applied

Figure 16. A capacitive pressure sensor. The pressure sensors are made from a fixed metal plate and a flexible diaphragm. The flat flexible diaphragm is clamped around its circumference. The bending of the flexible plate is proportional to applied pressure P . The deformation of the diaphragm results in changes in capacitance.

pressure P . The deflection y of this system at any radius r is given by

$$y = 3(1 - \nu^2)(a^2 - r^2)P / 16Et^3 \quad (30)$$

where

a is the radius of diaphragm
 t is the thickness of diaphragm
 E is the Young's modulus and
 ν is the Poisson's ratio

Deformation of the diaphragm means that the average separation of the plates is reduced. Hence, the resulting increase in the capacitance ΔC can be calculated by

$$\Delta C / C = (1 - \nu^2)a^4 P / 16Et^3 \quad (31)$$

where d is the initial separation of the plates, and C is the capacitance at zero pressure.

Capacitive Accelerometers and Force Transducers

Accelerometers based on capacitive sensing elements typically use the proof mass as one plate of the capacitor and the other plate as the base, as illustrated in Fig. 17. When the sensor

Figure 17. A capacitive force transducer. A typical capacitive micro-machined accelerometer has one of the plates as the proof mass. The other plate is fixed, thus forming the base. When the sensor is accelerated, the proof mass tends to move, thus varying the distance between the plates and altering the voltage across the capacitor. This change in the voltage is made to be directly proportional to the applied acceleration.

is accelerated, the proof mass tends to move, and the voltage across the capacitor changes. This change in the voltage corresponds to the applied acceleration.

In Fig. 17, let $F(x)$ be the positive force in the x direction. Neglecting all losses (due to friction, resistance, etc.), the energy balance of the system can be written for an infinitesimally small displacement dx , electrical energy dE_e , and field energy dE_f of the electrical field between the electrodes as:

$$dE_m + dE_e = dE_f \quad (32)$$

in which

$$dE_m = F(x)dx \quad (33)$$

also

$$dE_m = d(QV) = QdV + VdQ \quad (34)$$

If the supply voltage V across the capacitor is kept constant, it follows that $dV = 0$. Since $Q = VC(x)$, the Coulomb force is given by

$$F(x) = -V^2 \frac{dC(x)}{dx} \quad (35)$$

Thus, if the movable electrode had complete freedom of motion, it would have assumed a position in which the capacitance is maximal, and also if C were a linear function of x , the force $F(x)$ would be independent of x .

Capacitive silicon accelerometers are available in a wide range of specifications and sizes. A typical light weight sensor will have a frequency range of 0 to 1000 Hz with a dynamic range of ± 2 to $\pm 500 g$.

Capacitive Level Measurement

The level of a nonconducting liquid can be determined by capacitive techniques. This method is generally based upon the difference between the dielectric constant of the liquid and that of the gas or air above it. Two concentric metal cylinders are used for capacitance as shown in Fig. 18. The height of the liquid, l , is to be measured relative to the total height, h . Appropriate provision is made to ensure that the space between the cylindrical electrodes is filled by the liquid to the same height as the rest of the container. The usual operational conditions dictate that the spacing between the electrodes, s , should be much less than the radius of the inner electrode, r . Furthermore, the tank height should be much greater than r . When these conditions apply, the capacitance is approximately

$$C = \frac{\epsilon_1(l) + \epsilon_g(h-l)}{4.6 \log[1 - (s/r)]} \quad (36)$$

where ϵ_1 and ϵ_g are the dielectric constant of the liquid and gas (or air), respectively. The denominator of the above equation contains only terms that relate to the fixed system. A typical application is the measurement of the amount of gasoline in a tank in airplanes. The dielectric constant for most compounds commonly found in gasoline is approximately equal to 2, while that of air is approximately unity. These sensors are often incorporated with an ac deflection bridge.

Figure 18. A capacitive liquid level sensor. Two concentric metal cylinders are used as electrodes of a capacitor. The value of the capacitance depends on the permittivity of the liquid and that of the gas or air above it. The total permittivity changes depending on the liquid level. These devices are usually applied in nonconducting liquid applications.

Capacitive Humidity and Moisture Sensors

The permittivity of atmospheric air as well as of many solid materials is a function of moisture content and temperature. The capacitive humidity device is based on the changes in the permittivity of the dielectric material between the plates of capacitors. There are many types of capacitive humidity sensors. Aluminum types and tantalum types will be introduced here as examples.

Aluminum Type Capacitive Humidity Sensors. The majority of capacitive humidity sensors are aluminum oxide type sensors. In these sensors, high purity aluminum is chemically oxidized to produce a prefilled insulating layer of partially hydrated aluminum oxide which acts as the dielectric. A water permeable but conductive gold film is deposited onto the oxide layer, usually by vacuum-deposition, and forms the second electrode of the capacitor.

Another type of aluminum-aluminum oxide sensor has a pore structure as illustrated in Fig. 19. The oxide with its pore

Figure 19. A typical capacitive humidity sensor. The sensors have pore or cracked mosaic structures for the moisture in air or gas to reach the dielectric material. The characteristics of the dielectric material change with the amount of water absorbed, thus reducing the resistance and increasing the capacitance. The quantity measured can be either resistance, capacitance, or impedance.

structure forms the active sensing material. Moisture in the air reaching the pores reduces the resistance and increases the capacitance. The decreased resistance can be thought of as being due to an increase in conduction through the oxide. An increase in capacitance can be considered to be due to an increase in the dielectric constant. The quantity measured can be either resistance, capacitance, or impedance. The high humidity end is best measured by capacitance, since resistance changes are very small in this region.

Tantalum Capacitive Humidity Sensors. In some versions of capacitive humidity sensors, one of the capacitor plates consists of a layer of tantalum deposited on a glass substrate. A layer of polymer dielectric is then added, followed by a second plate which is made from a thin layer of chromium. The chromium layer is under high tensile stress, so that it cracks into a fine mosaic structure which allows water molecules to pass into the dielectric. A sensor of this type has an input range of 0 to 100% relative humidity, RH. The capacitance is 375 pF at 0% RH and a linear sensitivity of 1.7 pF/%RH. The error usually is less than 2% due to nonlinearity and 1% due to hysteresis.

Capacitive humidity sensors enjoy wide dynamic ranges, from 0.1 ppm to saturation points. They can function in saturated environments for longer lengths of time, which would adversely affect many other humidity sensors. Their ability to function accurately and reliably extends over a wide range of temperatures and pressures. Capacitive humidity sensors also exhibit low hysteresis and high stability with little maintenance requirements. These features make capacitive humidity sensors viable for many specific operating conditions and ideally suitable for a system where uncertainty of unaccounted conditions exists during the operations. However, in some applications, contaminants can block the flow of water vapor into the sensor material, thus affecting the accuracy of the instrument. Many sensors come with some form of casing to provide protection.

Capacitive Moisture Sensors

Measurements in capacitive moisture sensors are based on the changes in the permittivity of granular or powder type dielectric materials such as wheat and other grains containing water. Usually, the sensor consists of a large cylindrical chamber, for example 150 mm deep and 100 mm in diameter. The chamber is filled with samples under test. The variation in capacitance values with respect to water content is processed. The capacitor is incorporated as a part of an oscillatory circuit operating at a suitable frequency.

Capacitive moisture sensors need to be calibrated for samples made from different materials, as the materials, themselves, demonstrate different permittivity. Accurate temperature is necessary as the dielectric constant may be highly dependent on temperature. Most of these devices are built to operate at temperature ranges of 0°C to 50°C, supported by tight temperature compensation circuits.

CAVITY RESONATORS

Cavity resonators are enclosures that confine electromagnetic energy in space as illustrated in Fig. 2(a). Cavity resonators find extensive use in microwave and laser optic applications. The energy is stored in the form of electric and magnetic energy

Figure 20. Cavity resonator and equivalent circuit. (a) A cavity resonator is a container confining electromagnetic energy in space. The resonant frequency is set by the particular field configuration and by the cavity dimensions. A resonance is obtained when the cavity length l is equal to the multiple of the half of the wavelength. (b) The energy is stored in electric and magnetic energy forms inside the cavity, largely determined by equivalent capacitance, inductance, and resistance. In its simplest form, the equivalent circuit can be viewed as an inductive coupling supplying the capacitor C .

inside the cavity, largely determined by equivalent capacitance, inductance, and resistance, very similarly to circuits made from coil and capacitance combinations. The coupling of the cavity resonator is equivalent to the inductive coupling as shown in Fig. 20(b).

Cavity resonators come in many shapes, from rectangular to circular or semicircular. The most commonly used cavity resonators are rectangular types, Fig. 20(a). The cavity shapes can be related to associated waveguide modes. With each mode, a resonant frequency may be determined by the particular field configuration involved and by the cavity dimensions. A given resonator has an infinite number of resonant modes which correspond to definite resonant frequencies. At resonant frequencies, the maximum amplitude of the standing wave occurs. The mode of the minimum resonant frequency is called the dominant mode and the higher resonant frequencies are called higher order modes. The modes in cavities are classified as transverse electric and transverse magnetic. In the case of rectangular prisms, if the wave is travelling in the l direction, resonance will be obtained whenever the multiple of half a wavelength is equal to the cavity length l .

The resonant frequency of a cavity resonator can be derived from Maxwell's equations for the electrical and magnetic fields within the resonator. In practical applications, the resonator is obtained first by constructing a resonator of convenient size and measuring the resulting resonant frequency for the construction. The ratio of the desired wavelength to the practical wavelength gives a scale factor that can be applied to every dimension of the test model. The resonant frequencies of a cavity resonator can be changed in a number of ways, such as (1) altering the mechanical dimensions, (2) changing the coupling reactance into the resonator, and (3) using copper paddles.

The Q factor of a cavity resonator is significant, as in the case of any other resonant circuits. The Q factor can be defined by

$$Q = 2\pi \frac{\text{Energy stored}}{\text{Energy loss per cycle}} \quad (37)$$

The energy stored is proportional to the square of the magnetic flux density integrated throughout the volume of the resonator.

The energy loss is proportional to the skin depth and to the square of the magnetic flux density integrated over the surface of the cavity. As a result, the Q factor depends on the ratio of volume to surface area of the resonator.

CAPACITANCE MEASUREMENTS

Null Bridge Instruments and Resonance Methods

Bridges are used to make precise measurements of unknown capacitances and associated losses in terms of known external capacitances and resistances. Most commonly used bridges are series-resistance-capacitance bridges, parallel-resistance capacitance bridges, Wien bridges, and Schering bridges.

The Series RC Bridge. Figure 21 is a Series-Resistance Capacitance Bridge which is used for the comparison of a known capacitance with an unknown capacitance. The unknown capacitance is represented by its series equivalent circuit C_x and R_x . A standard adjustable resistance R_1 is connected in series with a standard capacitor C_1 . The voltage drop across R_1 balances the resistive voltage drop when the bridge is balanced. The additional resistor in series with C_x increases the total resistive component, so that small values of R_1 will not be required to achieve balance. Generally, the bridge balance is most easily achieved when capacitive branches have substantial resistive components. To obtain balance, R_1 and either R_3 or R_4 are alternately adjusted. This type of bridge is found to be most suitable for capacitors with a high-resistance dielectric, hence very low leakage currents. At balance,

$$Z_1/Z_3 = Z_2/Z_4 \quad (38)$$

Substituting impedance values gives

$$\frac{(R_1 - j/\omega C_1)}{R_3} = \frac{R_x - j/\omega C_x}{R_4} \quad (39)$$

Solving for the real terms gives

$$R_x = R_1 R_4 / R_3 \quad (40)$$

Figure 21. A series RC bridge. In these bridges, the unknown capacitance is compared with a known capacitance. The bridge balance is most easily achieved when capacitive branches have substantial resistive components. The resistors R_1 and either R_3 or R_4 are adjusted alternately to obtain the balance. This type of bridge is found to be most suitable for capacitors with a high-resistance dielectric, hence very low leakage currents.

and solving for the imaginary terms gives

$$C_x = C_1 R_3 / R_4 \quad (41)$$

An improved version of the series RC bridge is the substitution-bridge, which is particularly useful to determine the values of capacitances at radio frequencies. In this case, a series connected RC bridge is balanced by disconnecting the unknown capacitance and resistance C_x and R_x and replacing it by an adjustable standard capacitor C_s and adjustable resistor R_s . After having obtained the balance position, the unknown capacitance and resistance C_x and R_x are connected in parallel to the capacitor C_s . The capacitor C_s and resistor R_s are adjusted again for the rebalance of the bridge. The changes in the ΔC_s and ΔR_s lead to unknown values as

$$C_x = \Delta C_s \quad \text{and} \quad R_x = \Delta R_s (C_{s1} / C_x)^2 \quad (42)$$

where C_{s1} is the value of C_s in the initial balance.

Parallel-Resistance-Capacitance Bridge. Figure 22 illustrates a parallel-resistance capacitance bridge. In this case, the unknown capacitance is represented by its parallel equivalent circuit, C_x in parallel with R_x . The Z_3 and Z_4 impedances are pure resistors where either or both may be adjustable. The Z_2 impedance is balanced by a standard capacitor C_1 in parallel with an adjustable resistor R_1 . The bridge balance is achieved by adjustment of R_1 and either R_3 or R_4 . The parallel-resistance capacitance bridge is found to be most suitable for capacitors with a low resistance dielectric, hence relatively high leakage currents. At balance,

$$\frac{1/[1/R_1 + j\omega C_1]}{R_3} = \frac{1/[1/R_x + j\omega C_x]}{R_4} \quad (43)$$

Solving for real terms gives

$$R_x = R_1 R_4 / R_3 \quad (44)$$

and solving for the imaginary terms gives

$$C_x = C_1 R_3 / R_4 \quad (45)$$

Figure 22. A parallel-resistance-capacitance bridge. The unknown capacitance is represented by its parallel equivalent circuit: C_x in parallel with R_x . The bridge balance is achieved by adjustment of R_1 and either R_3 or R_4 . The parallel-resistance capacitance bridge is found to be most suitable for capacitors with a low resistance dielectric, hence relatively high leakage currents.

Figure 23. The Wien bridge. This bridge is used to compare two capacitors directly. It finds applications, particularly in determining the frequency in RC oscillators. In some cases, capacitors C_1 and C_x are made equal and ganged together, so that the frequency at which the null occurs varies linearly with capacitances.

The Wien Bridge. Figure 23 shows a Wien bridge. This is a special resistance-ratio bridge which permits two capacitances to be compared once all the resistances of the bridge are known. At balance, it can be proven that the unknown resistance and the capacitance are

$$R_x = R_3(1 + \omega^2 R_1^2 C_1^2) / (\omega^2 R_1 R_2 C_1^2) \quad (46)$$

and

$$C_x = C_1 R_2 / [R_3(1 + \omega^2 R_1^2 C_1^2)] \quad (47)$$

It can also be shown that

$$\omega^2 = 1 / R_1 C_1 R_x C_x \quad (48)$$

As indicated in Eq. (48), the Wien bridge has an important application in determining the frequency of RC oscillators. In frequency meters, C_1 and C_x are made equal, and the two capacitors are joined together so that the frequency at which the null occurs varies linearly with capacitances.

The Schering Bridge. Figure 24 illustrates the configuration of a Schering bridge. This bridge is used for measuring the capacitance, the dissipation factors, and the loss angles. The unknown capacitance is directly proportional to the known capacitance C_1 . That is, the bridge equations are

$$C_x = C_1 R_2 / R_3 \quad \text{and} \quad R_x = C_2 R_3 / C_1 \quad (49)$$

Figure 24. The Schering bridge. This bridge is particularly useful for measuring the capacitance, associated dissipation factors, and the loss angles. The unknown capacitance is directly proportional to the known capacitance C_1 . The Schering bridge is frequently used as a high-voltage bridge with a high-voltage capacitor as C_1 .

A Schering bridge is frequently used as a high-voltage bridge with a high-voltage capacitor as C_1 . It is also used as a high frequency bridge, since variable capacitors may be used for both adjustments.

Resonance Methods

Capacitors can be connected in parallel or series with inductors to form LC networks. In a series LC network, as the frequency, ω , increases the impedance of the circuit decreases. The decrease in the impedance reaches a point where the reactance becomes zero. That is

$$\omega_0 L - 1/\omega_0 C = 0 \quad \text{or} \quad \omega_0 = 1/\sqrt{LC} \quad (50)$$

The frequency ω_0 is called the resonant frequency of the circuit. The value of ω_0 is specified entirely in terms of the parameters of the energy storing elements of the circuit. In many instances, the unknown value of a capacitance is determined once the resonance frequency and the inductance are known.

ACCURACY AND SIGNAL PROCESSING

Generally, capacitive type measurements require relatively more complex circuitry in comparison to many other type of sensors, but they have the advantage of mechanical simplicity. They are also sensitive with minimum mechanical loading effects. For signal processing, these sensors are usually incorporated either in ac deflection bridge circuits or oscillator circuits. In practice, capacitive sensors are not pure capacitances but have associated resistances representing losses in the dielectric. This has an important influence in the design of circuits, particularly in oscillator circuits. Here, the most commonly used circuit based on charge amplifier is discussed.

Operational Amplifiers and Charge Amplifiers

One method of eliminating the nonlinearity in the relationship between the physical variable, for example two plate displacement sensors, and capacitance C is by the use of operational amplifiers, as illustrated in Fig. 25. In this circuit, if the input impedance of the operational amplifier is high, the output is not saturated, and the input voltage is small, it is

Figure 25. An operational amplifier signal processor. This method is useful to eliminate the nonlinearity in the signals generated by capacitive sensors. By this type of arrangement, the output voltage can be made to be directly proportional to variations in the signal representing the nonlinear operation of the device.

possible to write

$$1/C_f = \int i_f dt = e_{ex} - e_{ai} = e_{ex} \quad (51)$$

$$1/C_x = \int i_x dt = e_0 - e_{ai} = e_0 \quad (52)$$

$$i_f + i_x - i_{ai} = 0 = i_f + i_x \quad (53)$$

Manipulation of these equations gives

$$e_0 = -C_f e_{ex} / C_x \quad (54)$$

Substituting the value of C_x

$$e_0 = -C_f x e_{ex} / \epsilon A \quad (55)$$

Equation (55) shows that the output voltage is directly proportional to the plate separation x , thus giving linearity for all variations in motion.

However, a practical circuit requires a resistance across C_f to limit output drift. The value of this resistance must be greater than the impedance of C_f at the lowest frequency of interest.

A practical charge amplifier circuit is presented in Fig. 26. In this case, the effective feedback resistance R_{ref} is given by

$$R_{\text{ref}} = R_3(R_1 + R_2)/R_2 \quad (56)$$

It is possible to reduce the output drift substantially by suitably selecting the resistors. The accuracy of this circuit can be improved further by cascading two or more amplifiers. In this way, a substantial improvement in the signal-to-noise ratio can also be achieved.

In many applications, the resultant change in capacitance of capacitive transducers is measured with a suitable ac bridge, such as a Wien bridge or a Schering bridge. However, in a majority of cases, improvised versions of bridges are used as oscillator circuits for capacitive signal processing. The transducer is configured as part of the oscillatory circuit that causes changes in the frequency of the oscillations. This change in fre-

quency is scaled to be a measure of the magnitude of the physical variable.

SELECTION, RELIABILITY, ACCURACY, AND STANDARDS OF CAPACITORS

Selection of Capacitors

The capacitors used in electronic circuits can be classified as low-loss, medium-loss, and high-tolerance capacitors. The low-loss capacitors have good stability, such as mica, glass, low-loss ceramic, and low-loss plastic film capacitors. These capacitors are expensive and used for precision applications, for example, telecommunication filters. Medium-loss capacitors are paper, plastic film, and medium-loss ceramic capacitors. Their applications include coupling, decoupling, bypass, energy storage, and some power electronic applications, for example, motor starting, lighting, power line applications, and interference suppressions. High tolerance capacitors, such as aluminum and tantalum electrolytic capacitors, deliver high capacitances. Although their sizes are relatively greater, they are reliable and have longer service life. They are used in polarized voltage applications, radio, television, other consumer goods as well as military equipment and harsh industrial environmental usage.

The values of general-purpose capacitors tend to be grouped closely together in a bimodal distribution manner within their tolerances. Usually, the tolerances of standard capacitors are 5, 10 and 20% of their rated values. Nevertheless, tolerances of precision capacitors are much tighter in the range of 0.25, 0.5, 0.625, 1, 2, and 3% of their rated values. These capacitors are much more expensive than those in the standard range.

For capacitors in the small pF range, the tolerances can be given as ± 1.5 , ± 1 , ± 0.5 , ± 0.25 , and ± 0.1 pF. Usually, low tolerance ranges do not include additional values; the capacitors' values simply have tighter distribution.

Capacitors and capacitive sensors are offered by many manufacturers, and some examples are listed in Table 3.

Reliability and Accuracy of Capacitors

Experience shows that a substantial part of component failures in electronic equipment is due to capacitors. The major cause of this is the improper selection and inappropriate application of capacitors. The following factors are, therefore, important criteria in the selection of capacitors in circuit applications: (1) The capacitance values and tolerances are determined by operating frequencies or by the value required for timing, energy storage, phase shifting, coupling, or decoupling. (2) The type and nature of the sources, such as ac, dc, transient, surges, and ripples determine the applied voltages. (3) The stability is determined by operating conditions like temperature, humidity, shock, vibration, and life expectancy. (4) Life expectancy, leakage current, dissipation factor, impedance, and self-resonant frequency determine electrical properties. (5) Types and construction, for example, size, configuration, and packaging determine mechanical properties.

Some of the common causes of capacitor failure are due to voltage and current overloads. The voltage overload produces an excessive electric field in the dielectric that results in its breakdown and destruction. The current overload caused by rapid voltage variations results in current transients. If these currents are of sufficient amplitude and duration, the dielectric

can be deformed or damaged, resulting in drastic changes in capacitance values, thus leading to equipment malfunction. Overheating and high temperatures accelerate dielectric aging. This causes the plastic film to be brittle and also introduces cracks in the hermetic seals. Moisture and humidity due to a severe operating environment causes corrosion, reduces the dielectric strength, and lowers insulation resistances.

Standards and Computable Capacitors

Standards of Capacitors. Standard capacitors are constructed from interleaved metal plates using air as the dielectric material. The area of the plates and distance between them are determined and constructed with precision. The National Bureau of Standards maintains a bank of primary standard air capacitors that can be used to calibrate secondary and working standards for laboratories and industry. Generally, smaller capacitance working standards are obtained from air capacitors, whereas larger working standards are made from solid dielectric materials. Usually, silver-mica capacitors are selected as working standards. These capacitors are very stable, have very low dissipation factors, small temperature coefficients,

and very little aging effect. They are available in decade mounting forms.

Computable Capacitors. Another form of standard capacitors is the Thompson-Lampard calculable cross-capacitor. Thompson has shown that in cylindrical capacitors, the capacitance per unit length may be computed with good accuracy. The cylindrical cross-capacitor of Lampard and Thompson and the modified versions find wide use in many standards laboratories. There are many other types of standard calculable capacitors. For example, recently, new types of capacitors have been added to the classical-Kelvin parallel plates and coaxial cylindrical-calculable standards. Also, cubical capacitors, for which the direct capacitance between opposite faces can be estimated with high accuracy, are used as an independent check of the farad as established by means of a cross-capacitor.

The calculable capacitor is capable of determining the value of a 0.5 pF capacitor to within 2.2 parts in 10^8 . There are several computer-based models available that can be used to investigate the effect of changing the lengths and diameters of capacitors and their frequency dependence.

Q-FACTOR MEASUREMENT

This article reports on traditional and modern methods of measurement of the Q -factors of resonators. Many of the techniques which will be described were first developed to determine the Q -factors of microwave resonators. Bearing this in mind, the language of the microwave engineer will be used throughout, although the reader should note that the basic principles are just as applicable to measuring the Q -factors of radio-frequency, millimeter, sub-millimeter, and optical resonators. The chapter will commence with a definition of the Q -factor, and a clear description of the resonator parameters which need to be measured to define the Q -factor of a resonance. The methods of measuring these parameters will then be outlined, including the particular advantages and disadvantages of a technique, the equipment required for the measurement, and the potential

for accuracy. Finally, some of the latest developments in the field of Q measurement will be presented.

Measurement of the Q -factor is the measurement of one of the defining characteristics of a resonance. Resonances are seen in devices which are able to store energy for a length of time which is long when compared to the period of oscillation of the electromagnetic energy being stored. The Q -factor is a direct measure of the quality of the resonator, or in other words, the length of time for which the energy can be stored.

To store energy, a resonator must have a method to trap energy. Microwave resonators make use of two main methods to trap energy: storage of the fields in a volume which is surrounded by conductive material, and storage inside a high dielectric material by total internal reflection at the dielectric surface. The first class of resonators are termed microwave cavities, while the second class of resonators are termed dielectric resonators. Of course, it is also possible to build hybrid resonators which use both mechanisms to trap energy. Any electromagnetic field pattern which satisfies Maxwell's equations in the resonator volume and satisfies the boundary conditions imposed by the resonator surfaces is called a normal mode or resonance of the resonator (1).

For energy to enter and leave a resonator, there must be some electrical or magnetic pathway between the resonator and an external transmission line. This pathway is most commonly provided in three ways:

1. Magnetic loop or electric probe on the end of a coaxial transmission line which protrudes into a cavity resonator,
2. A direct opening in the metallic wall between a cavity and a waveguide transmission line (iris coupling),
3. Placing a dielectric resonator in close proximity to a microstrip conductor (evanescent field or reactive coupling).

The number of coupling ports and the type of coupling used on those ports are used to further characterize microwave resonators. Resonators with a single port using probe or iris coupling are termed reflection resonators. Resonators with two or more ports using probe or iris coupling are termed transmission resonators. Two port resonators making use of reactive coupling are termed reactive or absorption resonators.

Microwave resonators, and accurate Q measurements to characterize those resonators, are vitally important in microwave engineering and physics:

1. Filters can be constructed from resonators because of their selective behavior in the frequency domain. A filter is a device which can transmit or reflect a desired signal while rejecting other nearby unwanted signals.
2. Measurements of electrical conductivity can be performed by an accurate measurement of the Q -factor of a microwave resonator which has been constructed of the material of interest (2,3). This measurement technique has undergone a renaissance recently with the great interest in high critical temperature superconductors (4).
3. Microwave properties of materials can be measured by the influences they have on the Q -factor and resonant frequency of a microwave resonance when they are loaded into a microwave resonator (1,5,6). Highly sensitive measurements of the Q and frequency are required to gain accurate material characterization. The dielectric loss and

dielectric constants of fluids and gases have been reported by a number of workers using this method (7,8). Magnetic and electrical properties of solids have also been reported (9,10,11,12).

4. Oscillators which have a high frequency stability in the short term require high- Q resonators; the best stability which has so far been achieved was with a superconducting cavity microwave oscillator operating near 2 K with a Q -factor around 10^{11} (13), and more recently, by a sapphire microwave oscillator at 4 K operating with a Q above 4×10^9 (14).

Microwave Q -factors of interest range from 2 (15) up to 10^{11} for a high perfection superconducting cavity at cryogenic temperatures (13). Coupling factors to these resonances can vary from 10^{-3} for extremely lightly coupled wavemeter resonators up to 10^3 for superconducting cavities at cryogenic temperatures. No single technique can be expected to operate over this full range and always give high resolution and highly accurate measurements. The desire to generate accurate measurements over this full range of interest has led to the large number of Q measurement methods reported here.

Many traditional methods for obtaining the Q factor have fallen from favor either because of improvements in technology, or because the original cumbersome technique can now be circumvented. For example, one of the major reasons for devising time domain Q measuring techniques was to avoid difficulties arising from the typically poor frequency stability of microwave signal generators of the time. However, modern quartz-based synthesizer technology provides a frequency stability which is adequate to measure the Q -factors of all but the very highest Q resonators. A second example is found with the rare use of voltage standing wave ratio (VSWR) measurement techniques in modern laboratories. These techniques are slow (16) and cumbersome as they require a device to be moved mechanically to make measurements. Modern network analyzers can make equivalent measurements essentially instantaneously without the need for mechanical changes to the circuit. Nevertheless, traditional Q measurement techniques still have importance because of their simplicity, low cost instrumentation, and instructional value. For these reasons, they will still be discussed below. For highly detailed instructions on performing these methods, the reader should refer to the classical texts (17,18).

DEFINITIONS

The letter Q was first used to describe the ratio of reactance to resistance of low frequency inductors and capacitors (18). Because of the usual technique of describing microwave resonators in terms of low frequency circuit elements, the letter Q became associated with describing the ratio of reactance in a resonant circuit to the resistance in that circuit. A simple calculation (see Eq. 3) shows that there is also a close relationship between Q and the time for energy to dissipate in such an equivalent circuit. This led to the incorrect but widespread belief that Q is the initial letter of the expression *Quality factor* (abbreviated as Q -factor), a term related to the length of time that a resonant circuit stores energy. The agreed modern definition of the Q -factor of any general resonant circuit (including electronic, optical, and mechanical resonators) is (18) 2π times

the ratio of energy stored in the system to the energy dissipated per cycle or in symbols,

$$Q = \frac{2\pi U}{\Delta U} \quad (1)$$

where U is the maximum energy of the system, and ΔU is the energy dissipated in a cycle. This equation can be solved to find how the energy decays as a function of time. The energy dissipated in one cycle can be found from

$$\Delta U = -\frac{\partial U}{\partial t} \frac{1}{f_0} \quad (2)$$

where f_0 is the resonant frequency. Substituting Eq. (2) into Eq. (1), the time dependence of U is found as

$$U(t) = U_0 e^{-(\omega_0/Q)t} \quad (3)$$

where U_0 is the initial energy of the resonant system, and $\omega_0 \equiv 2\pi f_0$ is the angular resonant frequency. From inspection of Eq. (3), another more practical definition of Q can be stated: 2π times the number of cycles required for the energy in the system to decay to $1/e$ of some initial amount or

$$Q = \frac{2\pi \tau}{T_0} \quad (4)$$

where τ is the time taken for the energy to decrease to $1/e$ of its value (called the ring-down time), and $T_0 \equiv 1/f_0$ is the resonant period. As will be seen below, direct use is made of Eq. 4 in determining Q factors by a time domain technique. All other measurement techniques make use of the response of the resonator to forced oscillation. To understand these techniques, we will need to derive expressions which will describe the behavior of the resonator under this condition.

Microwave Resonators

A diagram of a transmission microwave resonator is given in Fig. 1(a). The figure shows an empty metallic cavity where coupling between the resonator and external transmission lines is provided by small openings in the walls of the cavity. A general low frequency analogue to this microwave resonator, its coupling arrangement, and the external transmission lines is given by Fig. 1(b). Each resonance of the cavity is represented by a parallel LCR circuit (19). The k th resonant frequency is given by the expression:

$$(f_0)_k = \frac{1}{2\pi \sqrt{L_k C_k}} \quad (5)$$

and the unloaded Q of the k th resonance can be determined by substituting the energy dissipation provided by R_k and the energy storage provided by C_k and L_k into Eq. 1:

$$(Q_u)_k = R_k \sqrt{\frac{L_k}{C_k}} \quad (6)$$

The iris coupling has been modeled as transformer of unknown turns ratio (17,20). X_{e1} and R_{e1} are the equivalent reactance

Figure 1. (a) A diagram of a general microwave cavity resonator with iris coupling on the input and output ports. (b) An equivalent LCR circuit for part (a). The cavity resonator has an infinite number of resonances which have been represented by the series of LCR circuits: $(R_1, C_1, L_1), \dots, (R_k, C_k, L_k), \dots, (R_\infty, C_\infty, L_\infty)$. The input and output coupling networks have been modeled with a series loss (R_{e1}, R_{e2}) and series inductance (X_{e1}, X_{e2}) to take into account any losses or reactance of the coupling network. The source and load series impedances are denoted by R_S and R_L . The iris coupling has been modeled as a transformer of unknown turns ratio. (c) A highly simplified version of part (b), where the traditional assumptions of Q -factor measurement have been made. The coupling reactance and loss are assumed to be zero. The source and load are assumed to have a resistance which is perfectly matched to the line impedance. All other resonances of the cavity are assumed to be sufficiently far from the resonance of interest that they can be safely ignored. All external components have been transformed across the transformers and into the resonant circuit.

and shunt resistance of the input coupling network and transmission line, while X_{e2} and R_{e2} are the equivalent parameters for the resonator output network. R_S is the series impedance of the signal generator, and R_L is the equivalent load resistance of the equipment that is monitoring the resonator. Any measurement of the resonant system represented by Fig. 1(b) will yield a result which is a combination of the properties of the transmission line, the coupling mechanism, and the resonator. However, under certain conditions, it is possible to measure the Q of a particular mode while ignoring the influences of the load, the coupling mechanism, the transmission line, and other modes. In this case, the external impedances can be transformed into the resonant circuit giving the circuit shown in Fig. 1(c). This circuit is far more amenable to analysis and is

Figure 2. Schematic diagram representing the scattering of microwave voltage waves by a microwave two-port.

the model usually assumed by traditional measurement techniques as it greatly simplifies the post-measurement analysis [attempts were sometimes made to allow for coupling losses; i.e., $R_{e1} \neq 0$ (18)]. These simplifications will lead to important errors if the resonator is strongly overcoupled, the Q of the resonance is relatively low, the generator or source are poorly matched to the transmission line, or there is an excessive amount of reactance in the coupling mechanism or transmission line. For the sake of a simple introduction, we will use the circuit shown in Fig. 1(c) and reserve discussion of the more complex situation until the “Modern Measurement Techniques” section later.

To describe how microwave radiation interacts with a resonator, we will use a scattering matrix formalism. Figure 2 shows a voltage wave, $\tilde{a}_1$, incident on an arbitrary microwave two port device. The wave is scattered by the two port, some of its energy going into a reflected wave, $\tilde{a}_2$, and part into a transmitted wave, $\tilde{b}_2$. We express all three waves as

$$A \exp[j(\omega t - \beta z)] \quad (7)$$

where ω is the applied angular microwave frequency, A is the normalized voltage amplitude of the wave, β is the propagation constant, and z is the measurement position. We define the resonator scattering terms s_{11} and s_{21} as

$$s_{11} \equiv \frac{\tilde{a}_2}{\tilde{a}_1} \quad \text{and} \quad s_{21} \equiv \frac{\tilde{b}_2}{\tilde{a}_1} \quad (8)$$

We can, of course, define equivalent parameters for port 2. By substituting Eq. 7 into Eq. 8, we note that s_{11} and s_{21} will depend on the measurement position. This leads to the difficulty that we need to specify the measurement plane each time we quote the resonator scattering parameters. Theoretically, we could avoid this difficulty by always referring the measurement to some special pre-agreed measurement plane, for example, the plane which is coincident with the coupling device. However, practically, it is difficult to make a measurement at that physical position. Instead, we choose to define some special planes which have a well defined measurable characteristic. If a measurement is made of s_{11} at a frequency which is far from the resonant frequency, we can always find a position on the line which responds as if there were a short circuit or an open circuit on the transmission line. These planes are termed the *detuned short* or *detuned open* positions (17,18,20). From the detuned short position, the equivalent low frequency circuit shown in Fig. 1(c) is an accurate representation of the real microwave circuit (given that all the above assumptions still hold). Modern measurements can avoid this difficulty of determining the reference plane (see the Modern measurement techniques section). The scattering parameters at the detuned short position

for the circuit shown in Fig. 1(c) have been calculated as (21,22)

$$S_{11}(\epsilon) = \frac{\beta_1 - \beta_2 - 1 - jQ_u\epsilon}{1 + \beta_1 + \beta_2 + jQ_u\epsilon} \quad (9)$$

$$S_{21}(\epsilon) \equiv S_{12}(\epsilon) = \frac{2\sqrt{\beta_1 + \beta_2}}{1 + \beta_1 + \beta_2 + jQ_u\epsilon} \quad (10)$$

where $\epsilon \equiv f/f_0 - f_0/f$, f is the incident frequency, f_0 is the resonant frequency as defined above in Eq. 5, Q_u is the unloaded Q of the resonator as defined in Eq. 6, and the coupling factors are defined as the ratio of the internal resonant resistance to the external resistances when transformed into the resonant circuit; that is,

$$\beta_1 = \frac{n^2 R_k}{R_s} \quad \text{and} \quad \beta_2 = \frac{m^2 R_k}{R_L} \quad (11)$$

where n is the effective turns ratio of the input coupling mechanism, and m is the effective turns ratio of the output coupling mechanism. If $\beta < 1$, then a resonator is termed undercoupled; if $\beta > 1$, then a resonator is termed overcoupled; and if $\beta = 1$, then the resonator is critically coupled. Eq. 9 also applies to single port reflection resonators if β_2 is set to zero.

It is useful to split Eqs. 9 and 10 into their real and imaginary parts as this will give us the in-phase response and quadrature phase response of the resonator, respectively. In other words, the real part of Eq. 9 gives us the portion of the reflected wave which is in phase with the incident signal and the imaginary part will give the fraction of the reflected signal, which is $\pi/2$ out of phase with the incident signal.

$$\text{Real}[s_{11}] = \frac{(1 + \beta_1 + \beta_2)(\beta_1 - \beta_2 - 1) - \epsilon^2 Q_u^2}{(1 + \beta_1 + \beta_2)^2 + \epsilon^2 Q_u^2} \quad (12)$$

$$\text{Imag}[s_{11}] = \frac{-2\beta_1 \epsilon Q_u}{(1 + \beta_1 + \beta_2)^2 + \epsilon^2 Q_u^2} \quad (13)$$

$$\text{Real}[s_{21}] = \frac{2\sqrt{\beta_1 \beta_2}(1 + \beta_1 + \beta_2)}{(1 + \beta_1 + \beta_2)^2 + \epsilon^2 Q_u^2} \quad (14)$$

$$\text{Imag}[s_{21}] = \frac{-2\sqrt{\beta_1 \beta_2} \epsilon Q_u}{(1 + \beta_1 + \beta_2)^2 + \epsilon^2 Q_u^2} \quad (15)$$

An interesting and novel way of summarizing this information is by using a three dimensional parametric plot of the resonator response as a function of frequency (see Fig. 3 for a plot of s_{11}). If we make two dimensional projections of this plot along the principal axes, we will see response curves that are more familiar to the microwave engineer. To display this, we have projected the three dimensional plot onto the faces of the box in Fig. 3 and then rotated these faces into view. Viewing the curve which has been projected onto the plane perpendicular to the real axis we see the imaginary response of the resonator [Fig. 3(b)], looking along the imaginary axis, we observe the real response of the resonator [Fig. 3(c)], and finally, looking parallel to the frequency axis, we observe a circle—which is termed the Q circle of the resonator [Fig. 3(d)]. This horizontal projection plane is more readily recognized as the Smith Chart (23). The Smith Chart gives the magnitude of s_{11} by the distance that a plotted point is from the origin, while the phase of s_{11} (ϕ) is given by the angle that the line joining the point to the origin makes with the real axis. The most important advantage of

Figure 3. (a) A three-dimensional display of the scattering parameter, s_{11} , from a reflection resonator. The curve has been projected onto the faces of the box, and then these faces have been rotated into view. (b) Shows the imaginary (or quadrature phase) reflection response of the resonator. (c) Shows the real (or in-phase) reflection response of the resonator. (d) Shows the Q -circle of the resonator on a Smith Chart. The phase and magnitude of the reflection coefficient at a particular frequency are given by the distance that a plotted point is from the origin and the angle it makes with the real axis.

this three-dimensional description of the resonator response is the clear demonstration of the intimate relationship which exists between the many descriptions of microwave resonators given in the literature: the real and imaginary components of the scattering matrix, the Smith Chart, and the magnitude and phase of the response.

Q -factor measurements of two port microwave resonators frequently employ measurements of the transmitted and reflected power as a function of frequency. In cases of moderate to high Q , the derived frequency variable ϵ can be simplified with negligible error to

$$\epsilon = \frac{2\Delta f}{f_0} \quad (16)$$

where $\Delta f \equiv f - f_0$. We will term Δf the frequency detuning. The squared magnitude of s_{11} and s_{21} (which gives the reflected and transmitted power coefficients respectively) can be derived from Eqs. 9 and 10 as

$$|s_{11}|^2 = \frac{(1 - \beta_1 + \beta_2)^2 + 4 \left(\frac{Q_u \Delta f}{f_0} \right)^2}{(1 + \beta_1 + \beta_2)^2 + 4 \left(\frac{Q_u \Delta f}{f_0} \right)^2} \quad (17)$$

$$|s_{21}|^2 = \frac{4\beta_1\beta_2}{(1 + \beta_1 + \beta_2)^2 + 4 \left(\frac{Q_u \Delta f}{f_0} \right)^2} \quad (18)$$

Plots of these functions have been given on Fig. 4.

Loaded Q (Q_L), Unloaded Q (Q_U) and External Q (Q_e)

There are three distinct Q -factors of which we commonly talk when we discuss the losses in a microwave circuit. The unloaded Q (Q_U) is the Q -factor that would be measured as the electromagnetic coupling to the resonator tended to zero. That is, it is associated with dissipation which occurs inside the resonator (R_k in Fig. 1(c) and see Eq. 6). The external Q (Q_e) is the dissipation which occurs external to the resonator but which is coupled into the resonance by the coupling to the external circuit [R_s and R_L in Fig. 1(c)]. We can derive an expression for the external Q -factors in the same way as we found the unloaded Q factor (Eq. 6):

$$Q_{e1} = \frac{R_s}{n^2} \sqrt{\frac{C}{L}} \quad \text{and} \quad Q_{e2} = \frac{R_L}{m^2} \sqrt{\frac{C}{L}} \quad (19)$$

The loaded Q (Q_L) is the Q -factor measured by any scalar Q measurement method. It includes the contributions of all losses in the circuit which provide a dissipation mechanism for the resonance (both internal and external to the resonant circuit). We can write the relationship between the loaded Q , the unloaded Q , and the external Q factors as

$$\frac{1}{Q_L} = \frac{1}{Q_U} + \frac{1}{Q_{e1}} + \frac{1}{Q_{e2}} \quad (20)$$

Using the definitions of the coupling factors (Eq. 11) and the definitions of the unloaded and external Q factors (Eqs. 6 and 19), we can simplify Eq. 20 to

$$Q_u = (1 + \beta_1 + \beta_2) Q_L \quad (21)$$

General Q -Factor Measurement Techniques

Let us simplify some of our original expressions to generate some practical ways to measure the Q factor. From an examination of Eq. 17, we see that the maximum power transmitted through the resonator occurs when the incident frequency is exactly equal to the resonant frequency. As we move away from the resonant frequency, the transmitted power falls as the square of the frequency difference. An important measure

Figure 4. The power reflection and transmission coefficients of a two-port resonator with $\beta_1 = 1$ and $\beta_2 = 2$. The loaded Q of the resonator is given by $Q_L = f_0/(f_2 - f_1)$, where f_1 and f_2 are the points at which the power transmission coefficient is half the maximum power transmission, or the points where the power reflection coefficient is the average of the on and off-resonance power reflection coefficients.

of such a resonant curve would be its sharpness. We choose to measure the sharpness of the curve by the frequency difference between the two frequency values which transmit half the maximum power; that is, we need to find the frequency detuning Δf which satisfies the equation:

$$|s_{21}(\Delta f)|^2 = \frac{1}{2} |s_{21}(0)|^2 \quad (22)$$

The solution to Eq. 22 is

$$\Delta f = \pm \frac{1}{2} \frac{(1 + \beta_1 + \beta_2) f_0}{Q_U} = \pm \frac{1}{2} \frac{f_0}{Q_L} \quad (23)$$

Let us define a new parameter, Δf_L : the loaded half bandwidth which is equal to the positive solution of Eq. 23; that is,

$$\Delta f_L = \frac{1}{2} \frac{f_0}{Q_L} \quad (24)$$

Equation 23 gives us a method of measuring Q_L in transmission resonators. By measuring the resonant frequency, the maximum transmission power and the two frequency points at which the transmitted power is down by half, we can calculate the loaded Q .

To derive Q_u from this measurement, we will need to determine the coupling factors and use Eq. 21. By measuring the reflected power coefficient on resonance and the transmitted power coefficient on resonance, we have two equations with two unknowns (Eqs. 17 and 18). These can be solved to find the coupling coefficients:

$$\beta_1 = \frac{(\Gamma_0 \pm 1)^2}{1 - \Gamma_0^2 - T_0^2} \quad \text{and} \quad \beta_2 = \frac{T_0^2}{1 - \Gamma_0^2 - T_0^2} \quad (25)$$

where $\Gamma_0 = |s_{11}(0)|$ and $T_0 = |s_{21}(0)|$. The first of these two equations can also be applied to finding the coupling coefficient for a one port resonator by letting β_2 be equal to zero. The equation can then be rewritten as

$$\beta_1 = \frac{1 \pm \Gamma_0}{1 \mp \Gamma_0} \quad (26)$$

It is not possible to determine which of the two solutions in Eq. (25) or (26) is, in fact, the correct one if we are limited to a scalar power transmission method of determining the Q -factor. We need to measure some phase information (16), or vary the physical coupling in a known way (18,24), to remove this ambiguity. If one is not interested in knowing the coupling factors individually but just for the purpose of determining the unloaded Q factor from the loaded Q factor, then one can use (22)

$$1 + \beta_1 + \beta_2 = \frac{2}{s_{11}(0) + s_{22}(0)} \quad (27)$$

If it is possible to measure the complex components of s_{11} either directly, with a network analyzer or using a phase bridge, or indirectly, through measurements of the line VSWR, then there are some alternative methods to estimating the Q -factor of a resonator. For simplicity, we will perform the following calculations for a one port reflection resonator ($\beta_2 = 0$). However, it should be noted that the equations which govern reflection,

transmission, and reaction resonators are all essentially equivalent (25), and so, most Q measurement techniques can be applied to all three types of resonator (26,25).

We need to determine the relationship which exists between the real and imaginary components of s_{11} when at a particular frequency detuning. This relationship may then be used to measure the Q . Let us define an unloaded half bandwidth in the same way as we did for a loaded half bandwidth (Eq. 24):

$$\Delta f_U = \frac{1}{2} \frac{f_0}{Q_U} \quad (28)$$

Substituting Δf_L and Δf_U into the real and imaginary parts of s_{11} (Eqs. 12 and 13), we find the following relationships:

$$\text{Im}[s_{11}(\pm \Delta f_L)] = \mp \{1 + \text{Re}[s_{11}(\pm \Delta f_L)]\} \quad (29)$$

$$\text{Im}[s_{11}(\pm \Delta f_U)] = \mp \left\{ 1 - \sqrt{2 - (\text{Re}[s_{11}(\pm \Delta f_U)])^2} \right\} \quad (30)$$

If the frequency detuning is varied until one of the above equations are satisfied, the value of the detuning will be equal to the loaded or unloaded half bandwidth. By back substitution into Eqs. 28 and 24, the unloaded and loaded Q may be found.

GENERAL SOURCES OF ERRORS IN Q MEASUREMENT

We can divide measurement error into two categories: systematic and random. Systematic error yields a consistent result on repeated measurements of a constant resonance but with a value which differs from the true value. Such a measurement would be termed one with high resolution but relatively poor accuracy. Random errors (noise) will result in a scattering of results on repeated measurements of a constant resonance. If the measurement system is dominated by random noise, it is relatively easy to estimate its accuracy by just making multiple measurements of a constant resonance and quoting some statistical measure of the deviation. An improvement in the quality of the measurement can also usually be made by averaging multiple measurements. An estimation of the accuracy of a system which is dominated by systematic errors is far more difficult. Typically, one would try to use two or more completely independent measurement techniques to measure the same resonance and quote the differences between the results.

Systematic Q Measurement Errors

Any Q estimation technique which samples the scattering parameters at a number of different frequencies requires that we place conditions on the amplitude and frequency stability of the source to achieve a given accuracy. Any constant drift in the source frequency during the measurement will result in distortions to the resonance curve shape with a consequent distortion of the loaded Q value. Drifts in the amplitude of the source will give rise to distortions in the measured coupling factors which will give errors in the estimation of the unloaded Q . The relative error in the Q -factor under these conditions depends on the order in which the measurements are taken. However, for a worst case estimate, if we assume the measurements are taken in ascending or descending frequency order

and are equally spaced, then we can estimate the fractional error in estimation of Q_L as

$$\frac{\Delta Q_L}{Q_L} = \pm \frac{tkQ_L}{f_0} \quad (31)$$

where t is the time required to sample the response between $+\Delta f_L$ and $-\Delta f_L$, and k is the frequency drift rate of the source in Hz/s.

Drifts in the resonant frequency of the resonance during the measurement will also cause distortions to the measured Q values in much the same way as drifts in the source frequency. This is especially important when the temperature coefficient of the resonator is large, and the resonator Q -factor is high. For example, in the case of a sapphire dielectric resonator at 77 K, the fractional frequency temperature coefficient is around $10^{-5}/K$, while Q_L is around 5×10^7 (27). Temperature drifts of the order of 200 μK during the period of measurement will limit the accuracy of the Q -factor measurement to 10%.

Almost all frequency domain Q -measurements have traditionally relied on being able to treat the resonance as a single resonance which is well described by an equivalent LCR network. In the situation where there are losses or reactance in the coupling network, or there are interfering resonances in the resonator or in the external transmission lines, there will be distortions to the classic resonance shape with consequent errors in the measured Q factors. It is difficult to give a summary of the errors induced by ignoring these effects as there are so many possibilities. However, for example, the Q circles method (see below) will give a Q_U which is 15% in error for each 1 dB of return loss which is ignored in the lines leading to a critically coupled resonator.

In resonators which are remote from the experimental apparatus, or in systems with poorly matched loads and sources, resonances can appear in the connecting transmission lines which cause distortions to the resonance shape. The best solution to this problem is to suppress these spurious resonances by using microwave isolators to better match the load and source. To overcome large amounts of coupling reactance or interfering resonances in the resonator, itself, one must refer to some of the methods covered in the "Modern measurement techniques" section below.

If the resonator contains materials which have properties (either reactive or resistive) which are altered by the amplitude of the incident microwave fields, there is a strong possibility the resonator will exhibit a level of nonlinear behavior (28,29). For example, resonators which have been loaded with maser materials such as ruby can exhibit Q -factors which are negative under certain conditions (28). If high power microwave sources are being used, it is also possible for temperature changes to be induced in the resonator which cause resonant frequency changes, or for electrical breakdown to occur. Most superconducting cavities demonstrate a very strong Q dependence on power (3). Under all these circumstances, great care must be taken to ensure that correct results are obtained. For example, the Q -factor can be measured at a number of different incident powers to determine if a consistent result is being obtained.

Finally, any errors in the calibrations of the measuring instruments will lead to inaccuracies in the measurement. For example, Sucher (18) has calculated the error in measurement of the Q of a transmission resonator from an error in the

attenuation measurement (ΔA) of the half power transmission points to be

$$\frac{\Delta Q_L}{Q_L} = -0.23\Delta A \quad (32)$$

Thus, a 0.1 dB error in measurement leads to an inaccuracy of 2.3%.

Random Q Measurement Errors

Random noise in parts of the measurement apparatus will lead to random variations in the measured Q value of an unchanging resonance. Many of the mechanisms mentioned in the previous section are also applicable to this section if, rather than smooth drift of the variable, it exhibits noisy behavior. For instance, rapidly varying frequency noise (phase noise) of the microwave source will create an amplitude noise in the reflected or transmitted power. This will limit the experimenter's ability to identify a particular point on a resonance curve. For example, to measure a typical X-band dielectric resonator Q of 10^5 to an accuracy of 1% requires that the position of the measured frequency points is determined to better than 1 kHz. Such frequency stability is only achieved by modern quartz synthesized microwave signal sources.

All Q measurements will be ultimately limited by the intrinsic noise of the amplitude or phase sensor in the analyzing instruments. The fractional noise in the Q measurement is given approximately by the fractional noise in the power measurement. It is very rare that this ultimate limit is achieved in practice as the other noise sources (particularly the frequency noise in the source) conspire to increase the measurement noise level.

TRADITIONAL METHODS OF Q MEASUREMENT

The methods of Q measurement have been classified into the categories shown in Fig. 5. A major distinction has been made between spatial and temporal techniques because of the very

Figure 5. The Q factor measurement techniques described in this chapter have been divided into the classification scheme which is shown in this figure.

Figure 6. Smith Chart plots of the s_{11} responses of over (OC) and undercoupled (UC) resonances. The reflection phase of the OC resonance changes by 2π across the resonance, while the reflection phase of the UC resonance reaches a maximum value of $\phi/2$ before returning to zero and then reaching a minimum value of $-\phi/2$ before once again returning to zero. The relative changes in magnitude of the reflection coefficient are much larger in the case of the undercoupled resonator.

different technology required for the two types of measurement. Spatial techniques rely on using a slotted line device to measure the voltage standing wave ratio (VSWR) in the incident microwave line. The VSWR gives a measure of the magnitude of the reflection coefficient of the resonator, and the positions of the voltage minima in the VSWR pattern give a measure of the reflection phase.

Temporal measures of the Q include measurements made in both the frequency and time domains. Frequency domain measures are the most commonly used techniques today. These techniques rely on measuring either or both of the components of the scattering parameters as a function of frequency. This can be done in a step-wise measurement of the scattering parameter at a number of frequency points, or it can be done with a continuously swept source as long as the time of the sweep is much longer than the ring-down time of the resonance. The term *static* in Fig. 5 implies that measurements are made slowly compared to the ring-down time, and that the measured output signal is synchronous with the source frequency sweep. Dynamic measurements are also made with a sweep which is slow compared to the ring-down time of the resonance, but in these measurements, the output signal is at a harmonic of sweep rate, and so they are intrinsically AC measurements.

Spatial Methods: Phase and Amplitude

If a measurement were made of the voltage along the incident line of the microwave resonator in Fig. 2, we would find a standing wave formed by the interference of the incoming and outgoing waves. The ratio of the minimum to maximum voltage as measured along this transmission line is termed the VSWR and can be directly measured with a slotted line device. The locations of the voltage minima (or maxima) in this pattern are determined by the phase of the reflected signal. The amplitude

of the VSWR is given by

$$\text{VSWR} = \frac{1 + |s_{11}|}{1 - |s_{11}|} \quad (33)$$

To compare s_{11} for under and overcoupled resonators, a plot of each is given on a Smith Chart in Fig. 6 (as viewed from the detuned short position). One notes that $|s_{11}|$ (and hence the VSWR also) of an overcoupled resonator is large and relatively constant although the reflection phase changes by 2π across the resonance. The undercoupled resonance demonstrates a relatively small phase variation although the relative VSWR change is large. This knowledge arms the engineer for an accurate measurement of the Q using a slotted line device. If the resonator is overcoupled, then a measurement of the position of the voltage minima should be made, while if the resonator is undercoupled, then a measurement of the magnitude of the VSWR will yield the more accurate result.

Substitution of Eq. 9 into Eq. 33 yields the result that the VSWR on resonance is equal to $\beta^{\pm 1}$ for a one port resonator. A measurement of the VSWR alone is unable to resolve the sign of the exponent although an additional quick measurement can determine this (see below).

The VSWR at $\pm \Delta f_L$ and $\pm \Delta f_U$ for the undercoupled case can be calculated as a function of the VSWR on resonance (V_0) to be

$$\text{VSWR}(\pm \Delta f_L) = \frac{\left| \frac{j + V_0}{1 + V_0} \right| + 1}{\left| \frac{j + V_0}{1 + V_0} \right| - 1} \quad \text{and} \quad (34)$$

$$\text{VSWR}(\pm \Delta f_U) = \frac{\left| \frac{1 - (1 + j)V_0}{1 + (1 + j)V_0} \right| + 1}{\left| \frac{1 - (1 + j)V_0}{1 + (1 + j)V_0} \right| - 1}$$

Thus, if we measure V_0 , substitute it into the equation above, and then measure the frequency detuning at which the VSWR is equal to the calculated value, we can immediately determine Q_U and Q_L .

For overcoupled resonators, the Q is accurately determined by measuring the position of the voltage minima (or maxima) as the resonant frequency is changed (for a tunable resonator) or as the incident signal frequency is changed. A plot of the position of the voltage minima for two one-port resonators ($\beta_1 = 0.6$ and 1.6) is given in Fig. 7 as a function of resonant frequency. The relatively large change in the position of the minima for overcoupled resonators is clearly visible. The points on the overcoupled resonator curve which are most easily identified experimentally occur where the minima shift is $\pm \pi/2$ (this is half the maximum shift). Given that the phase shift on reflection from the resonator is given by

$$\phi = \text{ArcTan} \left[\frac{\text{Im}[s_{11}]}{\text{Re}[s_{11}]} \right] \quad (35)$$

we see that a phase shift of $\pm \pi/2$ occurs when the real part of s_{11} (Eq. 12) is equal to zero. Solve this to find the $\pi/2$ frequency

Figure 7. Calculated position shift (in radians) of the minima in the VSWR pattern as a function of resonant frequency for two resonances with $\beta_1 = 0.6$ (upper curve) and 1.6 (lower curve). The position shift is seen to be much larger for the overcoupled resonator which is in accordance with our prediction from the Smith Chart plot in Fig. 6.

detuning points:

$$\Delta f_{\pi/2} = \pm \frac{1}{2} \frac{f_0}{Q_U} \sqrt{\beta_1^2 - 1} \quad (36)$$

So a measurement of the frequency detuning which gives a $\pi/2$ shift combined with a measurement of the VSWR when the resonator is tuned to resonance will yield the unloaded Q of the resonator.

Figure 7 also suggests a simple method to determine whether a resonator is under or overcoupled. For undercoupled resonators, we note that the position of the minima is the same when the resonator is tuned exactly to resonance and when it is tuned far from resonance. This is not the case for overcoupled resonators. Thus if the slotted line probe is adjusted onto a voltage minimum at resonance, and then the resonant frequency is shifted so that it is far from resonance, only in the case of an undercoupled resonator will the probe still be at a voltage minimum.

Time Domain Techniques

Decrement Method. The decrement method is one of the older methods of measuring the Q factors of high Q resonators (17,18). Before the advent of quartz based microwave synthesizers, the frequency stability of the best Gunn oscillators and klystrons meant that measurements of Q factors higher than 10^{4-5} would be inaccurate. To overcome this difficulty, a method to excite the resonance and measure the time for the energy to dissipate was developed.

A microwave oscillator which can have its output power switched on or off by an external signal is driven by a pulse generator with a repetition rate much slower than the resonator ring-down time (Eq. 4). This pulsed generator also triggers an oscilloscope which is monitoring the energy leaking from the resonator from either the input or output port using a crystal detector. The power leaking from the resonator is proportional to the stored energy in the resonator. If the crystal detector has an accurate square law response, that is, its output voltage is proportional to the incident power, then the oscilloscope screen display is an accurate representation of Eq. 3, and the Q is directly determined by measuring the time taken for the signal to

drop by a factor of e . This time interval can then be substituted into Eq. 4 and the loaded Q determined.

Care must be taken to ensure that the microwave source frequency remains resonant and that the source output power is constant; otherwise, the oscilloscope trace moves vertically causing difficulty with an accurate measurement of the time interval. To avoid this difficulty, a method making use of a continuously swept source has been suggested (30). The source is swept across the resonance, and when it becomes resonant, an electronic circuit monitoring the transmitted power automatically switches the source off and triggers the oscilloscope. Using modern equipment, decrement techniques can easily measure loaded Q -factors near 10 GHz in the range upwards from 10^{4-5} (ring down times longer than a few microseconds).

Inaccuracies enter the decrement techniques if the bandwidth of the power detector and/or the oscilloscope is inadequate to correctly capture the transient response of the resonator. The measured Q factor will also be in error if the crystal detector does not give an output which is strictly proportional to input microwave power.

Unfortunately, all time domain methods give no information on the coupling and, hence, can only measure the loaded Q of the resonators. This difficulty may be overcome if it is possible to vary the coupling to the resonator. In this case, the coupling can be made progressively smaller until the measured Q does not change with any further reduction in coupling. At this point, the measured loaded Q will be equal to the unloaded Q to within the experimental resolution. The accuracy of the decrement techniques is directly proportional to the fractional error in the estimation of the ring-down time.

Fast Sweep Decrement Method

The fast sweep decrement method (31) is a modification of the decrement method with three advantages: the researcher can make use of more widely available CW sweep microwave generators rather than the pulsed generator required above, the required frequency stability of the microwave source is much less stringent, and no sophisticated electronics are required.

This measurement is suitable for a reflection resonator and requires a microwave detector to monitor the signal reflected from the resonator. The source is swept over a frequency range which is much wider than the bandwidth of the resonance with a sweep repetition rate (seconds per sweep cycle) which is much longer than the ring-down time of the resonator. The frequency sweep rate (Hz/s), however, is set such that the source sweeps across the resonance in a time which is much shorter than the ring-down time. An instant after the sweep has passed through the resonance, the detector mounted on the reflected port receives two signals: the reflected off-resonance signal which has a frequency corresponding to the frequency of the source at this instant, as well as the weak signal leaking from the resonator at the resonant frequency. The detector mixes these two signals giving rise to a characteristic frequency chirp (caused by the frequency difference having a time dependence) which has an exponential envelope following the decreasing strength of the leaking signal. From (31), we see that the envelope of the chirp has an exponential time constant which is twice as long as that seen in the normal decrement method; that is,

$$Q_L = \pi \tau_e f_0 \quad (37)$$

where τ_e is the time required for the signal envelope to decrease to $1/e$ of its amplitude. A measurement of τ_e yields Q_L .

A colleague (32) has developed an automatic Q measuring system which can provide relatively high resolution results based on this technique. By monitoring the dc and ac voltage output from the reflected power detector, one can calculate the incident power on the resonator as well as a value which is proportional to the amplitude of the chirp. The amplitude of the chirp is proportional to both the incident power and the Q of the resonance. By forming the ratio of the ac and dc voltage, one can calculate a number which is proportional to the loaded Q factor of the resonance. The constant of proportionality can be determined by an initial calibration using one of the other techniques for measuring Q . From then on, a new value for the loaded Q is generated after every sweep cycle. The technique gives measurements with a resolution of around 5% under typical conditions. The technique has proved very useful when the Q is changing quickly as a function of time.

Scalar Static Frequency Domain Techniques

Half-Power Points Technique. We have already outlined a method to determine the loaded Q from a transmission measurement where we determined the frequency point at which half the on-resonance power is transmitted and then directly substituted into Eq. 23 to calculate Q_L . However, an implicit assumption is made in Eq. 23 that one can identify the resonant frequency accurately to calculate the value of Δf . However, because the resonance shape is flat at the center of resonance, it is frequently difficult to identify this point accurately. Furthermore, the fractional error induced in the Q is extremely sensitive to an error in the calculation of Δf arising from a misidentification of the resonant frequency (Δf_0):

$$\frac{\Delta Q_L}{Q_L} = \frac{\Delta f_0}{f_0} Q_L \quad (38)$$

Since we can measure source frequency differences very accurately using an electronic frequency counter, a better method of measuring the Q relies on measuring the two frequencies f_1 and f_2 at which the transmission power is down by half from the on-resonance value (17,18):

$$f_1 - f_0 = \frac{1}{2} \frac{f_0}{Q_L} \quad \text{and} \quad f_2 - f_0 = \frac{1}{2} \frac{f_0}{Q_L} \quad (39)$$

If we form the difference of these two equations, we get

$$f_1 - f_2 = \frac{f_0}{Q_L} \quad (40)$$

where we can determine Q_L without the need for an accurate determination of f_0 (see Fig. 4). An additional measurement of the on resonance reflection and transmission coefficients (Eq. 25) gives us the coupling information needed to calculate Q_U .

Nonetheless, it is important to note that for an accurate measurement of the Q using this method, the requirements on the attenuation measurement are extremely stringent (Eq. 32). An alternative microwave bridge method has been proposed which can find the half transmission points very accurately (33).

Calibrated Attenuator Method. One of the difficulties of the Half-Power points technique is the necessity for an accurately

calibrated power detector. To avoid this difficulty, we can make use of a calibrated attenuator. This method relies on finding the maximum transmission point, while there is a 50% attenuator placed in the signal path between the microwave source and the detector. This attenuation is then removed, and the source detuned to the two frequency points at which the original output voltage is regained on the detector. Once again, the loaded Q is calculated using Eq. 40.

Reflected Power Technique. To determine the power reflected from a one port resonator at $\pm \Delta f_L$, we substitute into Eq. 17 to get

$$|s_{11}(\pm \Delta f_L)|^2 = \frac{1 + \beta_1^2}{(1 + \beta_1)^2} \quad (41)$$

Thus, to measure the loaded Q , we need to measure the reflection coefficient on resonance and calculate the coupling using Eq. 26. We then substitute this into Eq. 41 and calculate the power reflection coefficient at the loaded half-bandwidth frequency points. Finally, we measure the frequency detuning corresponding to this power reflection in the resonator, and from this frequency detuning, we can calculate Q_L and Q_U .

Straight-Line Methods. Another method for measuring the Q factor from the scalar reflection or transmission coefficients has been suggested where transformed frequency coordinates are used so that the resonance shape appears to be linear (34,35,18). This method lends itself to either a manual graphical solution or a simple least squares fit on a computer. We can rearrange Eq. 17 for a one port resonator [we can also do the same thing for the transmission coefficients (34)] to define a new variable:

$$\delta_U(\Delta f) = \left(\frac{Q_U \Delta f}{f_0} \right) = \pm \sqrt{\frac{(1 + \beta_1)^2 |s_{11}(\Delta f)|^2 - (1 - \beta_1)^2}{1 - |s_{11}(\Delta f)|^2}} \quad (42)$$

If we have calculated β_1 from a measurement of the on-resonance reflection coefficient (see Eq. 25), then for each measurement of s_{11} we can calculate a value for the variable δ_U (all values are known on the right hand side of Eq. 42). If we make a plot of these values of δ_U as a function of frequency detuning (Δf), we will find a straight line which has a slope equal to Q_U/f_0 . From the slope, we can clearly generate the unloaded Q (35).

When implemented in a computer based system, this technique has the potential for excellent high accuracy measurements of the order of 0.01% for Q -factors of the order of 10^4 (34). This accuracy arises because the measurement makes use of reflection data which is in close proximity to the center of resonance and because of the enormous amount of data which can be taken. By limiting the data to that near the center of resonance, there is a reduction in the effect of interference from other resonator and transmission lines modes. To achieve the accuracy reported, the researchers used nearly 1000 data points to characterize the resonance. This technique also has another advantage in that the degree of linearity of the plot is a measure of the level of interference from other modes. This immediately gives the experimenter an idea of the veracity of the measurement.

A similar method to the above mentioned one has been suggested in connection with transmission measurements at

93 GHz (36,37). One of the potential problems with the above method is finding the exact center of resonance. Any errors in this identification introduce a large error because Δf in Eq. 42 will be incorrect (see Eq. 38). If we define a new variable, m ,

$$m^2 \equiv \frac{|s_{21}(0)|^2}{|s_{21}(\Delta f)|^2} \quad (43)$$

then we can rewrite Eq. 18 as

$$m^2 = 1 + 4 \left(\frac{Q_L \Delta f}{f_0} \right)^2 \quad (44)$$

If we measure the left hand side of Eq. 43 at a known frequency detuning, we can immediately calculate Q_L from Eq. 44. However, any error in the measurement of the resonant frequency will introduce large errors. We would like to perform the calculation in a way which is insensitive to the exact value of the resonant frequency. If we make a measurement of m^2 at two frequency points on either side of the resonance, we can rewrite Eq. 44 as

$$\begin{aligned} \Delta f_1 = f_1 - f_0 &= \frac{-f_0}{2Q_L} \sqrt{m_1^2 - 1} \quad \text{and} \\ \Delta f_2 = f_2 - f_0 &= \frac{f_0}{2Q_L} \sqrt{m_2^2 - 1} \end{aligned} \quad (45)$$

If we take the difference of these two equations, we can derive a further equation to define Q which is only dependent on a frequency difference which, in principle, we can measure very accurately:

$$Q_L(f_1, f_2) = \frac{f_0}{2(f_1 - f_2)} (\sqrt{m_1^2 - 1} + \sqrt{m_2^2 - 1}) \quad (46)$$

If we make N measurements of m^2 on either side of the resonant frequency, then we have N^2 pairs of m values. From each pair, we can calculate a value for Q_L using Eq. 46. The variance of the ensemble of Q_L values is a measure of the closeness with which the data follows the theoretical resonance curve. If there is any systematic variation of Q_L as a function of frequency, it suggests the effects of interfering resonances. This method, is therefore, a very useful indicator of the isolation of the resonance (38).

Single Frequency Technique. As mentioned above, resonators and the resonator Q factor are commonly used to measure the electrical, optical, or magnetic properties of materials. These measurements are usually undertaken by measuring the properties of a resonator before and after making some change to that resonator such as, for example, inserting a small sample into the resonator, changing the illumination level on a sample already in the resonator, or changing the resonator temperature. In these cases, we are more interested in a measurement of the change in Q rather than an absolute measurement of the Q -factor. The single frequency measurement technique determines changes in the Q -factor essentially instantaneously and doesn't require measurements in the time or frequency domain (39,40).

If the change we have made to the resonator is such that the electromagnetic field distribution near the coupling ports is unchanged, then we can expect that the coupling ratios m

and n in Fig. 1 will remain unchanged. If the change causes a modification to the losses in the resonator (R_k in Eqs. 6 and 11), then both the unloaded Q and coupling will change, but the ratio of these two parameters will remain constant:

$$\frac{Q_u}{\beta_1} = \frac{R_s}{n^2} \sqrt{\frac{L_k}{C_k}} = C \quad (47)$$

where C is some constant. Thus, if we continuously monitor the reflected power at resonance, we can determine any changes in the coupling, and from Eq. 47, the fractional change in Q_u will be exactly equal to the fractional change in coupling.

Dual Resonator Techniques. A novel method for determining all resonator parameters from a simultaneous measurement of two resonators has been described by a number of authors (41,42,43). In these techniques, the power transmission and/or reflection coefficient of a resonator is plotted as a function of the transmission coefficient of a tunable reference cavity. The output plots are a function of the difference in resonant frequency of the two resonators and the ratio of their Q factors. Analytic expressions for the shapes of these curves have been derived in terms of the difference frequency and Q factor ratio, and these can be adjusted to fit experimentally derived measurements (41,43). The accuracy of this method is similar to those of the other techniques reported here ($\sim 2\%$), although it is necessary to know the Q factor of the reference cavity in advance of these measurements using one of the other methods. The big advantage of the technique is that it is unnecessary to use calibrated power detectors, although the detectors must have a matched response. The second major advantage arises because the data is represented on a parametric plot so any source frequency instability is suppressed. The quality of the measurement is determined by the stability of the reference cavity.

Integration Technique. If a frequency stable source and/or calibrated power measuring device is unavailable so that accurate measurements of the half power transmission points are impossible then an integration method can be used (44). If we integrate the transmitted power coefficient (Eq. 18) as a function of frequency, we obtain the following expression:

$$\int_{-\infty}^{\infty} |s_{21}|^2 d\Delta f = \frac{P_0 \pi f_0}{2Q_L} \quad (48)$$

where P_0 is the power transmitted at the resonant frequency. This equation can be implemented experimentally if we use a microwave sweep oscillator to sweep the frequency over many loaded bandwidths and use an analog integrator to integrate the output of a crystal detector on the transmission port of the resonator. An additional measurement of the output voltage of the detector when the generator is on-resonance determines the only other unknown parameter so that Q_L can be determined.

The integration method has also been proposed as an accurate method to determine the small changes in Q associated with determining losses in materials via resonator perturbation methods (45).

Numerical Methods. One of the earliest computer-based methods of measuring the Q factor was reported by Pandrangi et al. (46). A computer directed a voltage controlled oscillator
